In addition to ME techniques to correct rib dysfunctions, a thorough examination of thoracic intervertebral mobility should be completed. Mobility impairments of the costovertebral joints can alter the mechanics of the thoracic facet joints. Thoracic intervertebral motion is discussed in chapter 16. Scapular stabilization exercises should also be prescribed as indicated for muscle weakness (see Chapter 17).

Sacroiliac Joint Dysfunction

Sacroiliac (SI) joint sprain has been shown to occur in 10% to 33% of patient population.[5,15,37,38,96,150] Impairments can be either traumatic or insidious onset. Patients will frequently complain of pain localized to the SI joint region with or without radiculopathy depending on the involvement of the sciatic nerve. Pain is usually relieved with rest and/or by unweighting the joint. Unresolved inflammation or a traumatic etiology may yield a hypomobile SI joint. It is beyond the scope of this textbook to discuss all the hypomobility impairments as they pertain to the sacrum and innominate. Four common impairments include: pubic symphysis hypomobility, an anterior rotated innominate, a posterior rotated innominate, and an upslipped innominate (Fig. 15.12). The first three can be corrected with ME techniques while the fourth may require a HVT.

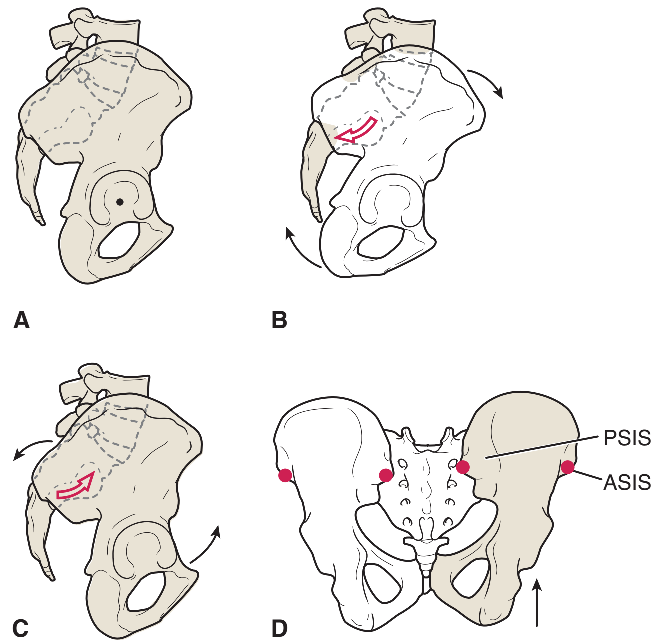

FIGURE 15.12 (A) Normal relationship of the sacrum and innominate, (B) anterior rotated innominate showing the ASIS inferior and PSIS superior, (C) posterior rotated innominate showing the ASIS superior and PSIS inferior, (D) upslipped innominate showing ASIS and PSIS superior on the right compared to contralateral side.

Identification of SI Joint Impairments

- *Observation and findings*. With the patient standing, view from the posterior aspect. Look for symmetry in the heights of the iliac crests, posterior superior iliac spines, and anterior superior iliac spines. With your hands on these boney landmarks, have the patient march in place (March Test) and observe movement of the innominate. If there are positive signs, conduct additional tests, supine and prone lying, to verify SIJ involvement.[37,95,135]
- *General SIJ hypomobility*. The pelvis will "rise up" on the restricted side during the March Test.
- *Anterior rotated innominate*. The PSIS with be higher and the ASIS will be lower on the involved side.
- *Posterior rotated innominate*. The PSIS will be lower and the ASIS will be higher on the involved side.
- *Upslipped innominate*. All boney landmarks of the pelvis will be higher on the side of the upslip.

Interventions VIDEO 15.2

"Shot-gun" technique. The "shot gun" technique is used to treat both pubic symphysis and general SIJ hypomobility. The idea used to describe the mechanics of this technique is that it creates a gapping followed by a compression of the pubic

symphysis joint to improve mobility, although no known studies have confirmed this concept.

- *Patient position*. Supine in a hook-lying position.
- *Technique.* Instruct the patient to contract against your resistance to submaximal contractions, alternating between hip abduction and adduction for a series of 3 to 5 repetitions holding each contraction for 3 to 5 seconds (Fig. 15.13).

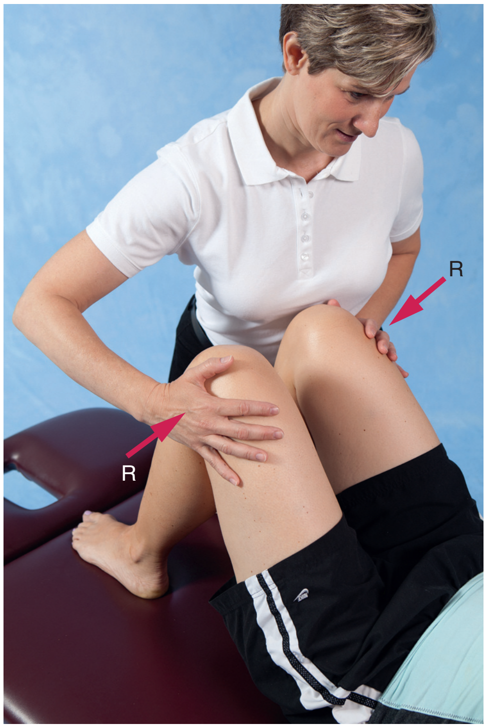

FIGURE 15.13 "Shot gun" ME technique.

FIGURE 15.14 ME technique of the gluteus maximus to correct an anteriorly rotated innominate bone.

Muscle energy techniques to correct an anterior rotated innominate. ME techniques to correct an anterior rotated pelvis use the force generated by the contracting gluteus maximus to rotate the innominate posteriorly.

- *Patient position:* Supine
- *Technique:* Flex the involved hip to the point of pain and/or restriction, then resists a series of submaximal isometric hip extension contractions (Fig. 15.14).

Muscle energy technique to correct a posterior rotated innominate. A patient that has a posterior rotated innominate can be treated with ME techniques using the rectus femoris muscle.

- *Patient position:* Prone
- *Technique:* Passively extend the involved extremity to the restriction or point of pain, then resists a series of submaximal isometric hip flexion contractions (Fig. 15.15). With one hand on the pelvis, assist gliding the pelvis anteriorly by pushing on the posterior superior iliac spine when the other hand lifts the femur.

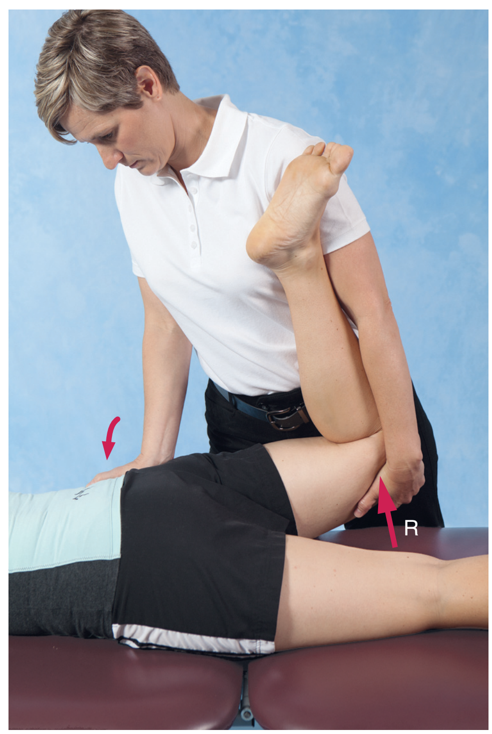

FIGURE 15.15 ME technique of the rectus femoris to correct a posteriorly rotated innominate bone.

HVT to treat an upslipped innominate. An upslip is usually the result of trauma (such as a fall) or scoliosis. Treatment utilizes a high-velocity thrust rather than an ME technique. **VIDEO 15.3**

- *Patient position:* Supine
- *Technique:* Hold the ankle on the side of the involved pelvis. Place the extremity in slight hip extension, abduction, and internal rotation. This will place the SI joint in a loose pack position while providing maximum stability to the hip joint. After a series of two to three inhalations and exhalations by the patient, provide a quick "tug" during the final exhalation (Fig. 15.16).

FIGURE 15.16 HVT to correct an upslip of the innominate bone.

Cervical and Upper Thoracic Region

The anatomy and arthrokinematics of the craniocervical region are described in Chapter 14, and physical therapy interventions are discussed in Chapter 16. It is, however, necessary to discuss the significance of this region as both a transitional area from the neck to the head and the precautions needed with respect to the vertebral artery as it courses through this region.

This region is important because the *greater occipital nerve* (sensory branch of C2) pierces the semispinalis capitis muscle prior to providing innervation to the posterior scalp. Irritation of this nerve can be a major cause of headaches.

This craniovertebral area is also important, as it pertains to the vulnerability of the *vertebral artery*. The two vertebral arteries arise from the subclavian arteries prior to entering the transverse foramen of C6, bilaterally, and traveling up through C1. These arteries are responsible for providing 20% of the blood to the brain. After they pass through C1, the arteries travel along the superior surface of the atlas before entering the brain through the foramen magnum. Extreme caution should be used during manipulation (use only non-thrust techniques), muscle energy techniques, and manual traction so as not to occlude these arteries. Only 45° of rotation is enough to "kink" the artery, and the lumen can narrow up to 90% of its original size with contralateral side bending.[57,130a] This can be exaggerated when coupled with backward bending. Thus, if the patient has a history of instability, such as rheumatoid arthritis or long-term steroid use, or complains of dizziness or balance impairments, extreme care must be utilized during manipulative movements of the craniovertebral region. Specific treatment of headaches and selected cervical impairments are discussed in the following sections.

Tension Headache/Cervical Headache

The three most common categories of headaches are: vascular (such as migraine or cluster), inflammatory (tumors or disease of eye, nose, and throat), and musculoskeletal. The final classification includes headaches that result from tension, cervical spine impairments, or temporomandibular dysfunction. Musculoskeletal headaches are a common complaint with impaired posture. About 15% to 20% of chronic and recurrent headaches are diagnosed as cervical headaches and are related to musculoskeletal impairments.[79] Often, there is associated tension in the posterior cervical muscles and pain at the attachment of the cervical extensors, at the cervico-thoracic junction, and/or radiating across the top, side, or back of the scalp.

Etiology

There are many factors that may cause a cervical headache.[100] Headaches may follow soft tissue injury or may be caused by faulty or sustained postures, greater occipital nerve irritation or impingement, or sustained muscle contraction (from faulty posture or emotional tension) leading to ischemia. With cervical headaches, the joints and ligaments of the upper cervical spine are often inflamed or in dysfunction. This includes inflammation of cranial nerves V, VII, IX, and X as they descend into the grey matter of C1–3 and provide sensation to the face, forehead, orbit, sinuses, and TMJ region.[130a] Headaches may be related to TMJ dysfunction or other conditions, such as allergies or sinusitis, or there may be vascular or autonomic involvement as with migraine or cluster headaches.[115] Cervical impairments, which may lead to headaches, can also arise from faulty thoracic joint mobility.[77,87] Whatever the cause, there usually is a cycle of pain, muscle contraction, decreased circulation, and more pain, which leads to decreased function and potential soft tissue and joint impairments.

Presenting Signs and Symptoms

Therapists can effectively treat headaches if they were caused by trauma or stress or if function triggers the onset and/or pain begins in the neck and becomes a headache.[149] Differentiating cervical headaches and related impairments in the musculoskeletal system from other kinds of headaches, such as cluster or migraine headaches, is important for developing a plan of care that effectively manages the headaches. Box 15.12 identifies common history and symptoms associated with cervical headaches as well as red flags that require referral to a physician.[79]

BOX 15.12 History and Symptoms of Cervical Headaches

- Unilateral headaches or bilateral headaches with one side predominant
- Pain in the neck or suboccipital region that spreads into the head
- Intensity can fluctuate between mild, moderate, or severe
- Precipitated by sustained neck postures or movements
- May be precipitated by stress (also common with other types of headache)
- May be related to trauma, DJD, or a sedentary lifestyle and postural stresses
- More prevalent in females but no familial tendency
- Pain or altered sensation in the face or TMJ region

Red Flags and Precautions

A referral to a physician is indicated if the patient complains of any of the following, as the headache is probably not of musculoskeletal origin.

- States this is either the first or worst headache they have ever experienced
- Reports sharp pain or spikes in intensity
- Reports headaches come in bunches, i.e. throughout the day or over several hours, the headaches come and go
- A change in personality or behavior is reported

Musculoskeletal Impairments

Musculoskeletal impairments include:

- Joint impairments in the upper cervical spine and craniovertebral region (pain and motion restrictions).
- Impaired muscle performance (impaired tonic postural control and endurance in upper and deep cervical flexors and possibly multifidus and small posterior suboccipital muscles).[79]
- Impaired shoulder girdle/scapular posture with related muscle imbalances.
- Impaired lumbar posture with related muscle imbalances.[100]
- Impaired neural tissue from pressure or inflammation in the upper cervical/craniovertebral region.
- Impaired neuromotor control.
- Impaired upper thoracic mobility.

General Management Guidelines

Management is directed toward reversing physical impairments, including posture correction, stress management, and prevention of future episodes.[79]

Pain Management

Modalities, massage, and muscle-setting exercises are used to break into the cycle of pain and muscle tension.

Mobility Impairments and Impaired Muscle Performance

Examine the flexibility and strength of the muscles in the cervical, upper thoracic, shoulder girdle, and lumbar spine, and design an exercise program to regain a balance in flexibility and neuromuscular control in conjunction with posture correction and training as described in the previous section (see Boxes 14.2 and 14.3). Interventions that have been reported to decrease the intensity and incidence of cervical headaches include the following.[79,100]

Mobility and flexibility. Increase joint mobility in the cervical spine and flexibility in the suboccipital muscles to relieve tension in that region as well as to activate and train the deep cervical flexors for control of capital flexion and cervical retraction (described in Chapter 16). Control and support from the deep segmental muscles is the foundation of management.

Cervical stabilization. Utilize cervical stabilization exercises as described in detail in Chapter 16, emphasizing tonic holding of the deep segmental muscles in isolation from the global muscles.[79]

Scapular stabilization and posture. Train the lower trapezius, rhomboids, and serratus anterior muscles in tonic holding postures to improve control of scapulothoracic posture (described in Chapter 17).

Stress Management

If the person is in tension-producing situations, relaxation techniques, ROM and muscle-setting techniques, and proper spinal mechanics are taught.

FOCUS ON EVIDENCE

Jull and associates[78] conducted a multicenter, randomized, controlled study of 200 individuals with cervicogenic headache. They looked at the effectiveness of manipulative therapy and a low-load exercise program alone and in combination compared to a control group, and found that both interventions reduced headache frequency and intensity and reduced neck pain compared to that in the control group, and that the effects were maintained at the 12-month follow-up. The exercise intervention primarily consisted of training postural control of the longus colli and other deep neck flexors as well as the serratus anterior and lower trapezius muscles and increasing muscular endurance. (See Chapter 16 for a description of the cervical stabilization exercises and Chapter 17 for a description of the scapular stabilizing exercises.) Postural correction exercises were also performed throughout the day and progressed to isometric resistance and flexibility exercises.

Prevention. Underlying the prevention of future episodes of cervical headaches is the education of the patient to correct postural stresses, maintain a healthy balance in the length and strength of the postural muscles, and adapt the home, work, or recreational environment to minimize sustained or repetitive faulty postural alignment.

Cervical Myelopathy

Cervical myelopathy is a disease of the spinal cord.[130a] It results from degeneration or stenosis of the central spinal canal. The prevalence of this disease is unknown. A person with cervical myelopathy may experience neurological symptoms in both his hands and feet. In addition to an uncoordinated gait, people who have cervical myelopathy may experience a variety of upper motor neuron lesions, including bowel and bladder impairments. Myelomalacia, seen on a MRI film, is the gold standard for the accurate diagnosis of this pathology.[29] There are no neurologic tests or signs that offer both a high sensitivity and specificity.[29]

Therapy interventions are based on the associated impairments and identifying the cause. As this pathology is caused by degeneration, stenosis, or spondylosis, the intervention sequence for cervical myelopathy will follow the same guidelines as described under those pathologies. This includes scapular stabilization, posture education, and cervical and thoracic joint manipulations.

Neck Pain

It is estimated that 22% to 70% of the American population will have neck pain in their life.[23] Prevalence increases with age, and nearly 37% of people have neck pain that lasts longer than 12 months.[23] Almost 25% of all patients seen in outpatient physical therapy clinics have this complaint.[23]

Therapy interventions for cervical pain follow the same guidelines described earlier (see Management Guidelines in Boxes 15.5, 15.7, and 15.8). As identified in the "Hypomobility: Manipulation" section, it is important to assess and treat the thoracic spine in people with cervical impairments,[77,87] because not only does the thoracic spine move during cervical motions, influence cervical posture, and have common muscle attachments, but also because the thoracic spine is prone to hypomobility impairments. Performing joint manipulation and high-velocity thrust to the thoracic spine will often improve outcomes in people with cervical symptoms.[26,77,87] Patients with neck pain also report more symptoms of temporomandibular joint dysfunction than healthy controls (for management guidelines, see the next section).[32]

Temporomandibular Joint Dysfunction

The function of the temporomandibular (TM) joint is closely related to the function of the upper cervical spine and posture. In 70% of patient cases, neck pain is associated with temporomandibular dysfunction (TMD).[122] Because of this close relationship and co-occurrence of neck pain and jaw dysfunction, a brief description of the structure, function, impairments, and interventions related to the TMJ are included.

Structure and Function

Each TMJ is described as a ginglymoarthrodial joint (combination of a hinge and plane joint), consisting of the mandibular condyle articulating with the TM disc and glenoid fossa of the temporal bone (Fig. 15.17). Together, these joints perform tasks such as chewing, talking, and yawning.

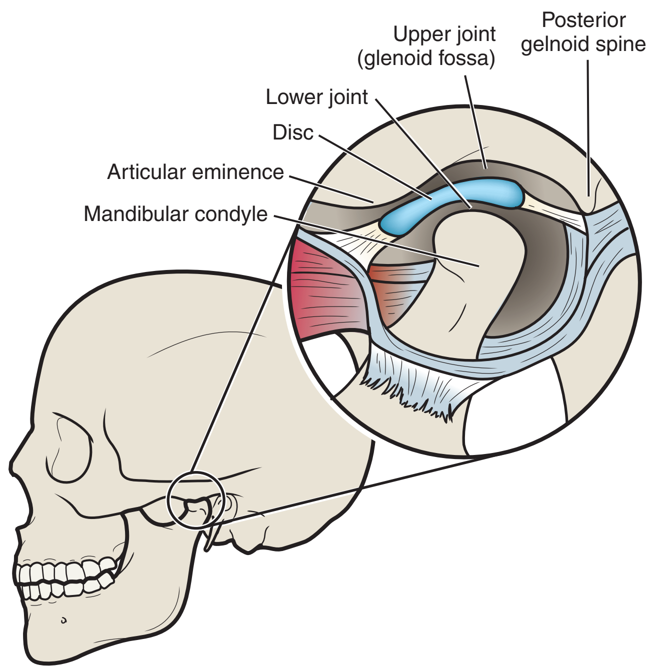

FIGURE 15.17 Structure of the TMJ.

Motions of the TMJs. The motions available at the TMJs include mandibular depression (mouth opening), lateral deviation, and protrusion.

- During mandibular depression, the condyle both rolls and slides anterior on the TM disc while the disc also slides anterior to maintain a congruent surface with the fossa (Fig. 15.18). Mouth opening is primarily facilitated by gravity with minimal assistance from the anterior digastric and the lateral pterygoid muscles.
- Protrusion occurs when both TMJs slide anteriorly.
- Lateral excursion involves the ipsilateral TMJ spinning in place with the contralateral TMJ sliding anterior. Both protrusion and lateral excursion are needed when grinding small foods, like lettuce.

Signs and Symptoms

The three cardinal (main) signs of TMJ impairments are[31,40,54,104,105,112,113,118]:

- Pain in the TMJ region that is affected by movement.
- Joint noise during movement.
- Restrictions or limitations with jaw movement.

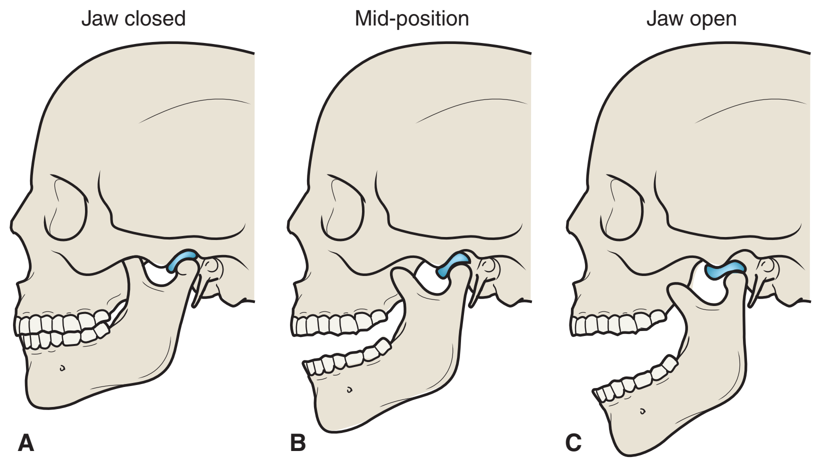

FIGURE 15.18 Mandibular depression: **(A)** relationship of the condyle, TM disc and glenoid fossa with jaw closed; **(B)** as the jaw opens the condyle rolls on the TM disc, then **(C)** the disc and condyle slid anterior on the articular eminence.

Pain from a variety of sources is often cited as part of the TM joint syndrome.[115]

- Pain may occur locally in the TMJ, in the richly vascularized and highly innervated retrodiscal pad located in the posterior region of the joint, or in the ear.
- Pain from muscle spasm or myofascial pain in the masseter, temporalis, or the medial or lateral pterygoid muscles may be described as a headache or facial pain.
- Tension in the muscles of the cervical spine may itself be painful or cause referenced pain from irritation of the greater occipital nerve that may be described as a tension headache.

Etiology of Symptoms

Possible Causes of TMJ Pain

TM joint impairments are usually the result of trauma, poor posture, or faulty movement patterns. Additionally, symptoms can result from:

- Poor oral hygiene.
- Gum chewing.
- Heavy kissing.
- Bruxism (grinding the teeth).
- Smoking.
- Inflammatory conditions such as rheumatoid arthritis.
- Open mouth breathing.

Relationship to Neck Pain

Two theories have been proposed as to why neck pain may cause TMJ discomfort.[146] Causes may be:

- A result of the neurophysiological influences from pain in masticatory muscles via the tonic neck reflex and/or the agonist/antagonist relationship of the anterior and posterior cervical muscles.
- Patients with neck pain respond by bruxing (grinding the teeth), which may lead to muscle or TMJ pain.

Mechanical Imbalances

Imbalance that occurs between the head, jaw, neck, and shoulder girdle may also precipitate TMD signs and symptoms. Causes may be:

- Malocclusion, decreased vertical dimension of the bite, or other dental problems.[90]
- Faulty joint mechanics from inflammation, subluxation of the meniscus (disc), dislocation of the condylar head, joint contractures, or asymmetrical forces from jaw and bite imbalances. Restricted motion results from periods of immobilization after reconstructive surgery or fracture of the jaw.
- Muscle spasm in the muscles of mastication, causing abnormal or asymmetrical joint forces. Muscle spasm can be the result of emotional tension, faulty joint mechanics, direct or indirect injury, or a postural dysfunction.
- Sinus problems, resulting in mouth breathing, which indirectly affects posture and jaw position.
- Forward-head posture resulting in retraction of the mandible, which places the anterior throat muscles in a lengthened position. Consequently, there is increased activity in the muscles that close the jaw to counter the mandibular depression force caused by the digastric muscles. Extension of the head on the upper cervical spine places the muscles and soft tissue in the suboccipital region in a shortened position, so they lose flexibility. Also, the nerves and joints in the upper cervical region become compressed or irritated.
- Sudden trauma, such as a flexion/extension accident in which the jaw forcefully opens when the head whips back into hyperextension; a direct blow from an auto accident, boxing, a fall, or similar trauma.
- Sustained trauma associated with prolonged dental surgery in which the mouth is held open for a lengthy period of time may initiate symptoms in the TMJ or supporting tissue. Excessive stresses, such as biting or chewing on large pieces of hard food, may also traumatize the joints.

Principles of Management and Interventions

The approach to management depends on the cause of symptoms and/or functional limitations. It is important to remember that "aggressive and irreversible treatments" should be avoided if possible.[56] In simple cases in which posture, joint dysfunction, or muscle imbalances are the source of the problem, intervention with therapeutic exercise can directly address the impairments. In many cases, a dental referral, otolaryngology referral, or psychological support may be necessary to deal with related pathology. A complete evaluation is necessary prior to initiation of any treatment. Successful management of TMJ impairments is directly related to the accuracy of diagnosing the underlying pathology.[36]

Reduction of Pain and Muscle Guarding

Use of modalities for pain modulation and relaxation are often indicated during acute and painful episodes. Extra- and intraoral myofascial techniques are indicated to improve joint and muscle mobility and decrease pain. In addition, the person should eat soft foods and avoid items requiring excessive jaw opening (i.e., apple, corn on the cob, large sandwich) or firm biting (i.e., carrots) and repetitive chewing motions (i.e., gum).

Soft Tissue Techniques

The following soft tissue techniques can be performed by the therapist and/or incorporated into a home exercise regimen. These techniques are suggested to reduce muscle tension and/or improve mobility in the TMJ region:

- *Extra-oral massage.* Perform using a circular motion technique in the region of either the masseter or temporalis muscle. Use a gentle massaging motion to facilitate muscle relaxation.
- *Intra-oral trigger point release.* Identify a point of muscle tension within either the temporalis or masseter tendons. Maintain gentle finger point pressure until the muscle is felt to relax. Repeat at multiple areas of the muscle where muscle tension is identified.
- *A Petrous sinus release.* This technique is indicated in patients with TMJ pain and limitations due to muscle guarding and/or sinus involvement. Place one finger on the buccal side of the maxillary teeth and move posterior and cephalad. Once resistance is met, then maintain pressure until a "release" or softening of the muscle occurs. It is judicious to advise the patient that this technique may be a little uncomfortable.

Fascial Muscle Relaxation and Tongue Proprioception and Control

The following are suggested techniques.

- Place the tip of the tongue on the hard palate behind the front teeth and draw little circles or letters on the palate. For additional stimulus, place a Lifesaver® between the tongue and palate; then follow the circular edge with the tip of the tongue.
- Place the tip of the tongue on the hard palate and blow air out to vibrate the tongue, making an "r r r r" sound.
- Fill the cheeks with air (mouth closed); then let the air out in a puff.
- Make a "clicking" sound with the tongue on the roof of the mouth. When doing so, the jaw drops open quickly and returns with the teeth slightly apart, and the tongue usually rests on the hard palate behind the front teeth. This is the resting position of the jaw and is also the first step in teaching relaxation exercises. (Relaxation exercises are described in Chapter 14.)

Control of Jaw Muscles and Joint Proprioception

First, teach recognition of the resting position of the jaw. The lips are closed, teeth slightly apart, and tongue resting lightly on the hard palate behind the front teeth. The patient should breathe in and out slowly through the nose, using diaphragmatic breathing. Resting position of the jaw should be maintained throughout the day.

- Teach control while opening and closing the jaw through the first half of the ROM. With the tongue on the roof of the mouth, the patient opens the mouth, trying to keep the chin in the midline. Use a mirror for visual reinforcement. The patient is also taught to lightly palpate the lateral pole of each condyle of the mandible bilaterally and attempt to maintain symmetry between movement of the two sides when opening and closing the mouth.
- An alternative for training joint proprioception is to have the patient place one finger on a maxillary canine tooth (i.e., cuspid). The patient slowly opens and closes his or her mouth, attempting to bring the corresponding mandibular canine in contact with his or her finger during end-range mandibular elevation. The technique can be advanced by instructing the patient to begin in lateral excursion and then attempt to return his or her mandible to the correct position.
- If the jaw deviates while opening or closing, have the patient practice lateral deviation to the opposite side. The lateral motion should not be excessive or cause pain.
- Progress to applying gentle resistance with the thumb against the chin. Do not overpower the muscles.

Stretching Techniques

If there is restricted jaw opening, determine if it is from hypomobile tissues or a dislocated meniscus. Passive stretching and joint mobilization/manipulation are used to stretch tight tissues. Joint distraction can be used to reposition a meniscus that is blocking opening.

Passive Stretching

Stretch to increase jaw opening if indicated. Begin by placing layered tongue depressors between the central incisors. The patient can gradually work to increase the amount of tongue depressors used until he or she can open approximately far enough to insert the knuckles of the index and middle fingers.

- Self-stretching is carried out by placing each thumb under the upper teeth and the index or middle fingers over the lower teeth and pushing the teeth open.

Joint Manipulation Techniques VIDEO 15.4

Patient position and procedures: Supine or sitting, with the head supported and stabilized. Perform joint techniques with a gloved hand or hands. Determination of dosages and precautions for administration of manipulative techniques are described in Chapter 5.

- *Unilateral distraction* (Fig. 15.19 A). Use the hand opposite the side on which you are working. Place your thumb in the patient's mouth on the back molars; the fingers are outside and wrapped around the jaw. The force is in a downward (caudal) direction.
- *Unilateral distraction with glide* (Fig. 15.19 B). After distracting the jaw as described above, pull it in a forward (anterior) direction with a tipping motion. The other hand can be placed over the TMJ to palpate the amount of movement.

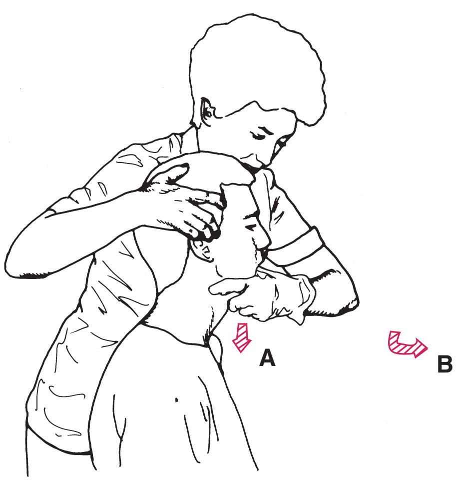

FIGURE 15.19 Unilateral mobilization of the temporomandibular joint. **(A)** Distraction is in a caudal direction. **(B)** Arrow indicates distraction with glide in a caudal, then anterior direction.

- *Bilateral distraction* (Fig. 15.20). If the patient is supine, stand at the head of the treatment table. If the patient is sitting, stand in front of the patient. Use both thumbs, placing them on the molars on each side of the mandible. The fingers are wrapped around the jaw. The force from the thumbs is equal in a caudal direction.
- *Self-manipulation.* Place cotton dental rolls between the back teeth and have the patient bite down. This distracts the condyles from the fossae in the joints.

FIGURE 15.20 Bilateral distraction of the temporomandibular joint with the patient supine.

Reduction of Upper Quarter Muscle Imbalances

Identify flexibility and strength imbalances in the upper quarter. Stretch restricting postural muscles, teach relaxation, and then retrain for proper muscle control. Cervical and shoulder postural stretching and retraining exercises are described in Chapters 16 and 17, respectively.

Independent Learning Activities

Critical Thinking and Discussion

1. What are the functional differences between the way the cervical spine and lumbar spine are used in daily activities?
2. Explain how different individuals who sustain back injuries can experience different symptoms of radiating pain down the leg, numbness and tingling into the foot, deep aching down the leg, or no leg symptoms at all. What does each of these symptoms mean?
3. Explain why some people experience diminished symptoms and improved function if the emphasis of intervention is spinal extension, whereas others improve if the emphasis of intervention is spinal flexion.
4. Identify three common causes of musculoskeletal headaches. What are the indications of headaches that could be identified that would warrant a referral to a medical physician?

Laboratory Practice

1. Practice identifying cervical and lumbar spine positions when in the supine, prone, side-lying, sitting, and standing positions. Determine what is needed to change the position.

For instance, if flexion is emphasized, what is needed to cause extension?

2. Identify and feel what happens to the various portions of the spine when moving from one position to another, such as rolling supine to prone and return, moving from supine to sit, moving from sit to stand and reverse.
3. Practice methods for developing gentle isometric muscle contractions that could be used during the acute phase of treatment for both the cervical and lumbar spines.
4. Practice the various proprioceptive exercises and manipulation techniques for the TMJ region.

Case Studies

Case 1

A 45-year-old man sustained injuries in a rear-end collision 4 days ago (car hit him going approximately 45 mph while he was stopped at a stop light). He was in an older car without an air bag or properly positioned headrest, although he was wearing a seatbelt. Initially, he hit the headrest at the mid-cervical spine as his neck extended, and then his head flexed forward but did not hit anything. He has been cleared of cervical fractures or instability. Medical history is unremarkable; he is a social drinker and gave up smoking 5 years ago. He is an accountant and usually works long hours at a computer but has been unable to work since the accident. He presents wearing a cervical collar and has a facial expression of distress. He states he has had difficulty sleeping because the pain wakes him whenever he moves.

Pain: constant posterior cervical pain, headaches, and pain radiating into the shoulder region bilaterally; intermittent tingling in the right thumb, index, and middle finger. Pain rated at 8/10 when at rest, 10/10 when attempting to move.

Positive findings: guarded forward-head posture. He is unwilling to move more than 10° into flexion or extension, 25° into side bending bilaterally; minimal rotation.

Gentle traction to the head relieves the neurological symptoms. Palpation tenderness in upper trapezius and posterior cervical and anterior throat muscles bilaterally. Increased tenderness along facet margins of C4–5, 5–6 and 6–7, right > left.

- Based on the above impairments and functional limitations, identify goals and interventions for this patient. Describe the techniques you would use and practice them on a laboratory partner.
- How long do you anticipate the patient will have these symptoms? At what point will you change your goals?

Case 2

Assume you did not see the patient described in Case Study 1 until 4 weeks after the accident. He no longer has constant pain and has returned to work. His complaints are an inability to sit at the computer for more than 30 minutes before his hand starts to tingle. Numbness occurs after 1 hour of work. Headaches begin within 2 hours of work. Neck and shoulder pain is 6/10 by midday at which time he takes NSAIDs so he can continue working. Positive tests include forward-head posture with forward shoulders; decreased flexibility in the suboccipital muscles, anterior thorax, and internal rotators of the shoulder. Cervical flexion is 75%, extension 50%, and side bending and rotation 75% bilaterally. Sustained extension of the cervical spine causes tingling in the thumb, index, and middle finger of the right hand. Strength of scapular adductors and lateral rotators of the shoulder is 4/5; myotome testing is normal bilaterally.

- What are your goals and interventions for this patient at this stage?
- After studying the techniques described in Chapter 16, describe the techniques you would use with this patient and practice them on a laboratory partner.
- For each therapeutic exercise technique, practice progressions and determine how you would progress this patient so he could work without exacerbation of symptoms.

Case 3

A 55-year-old woman presents with early signs of degenerative joint disease of the lumbar spine. She has been an active runner since college. Occasionally, she has participated in aerobic dance classes. Her history is unremarkable. She has three grown children and had no complaints of back pain related to the pregnancies.

Current symptoms: intermittent periods of pain extending from the mid-lumbar spine, through the right buttock and posterior thigh. The pain begins 15 minutes into her running and progresses to an 8/10 by 25 to 30 minutes. She also complains of increased stiffness after sitting > 1 hour, standing > 15 minutes, as well as when waking in the morning and getting out of bed. She is a middle-school teacher and track coach for a girls' high school team.

Key findings: lordotic posture, with tight low back, hip flexors, and tensor fasciae latae. Strength of lower abdominals is 4/5. Forward bending of the spine increases tension in low back, repeated backward bending and prone press-ups increase buttock pain. Side bending is decreased 25%, with some discomfort with overpressure into right side bending.

- Based on these impairments and limitations, identify the irritability of the condition and determine goals and intervention.
- What are the most important factors to emphasize with this individual to help her manage her symptoms?
- After studying the exercises in Chapter 16, practice the techniques you would have this patient do. Also, practice how you would progress the techniques and what criteria you would use for progressions.

Case 4

A 42-year-old man presents with a medical diagnosis of herniated nucleus pulposus at the L5–S1 area. Present symptoms began 4 days ago when rising out of bed. He is a sedentary person who plays social golf on the weekends (rides in a cart)

and is 50 lb overweight. He has had occasional episodes of low back pain over the past 15 years, but "nothing like this."

Medical history: smokes one pack of cigarettes per day and is on blood pressure medication. He describes the symptoms as a sharp pain beginning in the left buttock region and radiating down the back of the thigh; there is intermittent paresthesia along the lateral border of his foot, which is noticeable when sitting. He describes a considerable increase in symptoms when attempting to rise from bed or from a chair or when straining. He has been unable to walk because he cannot stand upright. On observation, you note that the patient is standing with a posterior pelvic tilt and forward-bend of the trunk, and the thorax is deviated to the right.

Examination maneuvers: all spinal flexion motions increase symptoms; side gliding of the thorax to the left followed by lumbar extension centralizes the symptoms primarily to buttock and low back pain.

- Based on this information, identify the impairments and functional limitations. What type of intervention should be used?
- Develop a sequence of treatment techniques that you would use during the first visit. Include instructions and precautions. Practice the techniques.

Case 5

A 61-year-old male underwent a transforminal lumbar interbody fusion at the levels of L4–S1 approximately 8 weeks ago. He is a retired high school teacher and would like to return to working in his yard and playing golf. He states his pain is localized to his low back region with a 3/10 with activity. His current complaints include difficulty standing from low surfaces, such as the commode and the couch. He also feels he has decreased endurance, as he is unable to walk his dog more than 10 minutes in the morning. He would like to be able to walk for up to 1 hour.

Medical history: patient reports he drinks one glass of wine with dinner and does not smoke. He has a positive history for hypertension. All other medical history is unremarkable.

Examination: patient has full trunk ROM with pain reported at end-range in all directions. Patient has bilateral 4/5 knee extension and 3+/5 hip flexion strength. Abdominals are 3/5. Sensation is intact to light touch bilaterally throughout his lower extremities. Patient ambulates without an assistive device but is still wearing a removable lumbar orthotic (chair-back brace) for the next 4 weeks. The physician has told the patient not to lift anything heavier than 20 pounds.

- What are your goals and interventions for this patient at this stage?
- After studying the techniques described in Chapter 16, describe what you would use with this patient at his current level of function and practice the regimen on a laboratory partner. What criteria would you use to progress his exercises? How would you incorporate functional progressions in his exercise routines?
- How would you discuss with your patient the resumption of his activities of yard work and golf? What modifications/precautions should he make?

Case 6

A 22-year-old female presents with left side TMJ pain with an onset of approximately 6 months ago. She is a graduate student (law school) and reports she has been extremely busy in school. She also reports she is planning her wedding, which will occur in 3 months. She cannot recall any previous trauma. She has been to the dentist, and he cleared her from any dental pathologies (abscess, fracture, etc.). The current complaint is pain with chewing and limited opening, especially with yawning. Her past medical history is unremarkable.

Examination: she has forward head posture with increased cervical lordosis and no deviation in the frontal plane. Bilateral upper extremity strength and sensation are normal and symmetrical. Cervical range of motion is approximately 25% limited with flexion and bilateral rotation. Patient demonstrates TMJ opening 50% of normal and lateral excursion 75% of normal. There is pain with palpation at the muscle bellies of the masseter and temporalis.

- Based on this information, identify the impairments and functional limitations. What type of intervention should be used?
- Develop a sequence of treatment techniques that you would use during the first visit. Include instructions and precautions. Practice the techniques.
- Identify methods the patient can use to manage and/or decrease her stress.

CHAPTER

16

The Spine: Exercise and Manipulation Interventions

CAROLYN KISNER, PT, MS ■ JACOB N. THORP, PT, DHS, MTC

Continued

The basic anatomy, spinal mechanics, and posture are presented in Chapter 14. In Chapter 15, the pathomechanics, common pathologies, and management guidelines related to the spine are presented. The management guidelines are outlined based on stages of healing as well as subgroupings based on diagnostic categories that reflect impairments and movement disorders. Chapter 16 is a continuation of this material in which the techniques of intervention using mobilization/manipulation and therapeutic exercise for management of neck and trunk impairments are described.

This chapter is divided into six main sections. The first section describes the underlying concepts and approaches to exercise interventions. Each of the remaining five sections describes elements of physical function for the neck and trunk. The topics covered in these sections include exercises for kinesthetic awareness, mobility/flexibility, muscle performance (including stability, muscle endurance, and strength), cardiopulmonary endurance, and functional activities. Stress relief and relaxation principles and techniques, important components of total rehabilitation, are covered in detail in Chapter 14.

Basic Concepts of Spinal Management with Exercise

It is important to recognize that, even though the material in this chapter is presented in separate sections, there is an overlap in the use of the techniques described in each section, and there are fundamental interventions basic to all exercise programs.

Fundamental Interventions

When patients seek treatment from a physical therapist, they come with different diagnoses, impairments, and functional limitations and are at different stages of tissue healing. Yet the treatment plan for each patient must begin with fundamental interventions in order to lay the foundation on which to build an effective therapeutic exercise program. *Fundamental interventions* are defined as exercises or skills that all patients with spinal impairments should learn regardless of their functional level at the time of examination and initial treatment. The interventions include basic kinesthetic training, basic spinal stabilization training, and functional training of basic body mechanics. These interventions are summarized in Box 16.1.

BOX 16.1 Fundamental Exercise Interventions for Spinal Rehabilitation

These fundamental interventions are adapted or modified based on patient abilities and responses.

Kinesthetic Training
- Awareness and control of safe spinal motion: head nodding and pelvic tilts
- Awareness of neutral spinal position (if needed begin in the patient's spinal bias) while supine, prone, sitting, and standing
- Awareness of effects of activities of daily living (ADLs) and extremity motion on the spine (see Functional Training)

Stabilization Training
- *Deep segmental muscle* activation and sustained contraction
  - Cervical region: controlled axial extension with craniocervical flexion and lower cervical/upper thoracic extension
  - Lumbar region: drawing-in maneuver and multifidus muscle activation techniques
- *Superficial multi-segmental (global) muscle* control of spinal posture with extremity loading
  - Passive support of spinal posture if needed; progress to active control
  - Coordinate segmental muscle activation with maintenance of a stable spine in neutral spinal position (or position of bias) with all arm and leg motions

Functional Training (Basic Body Mechanics with Stable Spine)
- Log roll supine to prone, prone to supine
- Transition from supine to side-lying to sitting and return
- Transition from sit to stand and return
- Walking

Once the fundamental skills are learned, exercise interventions then progress on a continuum at the level of the patient's abilities and willingness to learn. For example, a patient beginning treatment with chronic symptoms several months after the onset of symptoms must first become aware of positions or activities that increase the symptoms, and then learn how to move the spine safely as well as learn what effects the various postures and movements have on symptoms (*fundamental* kinesthetic awareness). The patient must learn how to activate the deep segmental stabilizing musculature and then how to use the deep stabilizers with the global musculature to stabilize the spine against various extremity loading exercises (*fundamental* muscle performance). Finally, the patient must learn basic body mechanics (*fundamental* functional activities) in order to minimize stresses to the spine during daily activities before progressing to exercises that can be tolerated at the chronic stage of healing and returning to desired functional activities. The fundamental exercises are described in detail preceding the exercise progressions in each of the respective sections of this chapter. The principles of management are similar for the cervical and lumbar spinal regions, and many of the same techniques may be used or modified for both regions.

Patient Education

Patient education is the key component of every goal and intervention. It encompasses several ideas. First, the patient is an active participant in identifying the desired outcomes; education as to potential outcomes is part of this process. Second, the patient may need to be educated about limitations at each stage of healing, so he or she will not become concerned that the acute symptoms will be forever disabling and will not "overdo" exercises and activities during the early subacute phase and cause exacerbation of symptoms. The patient may then need to be challenged to progress beyond perceived limitations during the later stages of recovery.

To ensure that each individual develops control over and learns to manage the symptoms and any impairments, it is important that the patient is engaged in all activities at each stage of recovery and is not just a passive recipient of "treatment." The patient needs to be instructed on how to safely progress self-management beyond the time spent under professional supervision so he or she can reach the maximum level of functional return with minimal activity or participation restrictions.

Finally, the patient needs instruction in prevention. This includes safe ways to exercise, safe body mechanics for return to high-intensity activities, modification of the work and home environment, and activities to minimize stresses.

General Exercise Guidelines

Therapeutic exercise is an important intervention in the management of impairments in the spinal region. Although this text does not deal with specific examination techniques, it is critical to emphasize the importance of identifying each patient's structural and functional impairments, their activity and participation restrictions (functional limitations), and the stage of tissue healing or stage of rehabilitation in order to establish a baseline for the initiation of intervention techniques and to measure progress toward the outcome goals. In many cases, tissue healing, stages of rehabilitation, and functional expectations parallel one another (Table 16.1).

In general, the following elements of physical function are used in all intervention programs for spinal problems. These five areas are listed in Table 16.2 with interventions for each stage of rehabilitation. The interventions are described in detail in the remaining sections of this chapter. Prior to developing an exercise program, it is important that the reader has knowledge of various spinal pathologies and the special precautions and contraindications (see Chapter 15), so each patient can safely achieve his or her maximum potential.

Kinesthetic Awareness

One of the fundamental interventions for spinal rehabilitation is to develop patient awareness of safe spinal positions and spinal movement as well as what effect the supine, prone, side-lying, sitting, and standing positions have on the spine.

TABLE 16.1 Spinal Rehabilitation

Stage of Tissue Healing	Phase of Rehabilitation and Level of Protection	Functional Expectations
Acute	Early training phase Maximum protection	Control symptoms; ADL if possible
Subacute	Basic training/controlled motion phase Moderate protection	IADL and limited work
Chronic	Intermediate to advanced training/return to function phase Minimal to no protection	Return to work, recreation, sports

The sequence of rehabilitation parallels the stages of healing and functional outcome expectations.

TABLE 16.2 Intervention for Each Phase of Rehabilitation

Phases of Rehabilitation **Intervention**	**Early Training/ Protection Phase** **Maximum to moderate protection of injured area, pathologically involved tissues, or painful region**	**Basic Training/Controlled Motion Phase** **Moderate to minimum protection**	**Intermediate to Advanced Training/ Return to Function Phase** **Minimum to no protection**
Kinesthetic awareness ■ Proprioception training of safe movement and postures	■ Pelvic tilt /cervical retraction: passive —> active assist —> active in comfortable positions.* ■ Awareness of what makes symptoms better vs. worse* ■ Learn neutral spine (or bias)*	■ Active spinal control in supine, prone, quadruped, sitting, standing ■ Dynamic maintenance of pain-free position with activities	■ Habitual use of neutral spine in all functional activities
Mobility/flexibility ■ Move, stretch, manipulate restricting tissues	■ Movement to relieve fluid stasis. ■ Trunk stretching: only in pain-relieving positions. ■ Extremity stretching: stretch U/LE if no stress to the spine. ■ Manipulation: grades I and II ■ High-velocity thrust if indicated	■ Gentle spinal movement into painful range ■ Stretch U/LE muscles; stabilize spine in position of bias ■ Manipulation: progress to grade III	■ Move into painful ranges to stretch and manipulate as indicated
Muscle performance ■ Stabilization training (deep muscles for segmental stability, global muscles for general stability) ■ Muscle endurance ■ Strength and power	■ Activation of deep musculature.* ■ Stabilization exercises with extremity loading (use of passive positioning of spine with pillows, splints, corsets if necessary)*	■ Stabilization exercises with extremity loading (active control of spine position) ■ Emphasize muscle endurance ■ Perturbation training ■ Low-intensity dynamic spinal exercises	■ Stabilization with transitional motions and functional activities; emphasize strength ■ Progression to dynamic trunk strengthening ■ Progress trunk and extremity strengthening exercises in patterns that reinforce activity goals
Cardiopulmonary Endurance ■ Aerobic training	■ Only if tolerated with maximum protection in position of comfort	■ Low to moderate intensity with moderate to minimal protection. ■ Use activities that emphasize spinal bias	■ High-intensity (target heart rate), multiple times per week
Functional Activities ■ Body mechanics ■ Skill in home, community, work, recreation, sport activities	■ Safe postures for recumbent, sitting, and standing* ■ Stabile-spine techniques while rolling over, moving supine to sit, sit to stand*	■ Strengthen U/LE while stabilizing spine ■ Stable spine body mechanics ■ Environmental and ergonomic adaptations	■ High-intensity functional activities. ■ Endurance and strengthening activities that replicate return to desired activities ■ Practice prevention
Conscious activation of segmental and global muscles with spine in neutral position in all stabilization exercises and activities.			

*Fundamental interventions for all patients.

Awareness of what postures make the symptoms better or worse and identifying the neutral spinal position or position of bias are important in helping patients manage their symptoms. Awareness and control of spinal posture and movement are progressed and incorporated into all the exercises described in the remaining sections of this chapter and underlie exercises for the extremities as well.

Mobility/Flexibility

Stretching and flexibility exercises as well as mobilization/manipulation techniques are used to increase mobility of restricting tissues, so the patient can assume an effective position of the spine when exercising to improve muscle performance and functional outcomes. For patients who fit the Mobilization/Manipulation diagnostic category (described in Chapter 15), spinal manipulation techniques or specific high-velocity thrust techniques (HVT) may be indicated during the early intervention period and then followed with stretching exercises.

NOTE: The terms *mobilization* and *manipulation* are currently being used interchangeably, with a trend towards using the term *manipulation* (see Chapter 5). The authors of this chapter are using *manipulation* to refer to graded oscillation techniques, and high-velocity thrust (HVT) to refer to high-velocity, small-amplitude motion performed at the end of the pathological limit of the joint.

Muscle Performance

In the spine, muscle performance involves not only strength, power, and endurance but also stability. Activation of the deep segmental-stabilizing muscles and exercises to develop spinal control in the global stabilizing muscles are fundamental for developing spinal stability. Emphasis is placed on awareness of muscle contraction and control of spinal position while moving the extremities. Exercises are then progressed to challenge the holding capacity of the stabilizing muscles, emphasizing muscle endurance, balance, and strength. Once the individual learns effective stabilization and management of symptoms, dynamic neck and trunk strengthening exercises are initiated. Most people are familiar with trunk curls, "crunches," and back lifts. The emphasis of therapeutic exercise is safe execution of the exercises combined with respect of the biomechanics of the spine. Exercises should be chosen with the functional outcome goals in mind and integrated with the principles discussed in the 'Functional Activities' section.

Cardiopulmonary Endurance

Aerobic conditioning exercises are initiated as soon as the patient tolerates repetitive activity without exacerbating symptoms. Emphasis is placed on using safe spinal postures while exercising. Aerobic activity increases the patient's feeling of well-being and improves cardiovascular and pulmonary fitness. Principles of aerobic conditioning are detailed in Chapter 4 and summarized in this chapter along with suggestions for safe application of aerobic exercises when there are spinal impairments.

Functional Activities

Fundamental functional activities include training the basic body mechanics of rolling, supine to sit, sit to stand (and reverse), walking. These activities are coordinated with kinesthetic training and segmental muscle activation and stabilization exercises. When the patient is able, stabilization exercises, muscle endurance, and strengthening exercises are integrated with skills for body mechanics (lifting, pushing, pulling, carrying), safe work habits (ergonomic adaptations), and effective recreational or sport activities to meet the goals of the individual.

Kinesthetic Awareness

Goal. To develop proprioception of spinal positioning, safe movement, and postural control.

Elements of Functional Training: Fundamental Techniques

Position of Symptom Relief

The patient must learn how to move the spine and find the range or position in which symptoms are minimized. The position of symptom relief is called the *position of bias* or *the resting position*. The *neutral* spine position is mid-range; the patient may or may not feel most comfortable in that position initially. See Chapter 15 for a discussion on spinal bias as it relates to relief of symptoms and common pathologies.

Cervical Spine

Patient position and procedure: Begin supine; progress to sitting and other functional postures as tolerated.

- Passively move the head and neck with gentle nodding motions of the head into flexion and extension, side bending, and/or rotation to find the most comfortable position for the patient. If necessary, prop the head and neck with pillows.
- Describe the mechanics of what you are doing to the patient.
- Have the patient identify the change in symptoms as movement occurs in and out of the position of bias.
- Have the patient practice moving into and out of that position to develop control.
- If the patient cannot maintain this position while sitting and standing, wearing a cervical collar may be appropriate during the acute stage, but it is important to use judiciously, so the patient does not become dependent on it.

Lumbar Spine

Patient position and procedure: Begin supine or hook-lying, then sitting, standing, and quadruped.

- Teach the patient to move his or her pelvis into an anterior and posterior pelvic tilt (PT) through the range that is comfortable.
- Once the patient has moved the pelvis and spine through a safe range of motion (ROM), instruct him or her to find the position of greatest symptom relief.
- If active movement and control are not possible, teach *passive positioning* (see Box 15.6). Have the patient assume each of the following positions, and draw the association between the spinal position and what is felt. While supine, passively position the pelvis in posterior PT by placing the lower extremities in the hook-lying position or anterior tilt by gently pulling on the extended legs or placing a small roll under the lumbar spine. Sitting encourages spinal flexion; if extension is more comfortable, instruct the person to use a lumbar pillow for support. Standing usually causes spinal extension; if flexion is desired, instruct the person to place one foot up on a stool while standing.

Effects of Movement on the Spine

Once the functional spinal position is determined, it is important for the patient to feel and learn what motions make the symptoms better or worse. In general, movement of the extremities away from the trunk (shoulder flexion and abduction, hip extension and abduction) causes spinal extension; movement of the extremities toward the trunk (shoulder extension and adduction, hip flexion and adduction) causes spinal flexion.

- Have the patient find the neutral or functional spine position (bias); then move the arms and then the legs to feel the effect on the spine. Control of the spinal position is emphasized; have the patient practice the arm and leg motions and attempt to maintain control of the spinal position. These motions are the same as the basic stabilization exercises and are described in detail in the muscle performance section.
- If the patient cannot maintain control or the symptoms are made worse, he or she requires passive support or passive positioning when initiating the stabilization exercises.

Blending of Kinesthetic Training, Stabilization Exercises, and Fundamental Body Mechanics

Once awareness of safe positions and movement is learned, teach the patient the fundamental stabilization techniques for developing neuromuscular control of the position ('Muscle Performance' section), and teach the fundamental body mechanics of rolling, moving supine to sit, sit to stand, and ambulation ('Functional Activities' section).

Progression to Active and Habitual Control of Posture

Awareness and control of posture is described in detail in Chapter 14 (see 'General Management Guidelines for Impaired Posture' and Box 14.1). The use of reinforcement techniques (verbal, visual, tactile) is described, as are activities to train cervical, scapular, thoracic, and lumbopelvic alignment and control. It is important to reinforce the relationship between faulty posture and the development of painful symptoms and to identify a need for postural support (temporary or long-term).

Integrate the awareness of posture and control of the spinal segments into all stabilization exercises, aerobic conditioning, and functional training activities. Observe the patient as greater challenges to activities are performed and, if necessary, provide reminders to find the neutral spinal position and to initiate contraction of the stabilizing muscles prior to the activity. For example, when reaching overhead, help the patient become aware of the need to contract the abdominal muscles to maintain a neutral spine position and not allow the spine to extend into a painful or unstable range; this is practiced until the stabilization becomes habitual. This principle is also incorporated into body mechanics, such as when going from picking up and lifting to placing an object on a high shelf, or into sport activities when reaching up to block or throw a ball.

Mobility/Flexibility

Goal. To increase ROM of specific structures that affect alignment and mobility in the neck and trunk.

In general, stretching is contraindicated in the region of inflamed tissue. However, if there are postures that relieve symptoms but are difficult to assume because of tissue restriction or fluid stasis, stretching or repetitive movement into the restricted range may be appropriate. For example, repetitive lumbar extension has been shown to relieve symptoms of fluid stasis or a disc lesion (see Chapter 15), yet a patient may not be able to get into an extended posture because of flexed postural dysfunction or swollen tissue. Prone propping and press-ups may stretch the tight tissue or may compress and massage swollen disc material or fluid stasis to reduce symptoms (see Fig. 15.7). (Management of disc lesions is described in Chapter 15.)

Acute nerve root irritation from boney spurs or lipping in an arthritic spine is another situation in which acute symptoms may be relieved with stretching. Reducing pressure on the nerve roots with a stretch traction force, which widens the intervertebral foramina, or with procedures that help position the spine in its optimal spinal position may relieve the symptoms.[1]

Decreased mobility in structures in the upper and lower extremities that restrict normal postural alignment may be stretched or mobilized if the techniques do not stress the area of inflammation.

Stretching is done on a continuum. Critical judgment is used to determine the intensity and duration of stretch based on proximity to the healing tissue and the integrity and tolerance

of the tissue. Principles of stretching for impaired mobility are described in Chapter 4.

Joint manipulation techniques and specific high-velocity thrust techniques may be used to stretch a hypomobile facet joint capsule. Principles of joint manipulation are described in Chapter 5; indications for their use in the spine are identified in Chapter 15 in the 'Management Guidelines: Mobilization/ Manipulation' section.

If indicated, the patient is also taught general stress-relieving movements to reduce fluid stasis after being in prolonged postures. These movements are described in Chapter 14 in the 'Management of Impaired Posture' section.

CLINICAL TIP

In general, stretching is contraindicated in the region of inflamed tissues.

Exceptions:

- Fluid stasis that restricts movement may respond to repetitive motion or sustained positioning into restricted range.
- Acute nerve root impingement may be relieved with traction to widen the intervertebral foramina.

Use clinical judgment to determine intensity and duration of stretch based on proximity to healing tissue, integrity, and tolerance of the tissue. Teach patient self-stretching and stress relieving movements (described in Chapter 14).

Cervical and Upper Thoracic Region: Stretching Techniques

Techniques to Increase Thoracic Extension

Self-Stretching

- *Patient position and procedure:* Hook-lying, with the hands behind the head and the elbows resting on the mat. Progress with both arms elevated overhead while maintaining back flat on the mat. To increase the stretch, place a pad or rolled towel lengthwise under the thoracic spine between the scapulae. Incorporate breathing exercises to increase mobility of the rib cage and assist with thoracic extension. Have the patient start with the elbows together in front of the face and then inhale as the elbows are brought down to the mat; hold the stretch position; then exhale as the elbows are brought together again.
- *Patient position and procedure:* Supine, with a foam roll placed longitudinally down the length of the spine. If the patient cannot balance on the roll or experiences tenderness along the spinous processes from pressure, tape two foam rolls together. The patient elevates both arms overhead in a "touchdown" position and allows gravity to apply the stretch force (Fig. 16.1 A). The patient then abducts and laterally rotates both shoulders (90/90 position) so the hands are facing the ceiling (Fig. 16.1 B). This position also stretches the pectoralis major and subscapularis muscles. Breathing exercises can be added to mobilize the ribs.

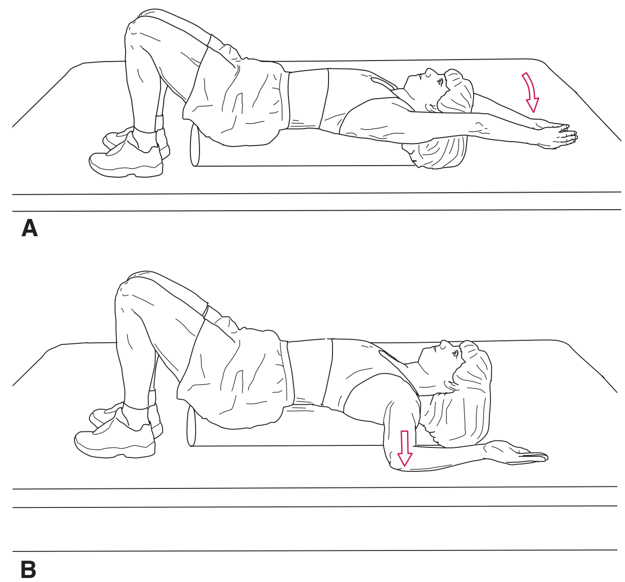

FIGURE 16.1 Foam roll stretch to increase flexibility of anterior thorax. **(A)** In the "touchdown" position, the shoulder extensors are also stretched. **(B)** With the shoulders abducted and laterally rotated, the pectoralis major and other internal rotators are also stretched. For a less intensive stretch, use a rolled towel placed longitudinally under the spine.

- *Patient position and procedure:* Sitting on a firm, straight-backed chair with the hands behind the head or held abducted and externally rotated 90°. The patient then brings the elbows out to the side as the scapulae are adducted and the thoracic spine is extended (head held neutral, not flexed). To combine with breathing, have the patient inhale as he or she takes the elbows out to the side and exhale as the elbows are brought in front of the face (Fig. 16.2).

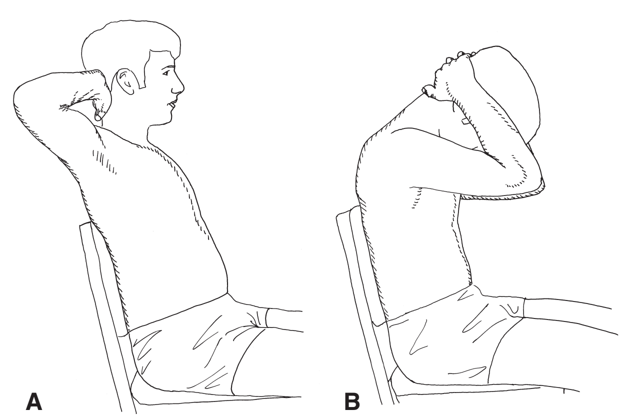

FIGURE 16.2 **(A)** Increase flexibility of anterior thorax and pectoralis muscles by adducting the scapula and extending the thoracic spine against the back of the chair. Inspiration increases the stretch; **(B)** facilitate expiration by bringing the elbows together and flexing the spine.

Techniques to Increase Axial Extension (Cervical Retraction): Scalene Muscle Stretch

CLINICAL TIP

Because the scalene muscles are attached to the transverse processes of the upper cervical spine and the upper two ribs, they either flex the cervical spine or elevate the upper ribs when they contract bilaterally. Unilaterally, the scalenes side bend the cervical spine to the same side and rotate it to the opposite side. To effectively stretch this muscle, stabilize the head and apply the stretch force against the upper portion of the rib cage.

Manual Stretching

Patient position and procedure: Sitting. The patient first performs axial extension (tucks the chin and straightens the neck) and then side bends the neck opposite and rotates it toward the tight muscles. Stand behind the patient and stabilize the head with the one hand around the side of the patient's head and face, holding the head against your trunk or shoulder. Place the other hand across the top of the rib cage on the side of tightness (Fig. 16.3). Instruct the patient to inhale and exhale; apply a downward pressure (resisting elevation of the rib cage) as the patient inhales again. As the patient relaxes (exhales), take up the slack. Repeat. This is a gentle, hold-relax stretching maneuver. This technique can also be done in supine.

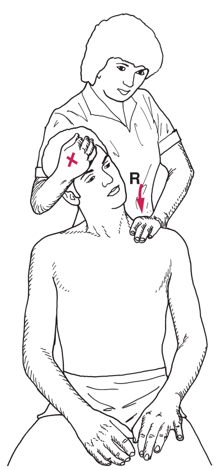

FIGURE 16.3 Unilateral active stretching of the scalenus muscles (manual stretch). The patient first performs axial extension, then side-bends the neck opposite and rotates it toward the tight muscles. The therapist stabilizes the head and upper thorax as the patient breathes in, contracting the muscle against the therapist's resistance. As the patient relaxes, the rib cage lowers and stretches the muscle.

Self-Stretching

Patient position and procedure: Standing next to a table and holding onto its underside. The patient positions the head in axial extension, side bends opposite, and rotates toward the same side as the muscle being stretched. To stretch, he or she leans away from the table, inhales, exhales, and holds the stretch position.

Techniques to Increase Upper Cervical Flexion: Short Suboccipital Muscle Stretch

Manual Stretching

Patient position and procedure: Sitting. Identify the spinous process of the second cervical vertebra and stabilize it with your thumb or with the second metacarpophalangeal joint (and the thumb and index finger around the transverse processes). Have the patient slowly nod, doing just a tipping motion of the head on the upper spine (Fig. 16.4). Guide the movement by placing the other hand across the patient's forehead.

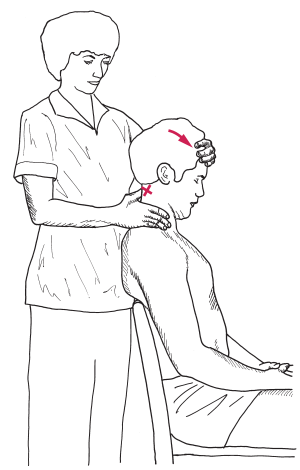

FIGURE 16.4 Stretching the short suboccipital muscles. The therapist stabilizes the second cervical vertebra as the patient slowly nods the head.

Self-Stretching

Patient position and procedure: Supine or sitting. Instruct the patient to first perform a chin tuck (axial extension), then nod the head, bringing the chin toward the larynx until a stretch is felt in the suboccipital area.

- Have the patient put a light pressure under the occipital region with the palm of his or her hand while tipping the head forward to reinforce the motion.
- For a *unilateral stretch*, instruct the patient to first perform a chin tuck, rotate slightly (up to 45°) to the left or right, and then nod.

NOTE: The weight of the head is enough stretch force in these exercises; the patient should not pull on the head when there is cervical pathology.

CLINICAL TIP

Shoulder girdle posture is directly related to cervical and thoracic posture. Techniques to increase flexibility in the

shoulder girdle muscles are described in Chapter 17. Of primary importance:

- Pectoralis major (see Figs. 17.30 to 17.32)
- Pectoralis minor (see Fig. 17.33)
- Levator scapulae (see Figs. 17.34 and 17.35)
- Shoulder internal rotator muscles (see Fig. 17.26)

Traction as a Stretching Technique

Manual Traction: Cervical Spine

Traction techniques can be used for the purposes of stretching the muscles and the facet joint capsules and widening the intervertebral foramina.[54] The value of manual traction is that the angle of pull, head position, and placement of the force (via specific hand placements) can be controlled by the therapist; thus, the force can be specifically applied with minimum stress to regions that should not be stretched.

Patient position: Supine on a treatment table. The patient should be as relaxed as possible.

Therapist position and hand placement: Standing at the head of the treatment table, supporting the weight of the patient's head in the hands. Hand placement depends on comfort, the size of the patient's head and the therapist's hands. Suggestions include:

- Place the fingers of both hands under the occiput (Fig. 16.5 A), or with the hands on the sides of the face (not covering the ears).
- Place one hand over the forehead and the other hand under the occiput (Fig. 16.5 B).
- Place the index fingers around the spinous process above the vertebral level to be moved. This hand placement provides a specific traction only to the vertebral segments below the level at which the fingers are placed. A belt around the therapist's hips can be used to reinforce the fingers and increase the ease of applying the traction force (Fig. 16.5 C).

Procedure: Vary the patient's head position in flexion, extension, side bending, and side bending with rotation until the tissue to be stretched is taut; then apply a traction force by assuming a stable stance and leaning backward in a controlled manner. If a belt is used, the force is transmitted through the belt. The force is usually applied intermittently with smooth and gradual building and releasing of the force. The intensity and duration are usually limited by the therapist's strength and endurance.

CLINICAL TIP

When applying cervical traction, the more a person's head is flexed, the lower in the cervical spine the force is directed. When side bending, caution should be used because the position may cause facet and foramen approximation on the side of the concavity, which, in turn, may cause radicular or facet joint symptoms on that side.

Self-Traction: Cervical Spine

Patient position and procedure: Sitting or lying down. Have the patient place his or her hands behind the neck with the fingers interlocking; the ulnar border of the fingers and hands are under the occiput and mastoid processes. The patient then gives a lifting motion to the head. The head and spine may be placed in flexion, extension, side bending, or rotation for more isolated effects. He or she may apply the traction intermittently or in a sustained manner.

NOTE: Various forms of mechanical traction can be used in the clinical setting and at home. The position, dosage, and duration of traction are determined by the therapist. Instruction for use of the equipment is not described in this text.

Cervical Joint Manipulation Techniques

Principles of joint mobilization/manipulation are discussed in detail in Chapter 5. As previously noted, the terms *mobilization* and *manipulation* are currently being used interchangeably, with a trend towards using the term *manipulation*. The authors

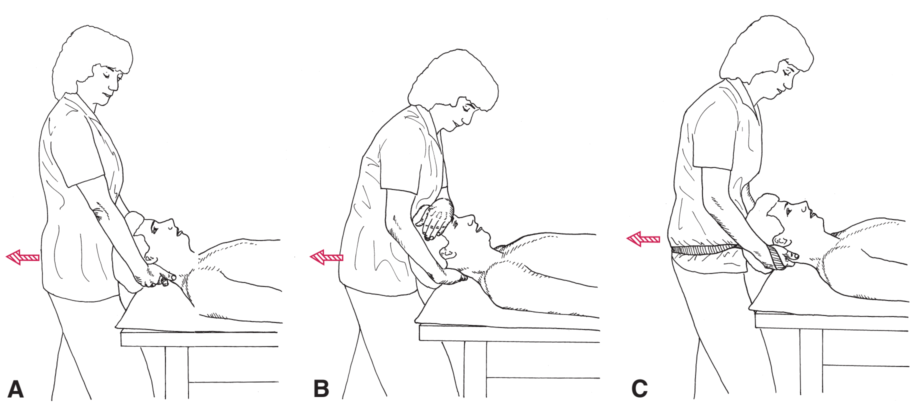

FIGURE 16.5 Manual cervical traction: **(A)** with the fingers of both hands under the occiput; **(B)** with one hand over the frontal region and the other hand under the occiput; and **(C)** using a belt to reinforce the hands for the traction force.

of this chapter are using *manipulation* to mean graded oscillation techniques, and high-velocity thrust (HVT) to mean high-velocity, small-amplitude motion performed at the end of the pathological limit of the joint (see clinical tip below).

Spinal manipulation is indicated for pain modulation and to improve range of motion. Although the application of HVT techniques is appropriate for the thoracic, lumbar, and sacral spinal areas (described later in this chapter), HVT for the cervical spine is beyond the scope of this textbook. Common cervical joint manipulation techniques, with the exception of craniocervical region, are described in this section. For the craniocervical region, muscle energy techniques are described to improve mobility at the occipito-atlantal and atlanto-axial joints

CLINICAL TIP

Spinal manipulations can be graded I–V and can be used to modulate pain or improve joint motion. All spinal and rib manipulations, with the exception of high-velocity thrust techniques, are performed for 1 to 2 minutes and then reassessed for increased motion or decreased pain. Intervention is terminated once the desired result is achieved or to patient tolerance.

- Grade I—small-amplitude oscillations are used for pain modulation, typically during the acute stage following injury.
- Grade II—large-amplitude oscillations are also used for pain modulation. Dosage and indications are similar to grade I manipulations.
- Grade III—large-amplitude oscillations that go up to the restrictive joint barrier are designed to improve joint range of motion and can be used during the subacute or chronic stages of healing.
- Grade IV—small-amplitude oscillations that go through the restrictive joint barrier. These manipulations are designed to improve joint range of motion and should be used only during the chronic stages of healing.
- Grade V (HVT)—high-velocity and low-amplitude thrust applied at the physiologic limit of joint motion. These manipulations are performed only one time and designed solely to improve range of motion.

PRECAUTIONS:

- If a manipulation procedure causes a change in sensation or an increased pain to radiate down an extremity, or if a patient reports a feeling of dizziness or light-headedness, do not perform additional manipulations.
- Use extreme caution if the patient reports either a current history of corticosteroid use or excessive pain.

CONTRAINDICATIONS:

- Unhealed fracture
- History of joint or ligamentous laxity caused by trauma or systemic diseases, such as rheumatoid arthritis
- Vertebral artery disease or occlusion
- Acute joint inflammation/irritation
- Cauda equina symptoms

Manipulation to Increase Cervical Flexion (Fig. 16.6)

FIGURE 16.6 Cervical Flexion Manipulation—prone

Patient position: Prone with arms resting comfortably at patient's side. Place a pillow under the clavicular region for patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Stand on one side of the patient with your body facing toward his or her head. Use a two-thumb contact on the spinous process of the superior restricted segment of the three-joint complex.
Manipulation force: Using force through the thumbs, slide the superior vertebra in a cephalad-anterior direction.

Manipulation to Increase Cervical Extension (Fig. 16.7)

FIGURE 16.7 Cervical Extension Manipulation—prone

Patient position: Prone with arms resting comfortably at patient's side, use a pillow for patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Stand at the head of the patient with your body facing toward his or her feet. Use a two-thumb contact on the spinous process of the superior restricted segment of the resticted three-joint complex.
Manipulation force: Using force through the thumbs, slide the superior vertebra in a caudal-posterior direction.

Manipulation to Increase Cervical Rotation (Fig. 16.8)

FIGURE 16.8 Cervical Rotation Manipulation—prone

Patient position: Prone with arms resting comfortably at patient's side, use a pillow for patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Stand on one side of the patient with your body facing toward their head. Use a two-thumb contact on the transverse process on the superior restricted vertebrae of the three-joint complex to cause rotaton toward the direction of restriction.
Manipulation force: Using force through the thumbs, slide the superior vertebra in a cephalad-anteromedial direction.

Manipulation to Increase Cervical Rotation and Side Bending (Fig. 16.9) VIDEO 16.1

This technique increases the diameter of the ipsilateral foramen, as seen with contralateral rotation and side bending.
Patient position: Supine.
Therapist position and hand placement: Stand at the head of the patient with one hand (the hand opposite the side of restriction) supporting the head and the other hand in contact with the lateral aspect of the verterbra to be manipulated. The medial side of the second MCP joint should be in contact with the edge of the facet and pillar to be manipulated and

FIGURE 16.9 Cervical Rotation and Side-bending Upglide Manipulation—supine

the rest of your hand relaxed on the postero-lateral portion of the patient's neck. Passively place the patient's head and neck into flexion, contralateral rotation, and side bending to take up the slack until the segment to be treated is identified.
Manipulation force: Using force through the metacarpal joint of the second digit, slide (or upglide) the cervical facet in an anterior-superior-medial direction at a 45° angle.

Manipulation to Increase Cervical Rotation and Side Bending: Alternate Technique (Fig. 16.10) VIDEO 16.1

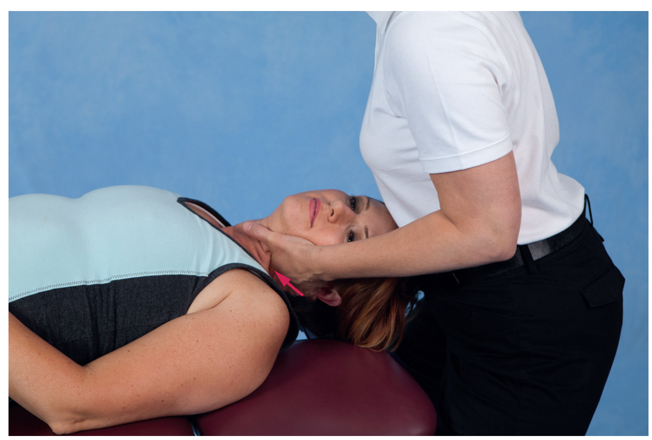

FIGURE 16.10 Cervical Rotation and Side-bending Downglide Manipulation—supine

This technique decreases the diameter of the ipsilateral foramen, as seen with ipsilateral rotation and side bending.
Patient position: Supine.
Therapist position and hand placement: Stand at the head of the patient with one hand (the hand opposite the side of restriction) supporting the patient's head and the other hand in contact with the verterbra to be manipulated. The medial

side of the second MCP joint should be in contact with the edge facet and pillar to be manipulated and the rest of your hand relaxed on the postero-lateral portion of the patient's neck. Passively place the patient's head and neck into extension, ipsilateral rotation, and side bending to take up the slack until the segment to be treated is identified.
Manipulation force: Using force through the MCP joint of the second digit, slide (or downglide) the cervical facet in an inferior-medial direction at a 45° angle.

Muscle Energy Techniques to Increase Craniocervical Mobility

Muscle energy (ME) uses the application of submaximum, isometric contractions of muscles whose line of pull can cause the desired accessory motion of a joint; ME techniques are designed to improve joint mobility (see Chapter 5). The patient holds the gentle muscle contraction against the therapist's graded resistance for 3 to 5 seconds and then relaxes. This process is repeated for three to five repetitions. When performed correctly, ME techniques are extremely safe and are indicated for most joint restrictions resulting from musculoskeletal disorders.

PRECAUTION: Great care should be used when applying the following techniques so as not to occlude the vertebral artery. The therapist should test the integrity of the vertebral artery prior to performing the following ME techniques. Do not perform ME techniques if the patient reports an altered sensation in either upper extremity or a feeling of dizziness or light-headedness during the set-up of these techniques.

To Increase Craniocervical Flexion (Fig. 16. 11) VIDEO 16.2

Patient position: Supine, with hands placed comfortably at the side.
Therapist position, hand placement, and patient effort: Stand at the head of the treatment table. Support the occiput with one hand and place the other hand across the forehead. Ask the patient to look upward gently as if nodding the head backwards and apply resistance against the patient's occiput, creating a gentle isometric contraction in the suboccipital muscles. When the patient relaxes, take up the slack by passively nodding the head through any new range.
Alternate technique: Sit on a stool at the head of patient with your forearms resting on the treatment table. One hand stabilizes the C2 vertebra by grasping the transverse processes between the proximal portions of the thumb and index finger; the other hand supports the occiput. Passively nod the patient's head with the hand under the occiput to take up the slack of the suboccipital muscles; then ask the patient to roll the eyes upward. This causes a gentle isometric contraction of the suboccipital muscles. The patient keeps looking upward for 3 to 5 seconds and then relaxes. After the patient relaxes, take up the slack by passively nodding the head through any new range. Repeat this procedure three to five times or until the desired outcome is achieved. Only motion between the occiput and C2 should occur. The contraction is gentle in order not to cause overflow into the multi-segmental erector spinae and upper trapezius muscles. This technique uses a gentle hold-relax, (Chapter 4) of the rectus capitis posterior minor muscle.

To Increase Craniocervical Rotation (Fig. 16.12) VIDEO 16.2

Patient position: Supine, with hands placed comfortably at the side.
Therapist position, hand placement, and patient effort: Stand at the head of the patient. Wrap hands around the side of the patient's head with fingers under the occiput. Place the patient's head in end-range cervical flexion. Next, rotate his or her head in the direction of the restriction (for example, with restricted

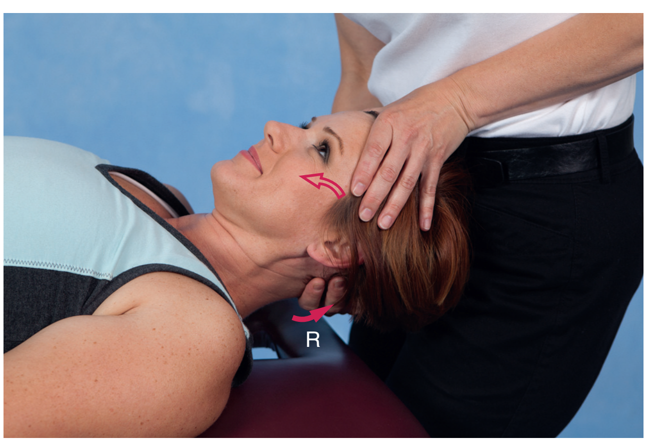

FIGURE 16.11 Muscle Energy: Craniocervical Flexion

FIGURE 16.12 Muscle Energy: Craniocervical Rotation

rotation to the left, place head in end-range left rotation). Once the patient is at end-range, instruct the patient to look in the opposite direction (example, toward the right) while you resist this movement with gentle pressure against the the side of the head. After a 3 to 5-second hold, have the patient relax and move the head into greater rotation. Repeat as needed.

Mid and Lower Thoracic and Lumbar Regions: Stretching Techniques

Techniques to Increase Lumbar Flexion

PRECAUTION: If flexion of the spine causes a change in sensation or causes pain to radiate down an extremity, reassess the patient's condition to determine if flexion is contraindicated.

Self-Stretching

- *Patient position and procedure:* Hook-lying. Have the patient first bring one knee and then the other toward the chest, clasp the hands around the thighs, and pull them to the chest, elevating the sacrum off the mat (Fig. 16.13). The patient should not grasp around the tibia; it places stress on the knee joints as the stretch force is applied.

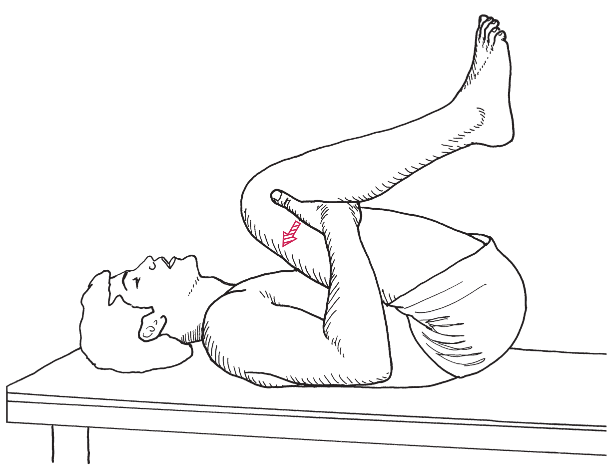

FIGURE 16.13 Self-stretching the lumbar erector spinae muscles and tissues posterior to the spine. The patient grasps around the thighs to avoid compression of the knee joints.

- *Patient position and procedure:* Quadruped (on hands and knees). Have the patient perform a posterior pelvic tilt without rounding the thorax (concentrate on flexing the lumbar spine, not the thoracic spine), hold the position, then relax (Fig. 16.14 A). Repeat; this time bring the hips back to the feet, hold, and then return to the hands and knees position (Fig. 16.14 B). This also stretches the gluteus maximus, quadriceps femoris, and shoulder extensor muscles.

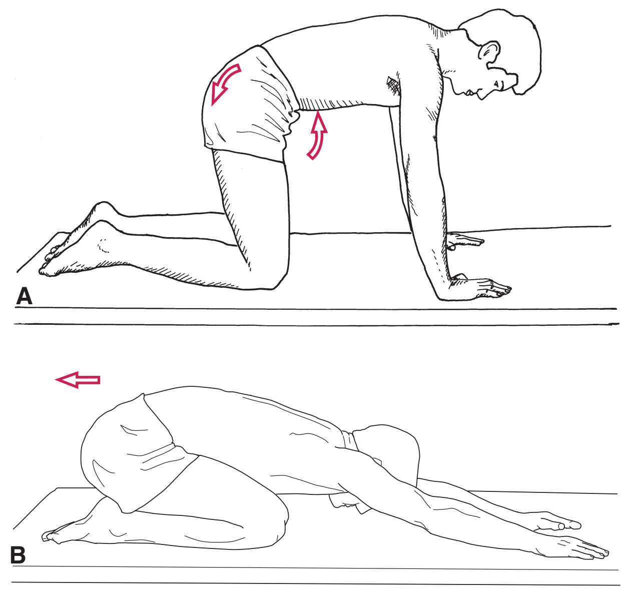

FIGURE 16.14 Stretching of the lumbar spine. **(A)** The patient performs a posterior pelvic tilt without rounding the thorax. **(B)** The patient moves the buttocks back over the feet for a greater stretch.

Techniques to Increase Lumbar Extension

PRECAUTION: Do not perform if extension causes a change in sensation or causes pain to radiate down an extremity (see Chapter 15).

Self-Stretching

- *Patient position and procedure:* Prone, with hands placed under the shoulders. Have the patient extend the elbows and push the thorax up off the mat but keep the pelvis down on the mat. This is a prone press-up (Fig. 16.15 A). To increase the stretch force, the pelvis can be strapped to the treatment table. This exercise also places the hip flexor muscles and soft tissue anterior to the hips in an elongated position, although it does not selectively stretch these tissues.
- *Patient position and procedure:* Standing, with the hands placed in the low-back area. Instruct the patient to lean backward (Fig. 16.15 B).
- *Patient position and procedure:* Quadruped (hands and knees). Instruct the patient to allow the spine to sag, creating lumbar extension. Alternating between this motion and a posterior pelvic tilt (as in Fig. 16.14) can be used to teach the patient how to control pelvic motion.

Techniques to Increase Lateral Flexibility of the Spine

Stretching techniques to increase lateral flexibility are used for intervention when there is asymmetrical flexibility in side bending as well as in the management of scoliosis. It is important to note that stretching has not been shown to correct or

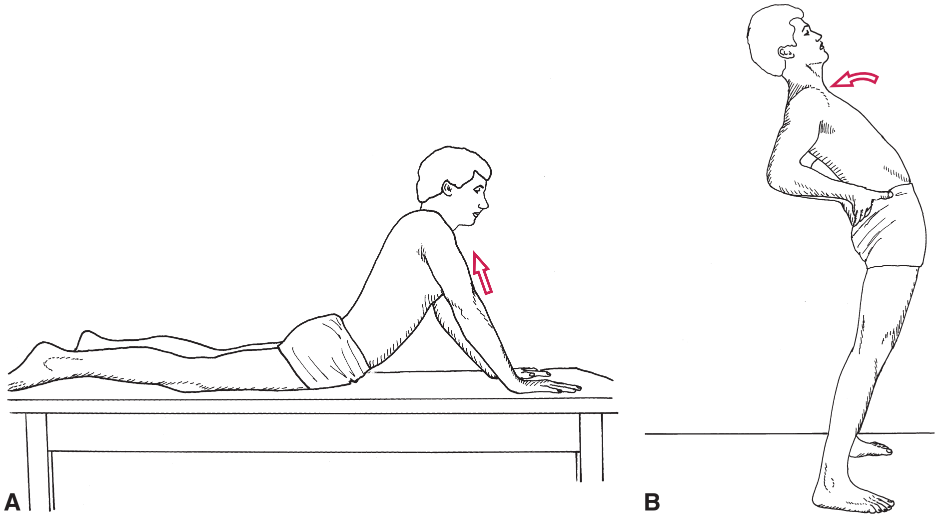

FIGURE 16.15 Self-stretching of the soft tissues anterior to the lumbar spine and hip joints with the patient **(A)** prone (using a press-up) and **(B)** standing.

halt progression of structural scoliosis. If these exercises are used for patients with structural scoliosis, they may be beneficial in gaining some flexibility prior to surgical fusion of the spine for correcting a scoliotic deformity. They may also be used to regain flexibility in the frontal plane when muscle or fascial tightness is present with postural dysfunction. All of the following exercises are designed to stretch hypomobile structures on the concave side of the lateral curvature.

When stretching the trunk, it is necessary to stabilize the spine either above or below the curve. If the patient has a double curve, one curve must be stabilized while the other is stretched.

- *Patient position and procedure:* Prone. Stabilize the patient (manually or with a belt) at the iliac crest on the side of the concavity. Have the patient reach toward the knee with the arm on the convex side of the curve while stretching the opposite arm up and overhead (Fig. 16.16). Instruct the patient to breathe in and expand the rib cage on the side being stretched.

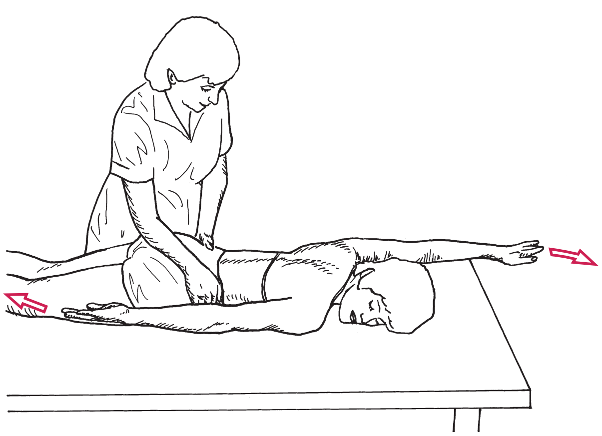

FIGURE 16.16 Stretching hypomobile structures on the concave side of the thoracic curve. Illustrated is a patient with a right thoracic left lumbar curve. The therapist stabilizes the pelvis and lumbar spine while the patient actively stretches the thoracic curve by reaching upward on side of concavity and downward on side of convexity.

- *Patient position and procedure:* Prone. Have the patient stabilize the upper trunk (thoracic curve) by holding onto the edge of the mat table with the arms. Lift the hips and legs and laterally bend the trunk away from the concavity (Fig. 16.17).

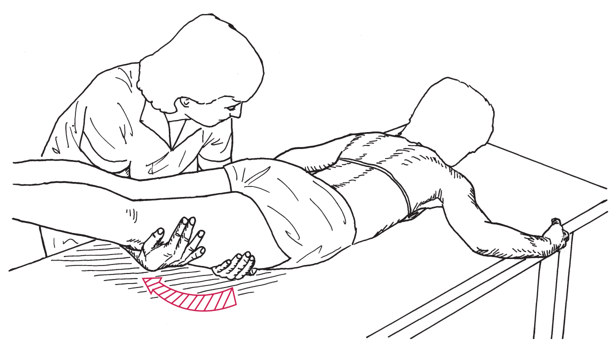

FIGURE 16.17 Stretching hypomobile structures on the concave side of a left lumbar curve. The patient stabilizes the upper trunk and thoracic curve as the therapist passively stretches the lumbar curve.

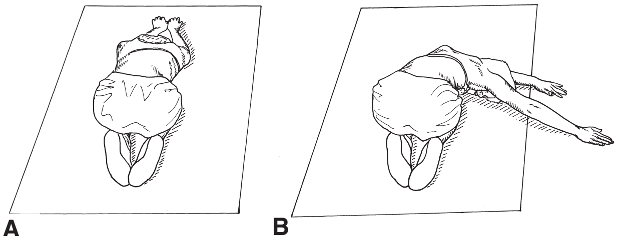
- *Patient position and procedure:* Heel-sitting. Have the patient lean forward so the abdomen rests on the anterior thighs (Fig. 16.18 A); the arms are stretched overhead bilaterally; and the hands are flat on the floor. Then have the patient laterally bend the trunk away from the concavity by walking the hands to the convex side of the curve. Hold the position for a sustained stretch (Fig. 16.12 B).
- *Patient position and procedure:* Side-lying on the convex side of the curve. Place a rolled towel at the apex of the curve, and have the patient reach overhead with the top arm. Stabilize the patient at the iliac crest. Do not allow the patient to roll forward or backward during the



A B

FIGURE 16.18 (A) Heel-sitting to stabilize the lumbar spine. (B) Hypomobile structures on the concave side of a right thoracic curve are stretched by having the patient reach the arms overhead and then walk the hands toward the convex side.

stretch. Hold this position for a sustained period of time (Fig. 16.19).

- *Patient position and procedure:* Side-lying over the edge of a mat table with a rolled towel at the apex of the curve and the top arm stretched overhead. Stabilize the iliac crest. Hold this head-down position as long as possible (Fig. 16.20).

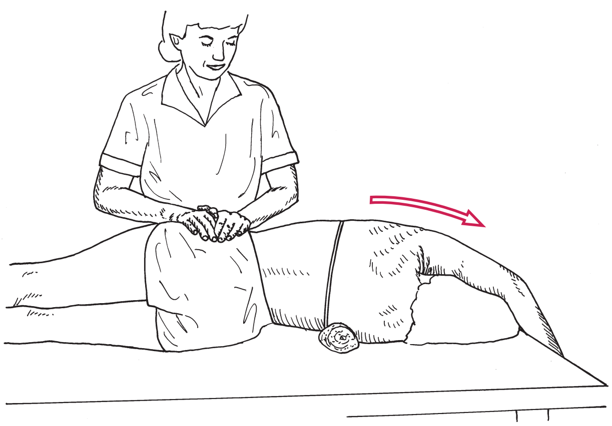


FIGURE 16.19 Stretching tight structures on the concave side of a right thoracic curve. The patient is positioned side-lying with a rolled towel at the apex of the convexity. The lumbar spine is stabilized by the therapist.

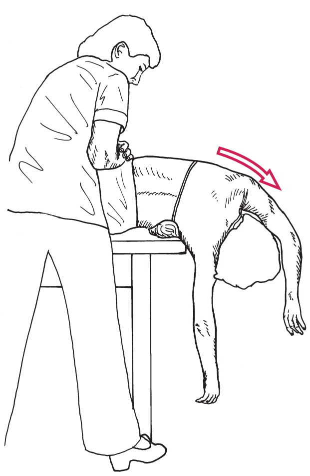

FIGURE 16.20 Side-lying over the edge of a mat table to stretch hypomobile structures of a right thoracic scoliosis. The therapist stabilizes the pelvis.

Techniques to Increase Hip Muscle Flexibility

Hip muscles have a direct effect on spinal posture and function because of their attachment on the pelvis. It is important that they have adequate flexibility for proper pelvic and spinal alignment. See Chapter 20 for specific stretching techniques of hip musculature.

Traction as a Stretching Technique

Manual Traction: Lumbar Spine

Manual traction is not as easily applied in the lumbar region as in the cervical region. At least one-half of the patient's body weight must be moved, and the coefficient of friction of the part to be moved also must be overcome to cause vertebral distraction and stretching. It is helpful to place the patient on a split-traction table for ease in moving and stretching the spine.

Patient position: Supine or prone. Stabilize the thorax with a harness secured to the head end of the table or have an assistant stabilize the patient by standing at the head of the table and holding the patient's arms. Position the patient so there is maximal stretch on the hypomobile tissue.

- To stretch into extension, extend the hips.
- To stretch into flexion, flex the hips.
- To stretch into side bending, move the lower extremities to one side.

Therapist position and procedures: Position yourself so effective body mechanics and body weight can be used.

- If the lower extremities are extended to emphasize spinal extension, exert the pull at the ankles.
- If the lower extremities are flexed to emphasize spinal flexion, drape both of the legs over your shoulder that is closest to the mid-line of the table and exert the stretch force with your arms wrapped across the patient's thighs. As an alternative, place a pelvic belt with straps around the patient and manually pull on the straps.
- For unilateral impairments, pull on one extremity.

Positional Traction: Lumbar Spine

The value of positional traction is that the primary traction force can be directed to the side on which symptoms occur, or it can be isolated to a specific facet, making it beneficial for selective stretching.

Patient position: Side-lying, with the side to be stretched uppermost. A rolled blanket or thick towel is placed under the spine at the level where the traction force is desired; this causes side bending away from the side to be treated and, therefore, an upward gliding of the facets (Fig. 16.21 A).

Therapist position: Standing, at the side of the treatment table facing the patient. Determine the segment that is to receive most of the traction force and palpate the spinous processes at that level and the level above.

Procedure: The patient relaxes in the side-bent position. Rotation is added to isolate a distraction force to the desired

level. Rotate the upper trunk by gently pulling on the arm on which the patient is lying while simultaneously palpating the spinous processes with your other hand to determine when rotation has arrived at the level just above the joint to be distracted. Then flex the patient's uppermost thigh, again palpating the spinous processes until flexion of the lower portion of the spine occurs at the desired level. The segment at which these two opposing forces meet now has maximum positional distraction force (Fig. 16.21 B).

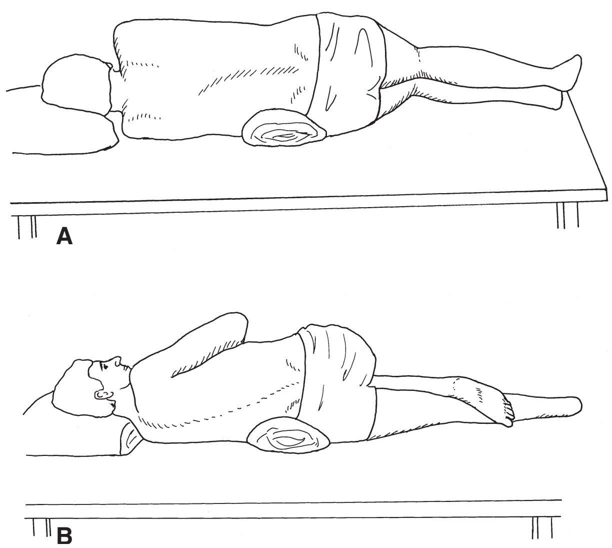

FIGURE 16.21 Positional traction for the lumbar spine. **(A)** Side bending over a 6- to 8-inch roll causes longitudinal traction to the segments on the upward side. **(B)** Side-bending with rotation adds a distraction force to the facets on the upward side.

CLINICAL TIP

Mechanical traction units can provide considerable stretch force to the tissues of the thoracic and lumbar spine. Positioning considerations are as described for manual traction. Instructions for use of the equipment are not part of this text.

Thoracic and Lumbar Joint Manipulation and HVT Techniques

Joint manipulation and HVT techniques have been shown to have minimal risk to patients[7,15] and also to be an effective intervention for spinal pain.[7,9,11,12,15,63] Although HVT has been practiced in physical therapy since the 1920s,[45] these techniques should not be performed by physical therapist assistants or physical therapy aides.[3,45] The indications for joint manipulation and HVT are discussed in Chapter 5.

High-velocity thrust techniques may be easier to perform if the application of the force is coordinated with the patient's breathing. Instruct the patient to breathe deeply several times and on the final exhalation, a high-velocity, low-amplitude force is delivered. Use caution that the patient does not hyperventilate during these procedures.

CLINICAL TIP

When applying spinal manipulation techniques:

- Modify the application force for pain modulation.
- Coordinate stretch manipulation and HVT techniques with patient breathing.
- HVT is a low-amplitude, high-velocity technique.
- HVT is applied with one repetition only.

PRECAUTIONS:

- Do not perform if manipulation causes a change in sensation or pain to radiate down an extremity.
- Extreme caution should be used when performing these techniques if the patient is pregnant, reports a current history of corticosteroid use, or has excessive pain.

CONTRAINDICATIONS:

- Unhealed fracture
- History of joint or ligamentous laxity caused by trauma or systemic diseases
- Spondylolisthesis
- Acute joint inflammation/irritation
- Cauda equine symptoms
- HVT is contraindicated in persons with a history of osteoporosis or osteopenia.

Manipulation Technique to Increase Thoracic Spine Extension (Fig. 16. 22) VIDEO 16.3

Patient position: Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Stand on one side of the patient with your body facing toward the head of the patient. Place the distal phalanx of your second and third fingers on the transverse processes of the superior vertebral segment to be manipulated (Fig. 16.22 A). This is also referred to as the "V-spread technique." Place the hypothenar eminence of your other hand on top of the two-finger contact (Fig. 16.22 B).
Manipulation force: Apply an anterior glide. The contact points on the transverse processes serve as a point of reference. Your other hand exerts a force through the hypothenar eminence in an anterior direction.

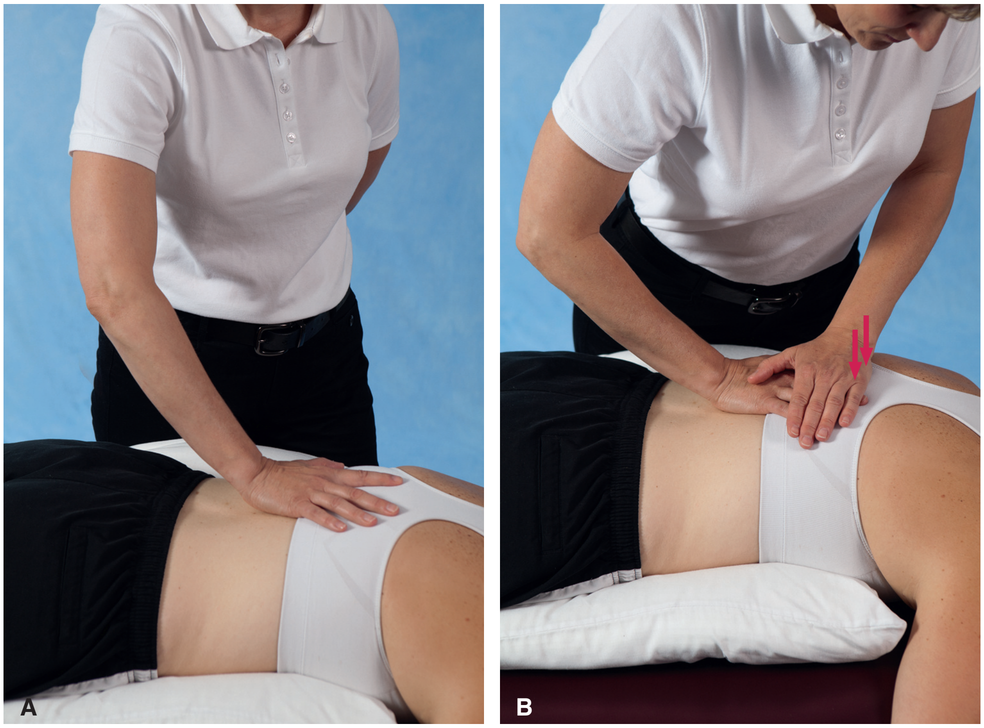

FIGURE 16.22 Thoracic Spine Extension Manipulation or HVT—prone: (A) "V-spread" finger placement on transverse processes and (B) force application with hypothenar eminence.

Manipulation Technique to Increase Thoracic Spine Flexion

Patient position: Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Same as for thoracic extension except the V-spread contact is on the transverse processes of the inferior vertebral segment to be mobilized.
Manipulation force: Apply an anterior glide. The contact points on the transverse processes serve as a point of reference. The other hand exerts a force through the hypothenar eminence in an anterior direction. Modify your forces for pain modulation or to improve motion.

Manipulation to Increase Thoracic Spine Rotation (Fig. 16.23) VIDEO 16.3

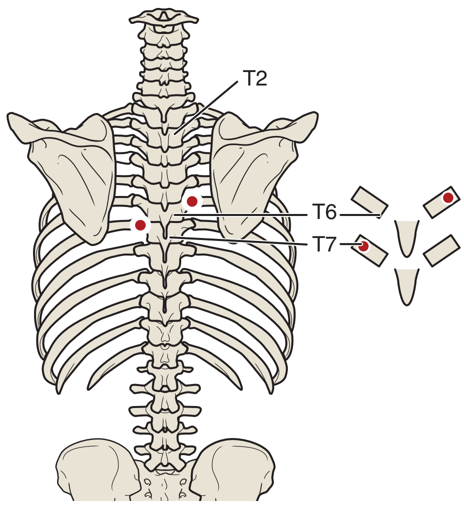
Patient position: Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Using the V-spread contact, place one finger on the superior transverse process and the second finger on the contralateral inferior transverse

FIGURE 16.23 Thoracic Spine Left Rotation Manipulation or HVT—prone.

process to be mobilized. The finger placement follows the "Rule of the Lower Finger" (see Clinical Tip).
Manipulation force: Apply an anteriorly directed force against the transverse processes with the contralateral hand pressing through the contact fingers.

CLINICAL TIP

Rule of the Lower Finger
When applying the V-spread contact on the contralateral transverse processes for thoracic rotation assessment or manipulation, rotation of a segment occurs in the direction of the finger on the inferior transverse process.



Example: Manipulation of the T6–7 segment into left rotation. The superior finger is on the right transverse process of T6, facilitating rotation to the left. Concurrently, the inferior finger on the left transverse process of T7 is facilitating a right rotation force (see Fig. 16.23). Since the lower finger is on the left transverse process, the "rule of the lower finger" makes it easy to remember this is a left rotation manipulation.

Pistol Thrust to Increase Thoracic Spine Mobility (Fig. 16.24) VIDEO 16.4

Patient position: Supine with arms crossed.
Therapist position and hand placement: Stand at the patient's side facing toward his or her head. Roll the patient toward you and reach across the patient's body; contact the inferior vertebra of the three-joint complex to be manipulated using the "pistol grip" (Fig. 16.24 A and C). Once contact is achieved, passively return the patient to the supine position. To improve rotation, use the rule of the lower finger as described in the clinical tip above.
Manipulation force: Place your trunk directly over the segment to be manipulated. A cephalad distraction force is initiated with the patient's body weight at the segment to be manipulated; this is followed by a high-velocity, posterior force against the patient's crossed arms toward the table (Fig. 16.24 B).

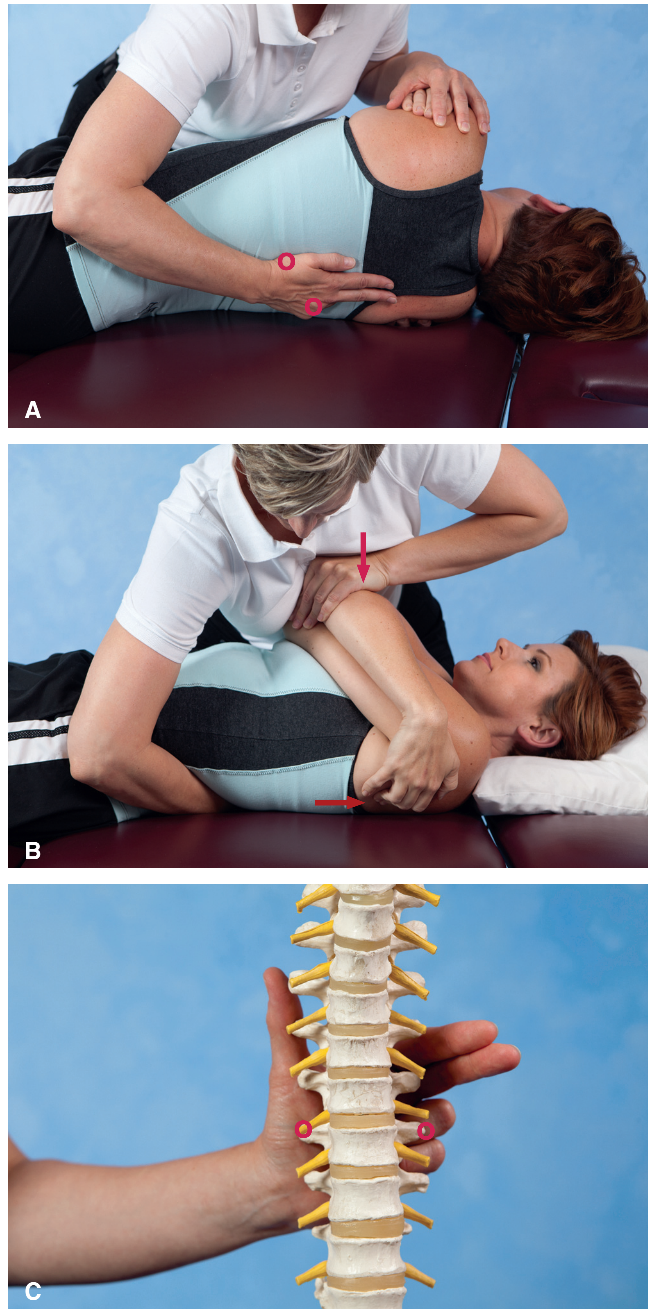


FIGURE 16.24 Thoracic spine manipulation: **(A)** hand placement on thoracic spine using a "pistol grip" and **(B)** manipulation force against patient's crossed arms. **(C)** Pistol grip on a spinal model, showing carpometacarpal joint of thumb on one transverse process and flexed middle phalanx on opposite transverse process.

Cross-Arm Thrust to Increase Thoracic Spine Mobility (Fig. 16.25)

Patient position: Prone with arms resting comfortably at patient's side. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.
Therapist position and hand placement: Stand beside the patient. Cross your arms and place the pisiform (hypothenar

FIGURE 16.25 Thoracic spine manipulation using cross-arm thrust

eminence) of one hand on a left and one on a right transverse process of the segment to be manipulated. Modify transverse process contact to promote flexion, extension, or rotation by placing the pisiform on the superior, inferior, or "rule of the lower finger" transverse processes as described in the preceding sections.

Manipulation force: An anterior force is applied simultaneously by the hypothenar eminences. This may be used as either a manipulation or HVT intervention.

Fall Thrust to Increase Thoracic Spine Mobility (Fig. 16.26) VIDEO 16.5

FIGURE 16.26 Thoracic spine manipulation using a fall thrust

Patient position: Standing with arms crossed.

Therapist position and hand placement: Stand behind the patient and wrap your arms around the patient. Place a mobilization wedge or folded towel at the desired spinal level to direct the force to a specific thoracic segment. Grasp patient's elbows (left hand grasps patient's right elbow and right hand grasps left elbow). If unable to grasp the elbows, interlock your fingers in front of the patient.

Manipulation force: Lean backwards on your heels while applying an extension force on the patient's spine, then quickly drop down so your feet are flat on the floor.

Rib Manipulation for Expiratory Restriction (Fig. 16.27) VIDEO 16.6

FIGURE 16.27 Expiratory restriction rib manipulation

Patient position: Prone with arms resting comfortably at the patient's side or overhead. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

Therapist position and hand placement: Stand beside the patient. The hypothenar eminence of your caudal facing hand is placed on the rib angle at the level of the hypomobility, and the rest of the hand relaxes on the patient's back. The other hand is placed on the opposite rib to stabilize the rib cage.

Manipulation force: During active patient expiration, exert a series of four to five progressive manipulations against the restricted rib in an anterior, caudal, and medial direction during the last half of the expiratory phase. Use caution that the patient does not hyperventilate.

Rib Manipulation for Inspiratory Restriction (Fig. 16.28)

Patient position: Prone with scapula protracted on the side of the rib restriction. This can be accomplished by having the patient dangle the arm off the side of the treatment table. Place a pillow under the thoracic region for increased patient comfort and to promote a neutral cervical-thoracic curve.

FIGURE 16.28 Inspiratory restriction rib manipulation

Therapist position and hand placement: Stand on the side opposite the restriction; reach across the thorax with your inferior extremity and contact the pisiform or hypothenar eminence of your hand on the inferio-medial aspect at the angle of the rib to be manipulated. Stabilize your upper body with the contralateral hand leaning on the table.

Manipulation force: During patient exhalation, apply the force to remove all the slack from the costovertebral joint; continue with four to five progressive oscillations approximately half way through the inspiratory phase. Apply the force perpendicular to the rib angle (in an anterior, caudal, and medial direction). Use caution that the patient does not hyperventilate.

Elevated First Rib Manipulation (Fig. 16.29) VIDEO 16.7

Patient position: Sitting in a firm chair with his or her back supported. The head and neck are laterally flexed towards and rotated away from the side of restriction to stabilize the facets in the closed-pack position and relax the scalene muscle.

FIGURE 16.29 Elevated first rib manipulation

Alternate head/neck position: The head and cervical spine are rotated towards the side of restriction to bring the transverse process posterior and place the first costotransverse articulation at end-range stretched position.

Therapist position and hand placement: Stand behind the patient and stabilize the head against your thorax. Place the second MCP of your other hand on the first rib just lateral to the costotransverse joint.

Manipulation force: Exert the manipulation force or HVT through the rib in a caudal and medial direction during patient exhalation.

Manipulation Techniques to Increase Lumbar Spine Extension (Fig. 16.30) VIDEO 16.8

FIGURE 16.30 Lumbar spine extension manipulation/HVT—prone

Patient position: Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

Therapist position and hand placement: Place your pisiform (hypothenar eminence) over the spinous process. Relax the rest of your hand on the patient's back.

Anterior glide manipulation force: Push with your hypothenar eminence in an anterior direction. Align your trunk directly over the segment, so the force is directed downward and not at an angle.

Manipulation to Increase Lumbar Spine Rotation (Fig. 16.31) VIDEO 16.8

Patient position: Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.

Therapist position and hand placement: Place your pisiform (hypothenar eminence) over one transverse process on the side opposite of the direction of the motion you wish to facilitate (i.e., if wanting to promote left rotation, place your hypothenar eminence on the right transverse process). Relax the rest of your hand on the patient's back.

FIGURE 16.31 Lumbar spine left rotation manipulation/HVT—prone

Anterior glide manipulation force: Push with your hypothenar eminence in an anterior and medial direction.

Manipulation to Increase Lumbar Intervertebral Side Bending (Fig. 16.32) VIDEO 16.9

Patient position: Side-lying with the restricted side down. Position the patient as close to the edge of the bed as possible and flex the hips and knees to 90°.

Therapist position and hand placement: Stand facing the patient. Place the finger tip from your caudal hand on the superior spinous process to monitor motion. Passively rotate the patient's trunk backward to "take up the slack" until just before you feel the vertebral segment move. Now, place the finger tip of your cephlad hand on the superior spinous process to monitor motion. Flex both of the patient's legs (hips) until just before you feel the vertebral segment move. The patient's legs can then be supported either on the plinth or your thigh.

FIGURE 16.32 Lumbar spine side-bending manipulation—sidelying

Manipulation force: Lift the patient's legs into hip rotation, causing the lumbar spine to side bend in the same direction as the lifted legs.

HVT Lumbar Roll to Increase Lumbar Rotation (Fig. 16.33) VIDEO 16.10

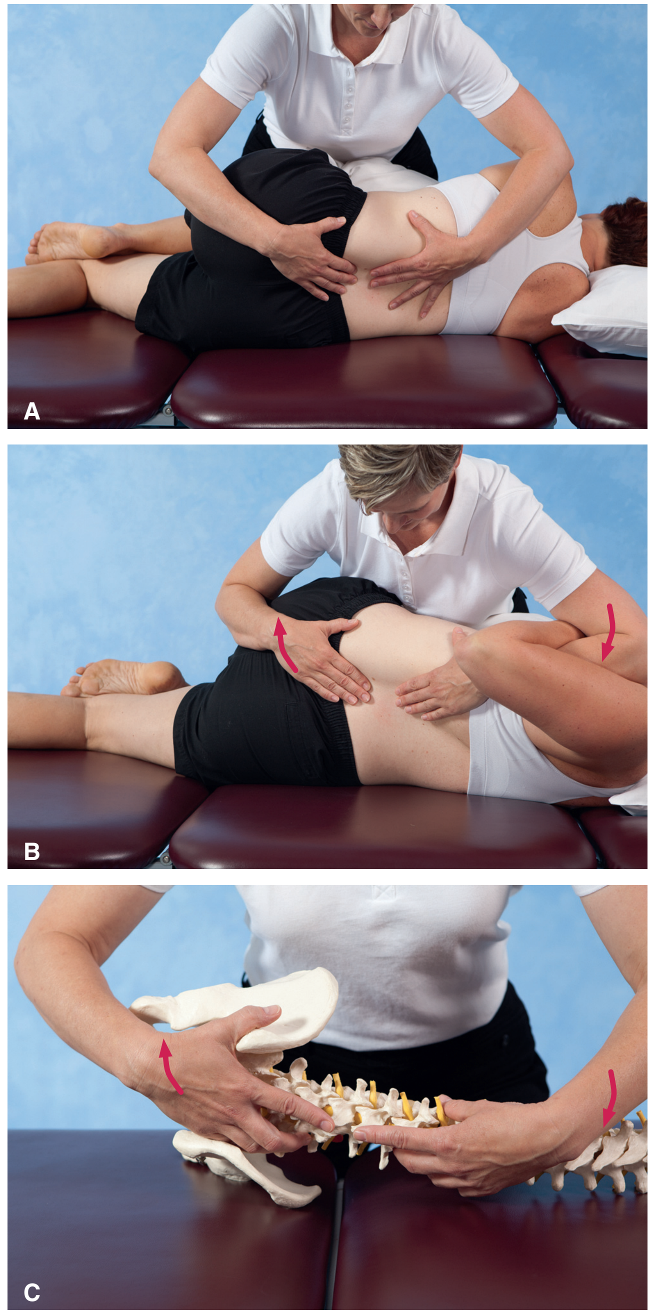

FIGURE 16.33 Lumbar roll HVT: **(A)** monitor motion at the spine as the hip is flexed then stabilized by the therapist's trunk; **(B)** rotate the patient's trunk backward to take up the slack, and apply a rotational force through the lower spine by moving the innominate forward; **(C)** rotational forces applied to the segment above and below, including the innominate, demonstrated on a spine model.

Patient position: Side-lying with the restricted side up. Position the patient as close to the edge of the bed as possible and flex the hips and knees to 90°. Provide a pillow for the patient to hold that can act as a physical barrier.
Therapist position and hand placement: Stand facing the patient. Place the finger tips of your cephlad hand on the inferior spinous process to monitor motion. Move the patient's top leg into hip flexion until just before you feel the inferior vertebral segment move. Maintain the patient's hip flexion by stabilizing the leg between the therapist's body and the treatment table, and move your cephalad hand to the superior spinous process to monitor motion (Fig. 16.33 A).
Passively rotate the patient's trunk backward to "take up the slack" until just before you feel the superior vertebral segment move, and rest the forearm on the patient's torso. The therapist's torso should be directly over the segment to be manipulated (Fig. 16.33 B).
Manipulation force:

- Therapist exerts a downward rotational thrust toward the table with the cephalad forearm and hand while exerting a rotational force through the caudal forearm by pulling the patient's lower trunk toward your body (Fig. 16.33 B and C).
- Altnernative method is to use the caudal forearm and apply a rotational force through the patient's innominate. This technique (patient contact) is particularly useful if attempting to increase rotation at L5–S1.

SI Joint Manipulation Technique to Increase Sacral Nutation (Flexion) (Fig. 16.34) VIDEO 16.11

Patient position: Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.
Therapist position and hand placement: Place your pisiform (hypothenar eminence) over the sacral base (S1) region. Relax the rest of your hand on the patient's back.
Anterior glide manipulation force: Push with your hypothenar eminence in an anterior-inferior direction.

FIGURE 16.34 SI Nutation (Flexion) Manipulation.

SI Joint Manipulation Technique to Increase Sacral Counternutation (Extension) (Fig. 16. 35) VIDEO 16.11

FIGURE 16.35 SI Counternutation (Extension) Manipulation

Patient position: Prone. Place a pillow under the abdominal region for patient comfort and to provide a neutral lumbosacral curve.
Therapist position and hand placement: Place your pisiform (hypothenar eminence) over the apex of the sacrum (S5) region. Relax the rest of your hand on the patient's sacrum.
Anterior glide manipulation force: Push with your hypothenar eminence in an anterior-inferior direction.

Posterior Rotation Manipulation to Innominate (Fig. 16.36) VIDEO 16.11

Patient position: Supine with arms crossed over chest. Move the patient's trunk and legs toward the side of the restriction to create sidebending in the lumbar spine.
Therapist position and hand placement: Stand on the side opposite the restriction. Contact the patient's opposite ASIS with your caudal hand. With the cephalad, roll the patient's trunk toward you.

FIGURE 16.36 Posterior Rotation Innominate Manipulation

Manipulation force: Exert a progressive oscillation or HVT force posterior through the hand contact at the innominate.

Muscle Performance: Stabilization, Muscle Endurance, and Strength Training

Goals. To: (1) activate and develop neuromuscular control of deep segmental and global spinal stabilizing muscles to support the spine against external loading; (2) develop endurance and strength in the muscles of the axial skeleton for functional activities; and (3) develop control of balance in stable and unstable situations.

This section is divided into two main sections. The first section presents principles and techniques of stabilization exercises for the cervical and lumbar spinal regions with a subsection on motor control exercises for segmental muscle activation and a subsection on global muscle stabilization. The second section presents principles and techniques of general isometric, dynamic, and functional exercises for the neck and trunk.

Stabilization Training: Fundamental Techniques and Progressions

"Proximal stability for distal mobility," a well known phrase, is an underlying principle of intervention with therapeutic exercise. The primary functions of the muscles of the trunk are to provide stability, so upright posture can be maintained against a variety of forces that disturb balance and to provide a stable base, so the muscles of the extremities can execute their function efficiently and without undue stress to the spinal structures. Several studies have demonstrated altered or delayed neuromuscular recruitment patterns in the deep stabilizing muscles of the lumbar spine during active movement in individuals with low back pain.[21,24,25,44] Results of other studies have shown improved ability to recruit these muscles with specific training[43] and improved outcomes compared with individuals not receiving the training.[20,43,44] Studies have also demonstrated improved outcomes in patients with cervical pain and cervicogenic headaches with recruitment of the deep stabilizing musculature in the cervical spine in conjunction with total trunk stabilization.[30,37]

The functions of the deep segmental musculature and the superficial global (multi-segmental) spinal musculature were identified and described in Chapter 14. Both muscle systems are necessary for spinal stability and function. Therefore, one of the primary areas of emphasis during rehabilitation after spinal problems is recruiting the segmental muscles and training them to respond along with the global musculature to various forces and demands imposed on the spine to improve coordination of their overall function. Activation of the stabilizing musculature is then reinforced when progressing to muscular endurance and strengthening exercises, when performing aerobic exercises, and when practicing functional activities throughout the rehabilitative process with the anticipation that muscle activation for stabilization will become automatic during all daily activities and functional challenges (Fig. 16.37).

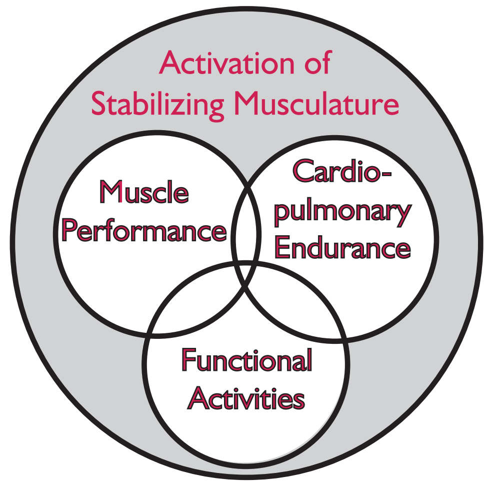

FIGURE 16.37 Exercises to improve muscle performance, cardiopulmonary endurance, and functional activities are integrated over a background of activating the deep segmental and global multi-segmental spinal stabilizing musculature.

Stabilization training follows the basic principles of learning motor control first by developing awareness of muscle contractions and spinal position, then by developing control in simple patterns and exercises, then progressing to complex exercises, and finally by demonstrating automatic maintenance of spinal stability and control in a progression of simple functional activities to complex and unplanned situations.[55] Many of the exercises can be used to accomplish more than one purpose; there is definite overlap with kinesthetic training, muscle performance, and functional training. The choice and progression of exercises described in each of the sections rely on clinical judgment of the patient's response and attainment of goals, not on a strict, time-based protocol or number of days from injury. The ability of the patient to control the spine in a neutral or nonstressful position is paramount for all the exercises.

CLINICAL TIP

Stabilization training follows basic principles of learning motor control.

1. Patient develops awareness of muscle contractions and spinal positions.
2. Patient develops control of spine when performing simple extremity patterns and exercises.

3. Patient demonstrates control of spine when progressing to complex exercises.
4. Patient demonstrates automatic maintenance of spinal stability and control in a progression of simple functional activities to complex and unplanned situations.

There is considerably more research on muscle function and its stabilization action in the lumbar spine than the cervical spine. The cervical spine requires more mobility to position the head, yet relies on the thoracic and lumbar spinal regions to provide a base for stability and postural control. Even though there are unique anatomical considerations in the cervical spine, there is overlap between stabilization training for cervical and lumbar problems.

Guidelines for Stabilization Training

It is important to understand and use the principles and progression of stabilization training for effective instruction.[6,41,51–53] The following guidelines are summarized in Box 16.2.

1. *Kinesthetic training* for awareness of safe motion and positions must precede stabilization training. The functional range and functional position in which symptoms are minimal or absent are used for stabilization exercises.[41] When the condition is not acute, most people find the mid-range (the neutral position) to be their functional position. It is important to recognize that this position or range is not static; nor is it the same for every person. In addition, it may change as the tissues heal, nociceptive stimuli decrease, and flexibility improves.[41]
2. *Activation* of the deep segmental muscles of the trunk, specifically the transversus abdominis (TrA) and multifidus (Mf), is often delayed or absent in patients with back pain.[21,25,44] In addition, ultrasound imaging studies on individuals with unilateral low back pain have shown decreased activation of these deep muscles on the side of symptoms compared to the uninvolved side when performing voluntary contractions.[59]

   Learning conscious activation of the deep segmental muscles without contracting the global trunk musculature is the first step in developing habitual activation for spinal stability in patients with pain related to poor spinal control and segmental instability. Once the individual learns correct activation of the segmental stabilizers using the "drawing-in" maneuver, this maneuver is used prior to all exercises and activities to develop the activation and stabilizing function and eventually automatic feedforward stabilization from the muscles.[26] A study involving 42 subjects demonstrated that it is possible to alter abdominal muscle activation consciously and automatically with specific exercises.[43]

   In the cervical region, the deep cervical flexors, the longus colli and longus capitis, and the deep cervical and upper thoracic extensors are activated to stabilize the cervical spine in a neutral spinal position (axial extension with mild lordosis).
3. *Extremity motions* are added to the stabilization program to coordinate segmental muscle activity with the global stabilizing musculature. Loading via the extremities increases the stabilizing challenge to the musculature. The patient positions the spine in the neutral position (using pelvic tilt motions in the lumbar region and gentle head nodding in the cervical region), performs the drawing-in maneuver, and then begins moving one or several extremities while maintaining the neutral position. Extremity motions are performed within the tolerance of the trunk or neck muscles to control the neutral or functional position. This is called *dynamic stabilization*, because the stabilizing muscles in the spinal area must respond to the changing forces coming from the dynamic movement of the extremities. Exercises that require stabilization against transverse plane rotational forces on the pelvis more consistently activate the oblique abdominal and deep spinal stabilizers than sagittal plane resistive forces.[50]
4. *Increase muscular endurance and strength* once control of the spinal position is established and the patient can activate the stabilizing muscles. Repetitions of extremity motions are increased, and resistance is applied to the extremities. The intent is to challenge the trunk muscles to stabilize against these increased forces yet stay within their tolerance and ability to control the spinal position. Repetitions also help develop *habit*; therefore, it is important to use careful instructions and provide feedback. Fatigue is determined by the inability of the trunk or neck muscles

BOX 16.2 Guidelines for Stabilization Training: Principles and Progression

1. Begin training with awareness of safe spinal motions and the neutral spine position or bias.
2. Have patient learn to activate the deep stabilizing musculature while in the neutral position.
3. Add extremity motions to load the superficial global musculature while maintaining a stable neutral spine position (dynamic stabilization).
4. Increase repetitions to improve holding capacity (endurance) in the stabilizing musculature; increase load (change lever arm or add resistance) to improve strength while maintaining a stable neutral spine position.
5. Use alternating isometric contractions and rhythmic stabilization techniques to enhance stabilization and balance with fluctuating loads.
6. Progress to movement from one position to another in conjunction with extremity motions while maintaining a stable neutral spine (transitional stabilization).
7. Use unstable surfaces to improve the stabilizing response and improve balance.

to stabilize the spine in its functional position or by increased pain. For example:

- Begin at a resistance force that the patient can repeat for 30 to 60 seconds and maintain the neutral position of the spine; progress the repetitions to 3 minutes.
- Progress by adding resistance to or increasing the lever arm of the extremities; initially, reduce the time and again progress to doing the new activity for 1 to 3 minutes.
- Another way to develop endurance in the trunk muscles is to begin exercising at the most difficult level for that patient, then shift to simpler levels of resistance as fatigue begins in order to keep moving. It is important that the patient does not lose control of the functional position or experience increased symptoms.

5. *Alternating isometric contractions* between antagonists and *rhythmic stabilization* of the trunk muscles against manual resistance also enhance stabilizing contractions. When performed while sitting and standing, the alternating contractions and co-contractions also develop control of balance.
6. *Transitional stabilization* develops as the patient moves from one position to another in conjunction with extremity motions. This requires graded contractions and adjustments between the trunk flexors and extensors and requires greater awareness and concentration.[6,41] For example, any motion of the arms or legs away from the trunk tends to cause the spine to extend. The abdominals (trunk flexors) must contract to maintain control of the functional spinal position. This occurs, for example, when lifting a load from the floor to overhead. Then, as the arms or legs move anteriorly toward the center of gravity, the spine tends to flex, which requires the extensors to contract to maintain the functional position (as would occur when lowering a weight to the floor). Greater concentration on maintaining the functional spinal position is necessary when doing more advanced functional activities.
7. *Perturbation (balance) training*, exercising against destabilizing forces or on unstable surfaces, develops neuromuscular responses to improve balance.

Deep Segmental Muscle Activation and Training

The function of the deep musculature (TrA and Mf in the lumbar spine and longus colli and other deep musculature in the cervical spine) is described in Chapter 14, and the results of impaired function in these muscles are described in Chapter 15. Techniques for activation of the segmental musculature are described in this section.

FOCUS ON EVIDENCE

Methods for testing and training activation of the deep segmental musculature have been developed and used in both research and clinical settings.[47] Placement of fine-wire electrodes with ultrasound guidance has provided valuable information regarding the muscle function and recovery in research settings,[26,27] and ultrasound imaging has provided a valuable tool for biofeedback in training.[19,22,23,60] As of 2012, use of ultrasound biofeedback imaging has been prohibitively expensive to use clinically for training activation of the deep musculature. As an alternative device, a pressure biofeedback unit (Stabilizer™; © 2006 Encore Medical, L.P.) was developed and has been shown to have clinical usage in training activation and control of the stabilizing musculature of the trunk and neck.[28,56]

Cervical Musculature

In the cervical region, the goal is to activate and control the muscles that control axial extension (cervical retraction). This requires capital flexion, slight flattening of the cervical lordosis, and flattening of the upper thoracic kyphosis (Fig. 16.38).

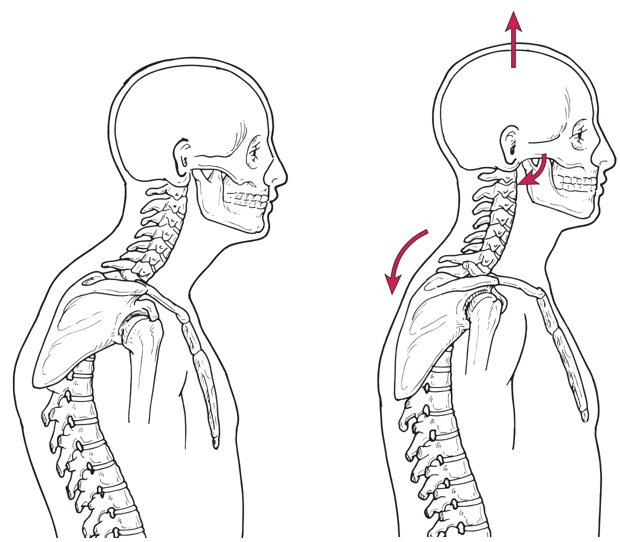

FIGURE 16.38 Axial extension (cervical retraction) involves the motion of capital flexion and movement of the lower cervical and upper thoracic spine toward extension, resulting in slight flattening of the cervical lordosis and "lifting" of the head.

Deep Neck Flexors: Activation and Training VIDEO 16.12

Patient position and procedure: Supine. For craniocervical flexion and gentle axial extension, teach the patient to perform slow, controlled nodding motions of the head on the upper cervical spine ("yes" motion). If the patient has a significant forward head posture, place a folded towel under the occipital area, so extension of the head on the neck does not occur. Facilitate the motion with manual cues to ensure the longus colli is contracting, or the sternocleidomastoid is at a relative state of rest. Once the patient is able to activate the motion, the Stabilizer™ (or blood pressure cuff) may be used to monitor the amount of cervical flattening and measure the muscular endurance for holding the contraction (Fig. 16.39). The protocol for use of the Stabilizer™ is summarized in Box 16.3.

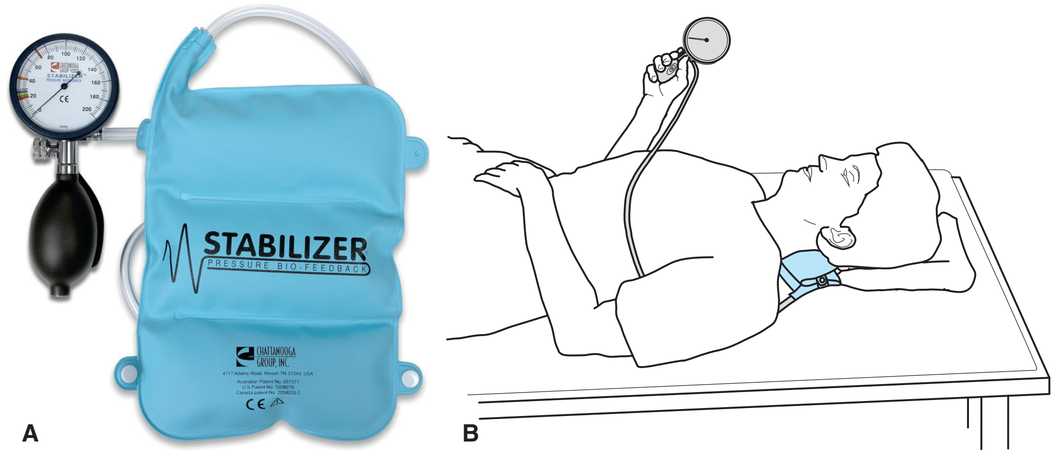

FIGURE 16.39 **(A)** The Stabilizer™ pressure biofeedback unit (© 2006 Encore Medical, L.P.) is used to provide visual feedback to the patient while training for spinal stabilization. **(B)** Stabilizer folded into thirds under the cervical spine to test and train capital flexion with neutral spine axial extension.

BOX 16.3 Testing and Training Deep Segmental Muscle Activation in the Cervical Spine

- Place blood pressure cuff or the folded Stabilizer™ pressure biofeedback unit (folded into thirds) under the upper cervical spine and inflate to 20 mmHg.
- Instruct the patient to nod and increase pressure on the cuff to 22 mm Hg and hold the pressure steady for 10 seconds.
- If the patient is successful (i.e., can hold the position with minimal superficial muscle activity), have him or her relax and repeat the flexion, this time increasing pressure to 24 mm Hg. Repeat this incremental activation up to 30 mm Hg (total 10 mm Hg increase).
- The final pressure is the one at which the patient can hold steady for 10 seconds.
- Muscle endurance (holding or tonic capacity) of the deep neck flexors is measured by the number of 10-second holds (up to 10) at the final pressure.

A *performance index* can be used to document an objective measure. Multiply the pressure increase by the number of times the patient can repeat the 10-second holds—with 100 reflecting the holding of a 10-mm Hg increase for 10 repetitions.[31]

Adapted from the instruction manual that accompanies the Stabilizer™ © 2006 Encore Medical, L.P., with permission.

FOCUS ON EVIDENCE

Jull and associates[31] reported that the controlled performance of upper cervical flexion increases the pressure in the Stabilizer™ to 30 mm Hg and that the test-retest reliability of the craniocervical flexion test (conducted on 50 asymptomatic subjects 1 week between tests) was an ICC of 0.81 for the activation score and 0.93 for the performance index (see Box 16.3).

Lower Cervical and Upper Thoracic Extensor Activation and Training

Patient position and procedure: Prone with forehead on the treatment table and arms at the sides. Have the patient lift the forehead off the treatment table, keeping the chin tucked and eyes focused on the table to maintain the neutral spinal position (reinforces the craniocervical flexion motion learned in the supine position). Lifting the head is a small motion (Fig. 16.40).

Progression

Once the patient learns to activate the deep musculature and assume the neutral posture in the cervical spine, practice throughout the day is encouraged in order to develop good postural control. Stabilization training is initiated by coordinating control of the neutral spinal position with upper extremity loading. The extremity motions are used to stimulate muscular endurance as well as strengthen the stabilizing musculature in the spine. These exercises are described in the next section 'Global Muscle Stabilization Exercises.'

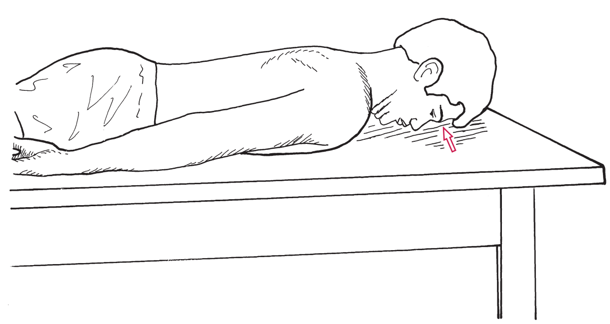

FIGURE 16.40 Axial extension (cervical retraction) exercises.

Lumbar Musculature

Three techniques for abdominal muscle activation have been described and used in clinical practice: the drawing-in maneuver; abdominal bracing; and posterior pelvic tilt (Fig. 16.41). Each technique differs in the stabilization activity of the abdominal and multifidus muscles.[49] Studies have demonstrated that the drawing-in maneuver is more selective in co-activating the transversus abdominis and multifidus muscles than the abdominal bracing and posterior pelvic tilt techniques,[28,49] and that the drawing-in maneuver leads to improvement in feedforward postural strategies.[62] The drawing-in maneuver also functions to increase intra-abdominal pressure by inwardly displacing the abdominal wall. Because of this, the drawing-in maneuver is recommended for stabilization training; the other two methods are also described, primarily so the reader can recognize the differences.

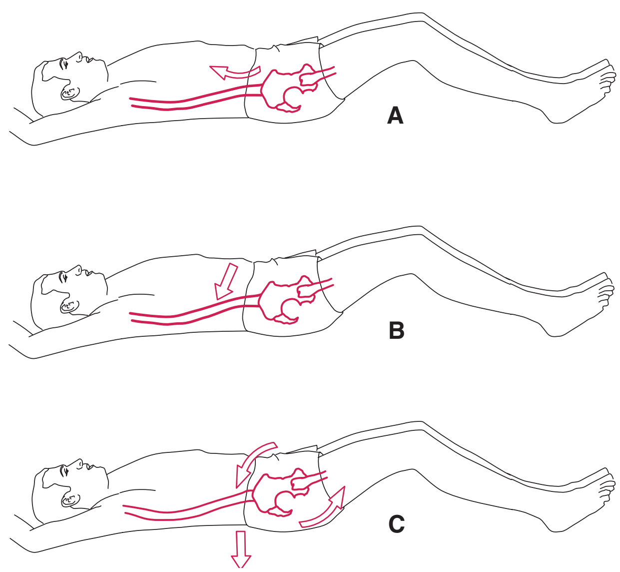

FIGURE 16.41 Three methods to activate the stabilizing musculature in the lumbar spine. **(A)** Drawing-in maneuver in which the patient hollows the abdominal region ("draws" the belly button toward the spine). **(B)** Abdominal bracing in which setting the abdominal muscles results in flaring laterally around the waist. **(C)** Posterior pelvic tilt in which the pelvis is actively tilted posteriorly and the lumbar spine flattens.

Drawing-In Maneuver (Abdominal Hollowing Exercise) for Transverse Abdominis Activation VIDEO 16.13

Patient positions: Training may be easiest in the quadruped position in order to use the effects of gravity on the abdominal wall. Hook-lying (with knees 70° to 90° and feet resting on an exercise mat), prone-lying, or semireclined positions may be used if more comfortable for the patient. It is important to progress training to sitting and standing as soon as possible.[38,40]

Procedure: Teach the patient using demonstration, verbal cues, and tactile facilitation. Explain that the muscle encircles the trunk, and when activated, the waistline draws inward (see Fig. 16.41 A).

- Palpate the transversus abdominis (TrA) muscle just distal to the anterior superior iliac spine (ASIS) and lateral to the rectus abdominis (RA) (Fig. 16.42). When the internal oblique (IO) contracts, a bulge of the muscle is felt; when the TrA contracts, flat tension is felt. The goal is to activate the TrA with minimal or no contraction of the IO. This is a gentle contraction.

FIGURE 16.42 Palpation of the transversus abdominis (TA) muscle just distal to the ASIS and lateral to the rectus abdominis muscle. The TA feels like a tense sheet (a bulge is the internal oblique) when performing a gentle drawing-in maneuver.

- Have the patient assume a neutral spinal position and attempt to maintain it while gently drawing in and hollowing the abdominal muscles.[47] Instruct the patient to breathe in, breath out, then gently draw the belly button in toward the spine to hollow out the abdominal region. When done properly, there are no substitute patterns; that is, there is minimal to no movement of the pelvis (posterior pelvic tilting), no flaring or depression of the lower ribs, no inspiration or lifting of the rib cage, no bulging out of the abdominal wall, and no increased pressure through the feet. Performing the drawing-in maneuver with the spine in a neutral position results in increased TrA response (measured as increased thickness in ultrasound imaging) compared to slouched sitting or slouched standing postures.[46]

If a patient has difficulty activating the TrA, the following two feedback techniques have been shown to assist with learning.[17,48,49]

- *Pressure biofeedback for clinical testing and visual feedback.* With the patient prone, the Stabilizer™ (or blood pressure cuff) is placed horizontally under the abdomen (centered under the navel). Inflate the Stabilizer™ to 70 mm Hg. Have the patient perform a drawing-in maneuver, as described above. A decrease of 6 to 10 mm Hg during the drawing-in maneuver (without substitutions) indicates proper activation of the deep abdominal muscles. The dial on the unit is large and easily read by the patient for immediate feedback.

- *Biofeedback with surface electrodes.* Surface electrodes placed over the rectus abdominis and external obliques (near its attachment on the eighth rib) may be used in conjunction with the inflatable cuff. There should be minimal to no activation of these muscles if the drawing-in maneuver is done correctly.

As with the cervical spine, the Stabilizer™ can be used not only to train and reinforce activation of the TrA but also to measure control for a measured period of time as well as number of repetitions. The protocol is summarized in Box 16.4.

Abdominal Bracing

In contrast to the drawing-in maneuver, abdominal bracing occurs by setting the abdominals and actively flaring out laterally around the waist (see Fig. 16.41 B). There is no head or trunk flexion, no elevation of the lower ribs, no protrusion of the abdomen, and no pressure through the feet. The patient should be able to hold the braced position while breathing in a relaxed manner. This technique has been taught for a number of years as the method to stabilize the spine; it has been shown to activate the oblique abdominal muscles consistent with their global stabilization function.[49]

Posterior Pelvic Tilt

Posterior pelvic tilt exercises (see Fig. 16.41 C) principally activate the rectus abdominis muscle, which is used primarily for dynamic trunk flexion activity. It is a superficial muscle that does not have segmental attachments; therefore, it is not emphasized in the training for stabilization.[49] Pelvic tilt exercises are used to teach awareness of the movement of the pelvis and lumbar spine as the patient explores his or her lumbar ROM to find the functional spinal range and the neutral position.

Multifidus Activation and Training VIDEO 16.14

Patient position and procedure: Prone or side-lying. Place your palpating digits (thumbs or index fingers) immediately lateral to the spinous processes of the lumbar spine (Fig. 16.43).

- Palpate each spinal level so comparisons in the activation of the multifidus (Mf) muscle can be made between each segment as well as from side-to-side.
- Instruct the patient to "swell the muscle" out against your digits. Palpate for consistency of muscle contraction at each level.
- Facilitation techniques include using the drawing in maneuver and gently contracting the pelvic floor muscles (as in Kegel exercises, described in Chapter 24).
- In the side-lying position, facilitate by gently applying manual resistance to the thorax or pelvis to activate the rotation function of the Mf.
- The patient may be taught to self-palpate a Mf contraction in the following manner. Sit and rock the pelvis to find the neutral position; with the fingers or thumbs placed along the lumbar spinous processes, lean forward a couple degrees. The Mf is thus activated. Differentiate a Mf contraction from tension in the aponeurosis of the global erector spinae.

Progression

Once the patient learns to activate the deep segmental musculature, practice throughout the day is encouraged. Segmental

BOX 16.4 Testing and Training Deep Segmental Muscle Activation (Transversus Abdominis) in the Lumbar Spine

- Patient is prone lying.
- Place a blood pressure cuff or the Stabilizer™ pressure biofeedback unit horizontally under the abdomen with the lower edge just below the anterior superior iliac spine (ASIS) (navel at center of unit).
- Inflate to 70 mm Hg and instruct the patient to perform the drawing-in maneuver.
- If done properly, the pressure drops 6 to 10 mm Hg.
- See if the patient can maintain the pressure drop for up to 10 seconds.
- Muscle endurance (holding or tonic capacity) of the transversus abdominis (TrA) is measured by the number of 10-second holds (up to 10).

Adapted from the instruction manual that accompanies the Stabilizer™ © 2006 Encore Medical, L.P., with permission.

FIGURE 16.43 Palpation of the multifidus muscle lateral to the spinous processes in the lumbar spine, **(A)** bilaterally in the supine position and **(B)** unilaterally in the side-lying position.

muscle activation is then coordinated with stabilization training, using the global musculature and extremity loading. Extremity motions are added and used to stimulate muscle endurance as well as strengthen the trunk muscles. Global stabilization exercises are described in the next section.

Global Muscle Stabilization Exercises

Even though this section is divided into cervical and lumbar regions, many of the same exercises may be used for impairments in either region because of the functional relationships of the entire axial skeleton.

Stabilization Exercises for the Cervical Region

Stabilization with Progressive Limb Loading

In general, stabilization exercises begin in the recumbent position and progress to sitting, sitting on a large gym ball, standing with the back supported against a wall, and finally standing without support. For advanced training, exercises are progressed to standing on an unstable surface.

- Begin all exercises with gentle craniocervical nods and axial extension to the neutral spinal position to activate the deep segmental muscles as described in the previous section. During the early phases of training, if the patient has difficulty maintaining a neutral spinal position, a small towel roll may be placed under the neck for passive support.
- Initially, the only resistance load comes from simple upper extremity movements. When the patient can perform multiple repetitions of the upper extremity motions without losing control of the spinal position or causing an increase in symptoms, resistance is added with handheld weights or elastic resistance.
- The principles of muscle endurance and strengthening described in Chapter 6 are used to challenge the spinal stabilizing musculature.
- Table 16.3 summarizes limb-loading exercises that emphasize the flexor muscles, and Figure 16.44 illustrates the basic exercise progression in the supine position.
- Table 16.4 summarizes limb-loading exercises that emphasize the lower cervical/upper thoracic extensor muscles, and Figure 16.45 illustrates a basic exercise progression in the prone position. It is important to note that these exercises do not isolate the flexors or extensors, but the designation is primarily for emphasis due to the effects of gravity.

Variations and Progressions in the Stabilization Program

Remind the patient to find and maintain the neutral spinal position when doing these exercises.

- *Extremity loading.* During the early phases of training, limit shoulder flexion to 90° flexion and abduction. Once the patient can maintain stability and symptoms are not provoked, greater challenges occur with elevating the upper extremity full ROM. Unilateral and asymmetrical upper extremity motion require greater control than bilateral motion.
- *External resistance.* Tables 16.3 and 16.4 summarize progressions based on position changes. In addition, use of resistance loads (free weights, elastic resistance, or manual resistance) to any of the exercises adds to the stabilizing challenge. Even though external resistance applied through

TABLE 16.3 Cervical Stabilization with Progressive Limb Loading—Emphasis on Cervical Flexors **VIDEO 16.15**

Instructions: Determine amount of support needed and amount of protection. Begin each exercise with axial extension to the neutral spinal position and maintain it while exercising; increase extremity repetitions, then increase resistance before progressing to a new challenge.		**Maximum Support** ⟷ **Minimum Support**			
		Supine	Sitting (sitting on ball for less stability)	Standing with wall support	Standing with no support (standing on unstable surface for less stability)
Deep Segmental Activation		Gentle craniocervical flexion/axial extension hold 10 seconds × 10 repetitions			
Minimum limb loading ↕	***Maximum to moderate protection phase***	Shoulder flexion to 90°			
		Shoulder abduction 90°			
		Shoulder external rotation with arms at sides			
	Moderate to minimum protection phase	Shoulder flexion to end of range			
		Shoulder abduction combined with external rotation to end of range			
		Diagonal patterns			
Maximum limb loading	***Minimum to no protection phase***	Reaching forward, outward, upward in functional patterns			
		Pushing/pulling and lifting activities			

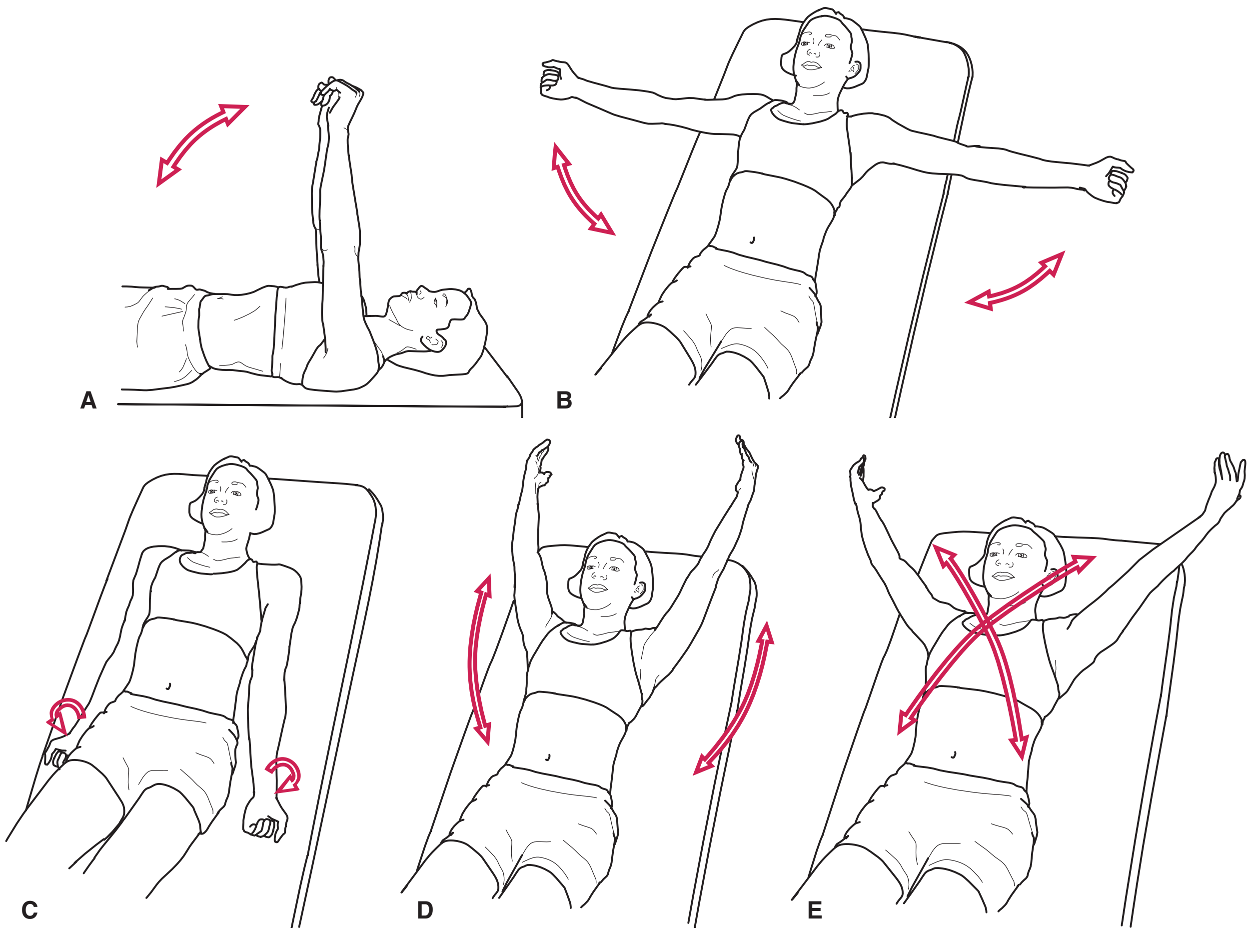

FIGURE 16.44 Limb loading for basic stabilization progression of cervical musculature in the supine position. Maximum protection phase: **(A)** shoulder flexion to 90°; **(B)** shoulder abduction to 90°; **(C)** shoulder external rotation arms at the side. Moderate protection phase: **(D)** shoulder flexion and abduction to end-range; **(E)** diagonal patterns.

the extremities has the benefit of increasing strength in the extremity musculature, the primary goal is to increase the stabilizing response of the cervical musculature. Therefore, any loss of the neutral spinal posture or increase in cervical symptoms signals the need to decrease the intensity of the resistance force.

- *Unstable surfaces.* The application of external resistance while on an unstable surface, such as sitting on a large ball (Fig. 16.46 A), lying prone over a ball (Fig. 16.46 B), or standing supporting the ball between the head and the wall (Fig. 16.46 C), provides additional challenges to the muscles as they respond to perturbations. Many variations of these exercises can be used to challenge the stabilizing muscles so long as the patient is able to maintain control.
- *Muscular endurance and strength.* Determine the maximum level of resistance tolerated by the cervical-stabilizing musculature that does not reproduce symptoms. Decrease the intensity and have the patient exercise with multiple repetitions at that level (20 to 30 repetitions or for 1 minute). Resistance can then be added for strengthening (decrease the number of repetitions) at that level before progressing to endurance training at the next level.

Integration of Stabilization Exercises and Posture Training

Good postural alignment of the neck begins with the pelvis and lumbar spine and moves up to the scapular and thoracic regions. The thorax must be lifted up from the pelvis and scapula retracted in a comfortable position for the cervical spine to assume an efficient position of axial extension (cervical retraction). Therefore, begin with lumbopelvic control if necessary and develop thoracic extension and scapular retraction. While the patient is performing the extremity motions to develop stability, reinforce good scapulohumeral alignment. It is important to remember that strengthening alone does not correct faulty posture and, therefore, to utilize the reinforcement techniques and environmental adaptations that are discussed in Chapter 14.

Progression of Isometric and Dynamic Strengthening in Conjunction with Functional Activities

When the patient demonstrates good cervical stabilization and response to various upper extremity resistance changes, isometric and dynamic exercises are integrated into the program. These are described in the 'Isometric and Dynamic Exercise' section following this section.

TABLE 16.4 Cervical Stabilization with Progressive Limb Loading—Emphasis on Cervical and Thoracic Extensors **VIDEO 16.16**

Instructions: Determine amount of support needed and amount of protection. Begin each exercise with axial extension to the neutral spinal position and maintain it while exercising; increase extremity repetitions, then increase resistance before progressing to a new challenge.		**Maximum Support** ⟷ **Minimum Support**			
		Prone forehead on treatment table—lift forehead off table (Fig. 16.19)	Quadruped over padded stool or gym ball—maintain eyes focused on floor	Standing back supported by wall (ball behind head for less stability)	Standing, no support, (standing on unstable surface for less stability)
Deep segmental muscle activation—gentle craniocervical flexion/axial extension		Lift forehead off exercise mat; hold 10 seconds × 10 repetitions			
Minimum limb loading	***Maximum to moderate protection phase***	Arms at side: laterally rotate shoulders and adduct scapulae			
↕		Arms in 90/90 position (abducted and laterally rotated), horizontally abduct shoulders and adduct scapulae			
	Moderate to minimum protection phase	Elevate shoulder in full flexion			
		Arms abducted to 90° and laterally rotated, elbows extended: horizontally abduct shoulders and adduct scapulae			
Maximum limb loading		Upper extremity diagonal patterns			
	Minimum to no protection phase	Standing, no support → standing on unstable surface: ▪ Reaching forward, outward, upward in functional patterns ▪ Pushing/pulling and lifting activities			
		Standing on unstable surface: ▪ Reaching, pushing, pulling			

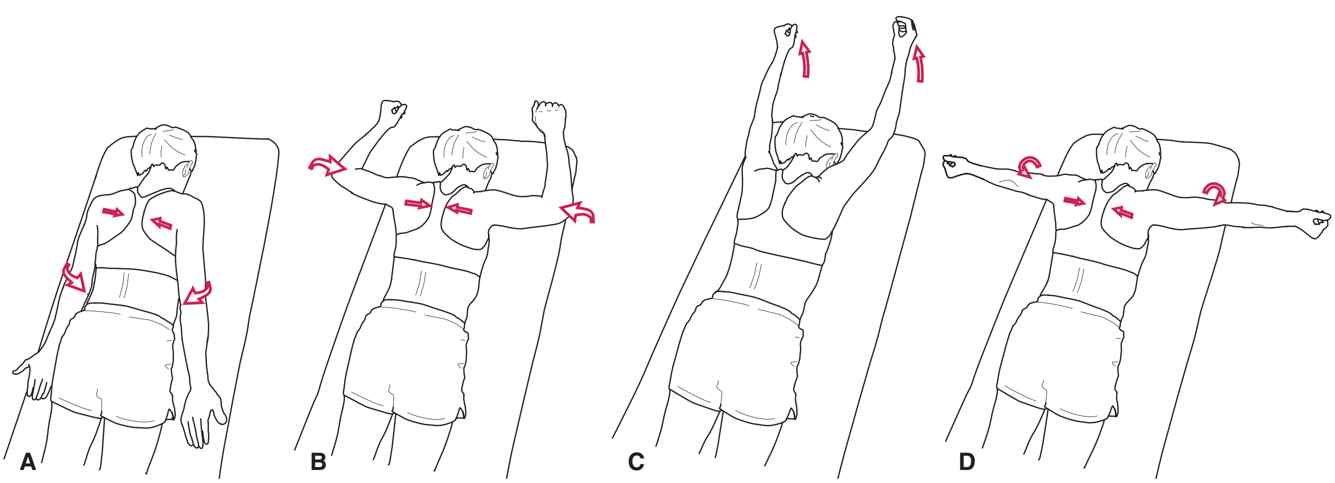

FIGURE 16.45 Limb loading for basic stabilization progression of cervical musculature in prone position. Maximum protection phase: **(A)** arms at side, shoulder lateral rotation, and scapular adduction; **(B)** arms at 90/90, horizontal abduction, and scapular adduction. Moderate protection phase: **(C)** shoulder elevation full range, **(D)** shoulders 90° with lateral rotation and elbow extended, horizontal abduction, and scapular adduction.

A B C

FIGURE 16.46 Unstable surfaces provide increased challenges to the cervical stabilizing musculature, requiring greater control. Examples include performing upper extremity motions, such as diagonal patterns **(A)** while sitting on a gym ball, **(B)** while quadruped over a gym ball, and **(C)** while pressing a ball against the wall. Use of external resistance is also illustrated.

Stabilization Exercises for the Lumbar Region

Once the patient learns to activate the deep segmental muscles in the lumbar region, explain that prior to each exercise the patient is to find the neutral spinal position, perform the drawing-in maneuver, and then maintain control while applying an exercise load with extremity motions. The drawing-in maneuver develops the pattern of setting the deep abdominal and multifidus muscles in a feedforward pattern and then trains their holding capacity in coordination with the global muscles.[17]

Stabilization with Progressive Limb Loading

Begin with the patient supine for greatest support, adding quadruped exercises when able. If the patient cannot control the position, pre-position him or her using pillows or supports (see Box 15.6).

- To improve the holding capacity of the stabilizing muscles, increase the amount of time the patient does the exercises. It is important that no exercise is continued if the patient cannot maintain the stable position. If the deep abdominals cannot stabilize, substitute patterns in the superficial muscles that override the deep muscle activation.
- The Stabilizer™ Pressure Biofeedback unit (or blood pressure cuff) may be used for feedback during this early training (see Box 16.5 for guidelines).
- Table 16.5 summarizes basic limb-loading exercises in the supine position that emphasize the abdominal muscles, and Figures 16.47 and 16.48 illustrate the exercise progression.
- Table 16.6 summarizes limb-loading exercises in the quadruped and prone positions that emphasize the extensor muscles, and Figure 16.49 illustrates a basic exercise progression.

TABLE 16.5 Basic Lumbar Stabilization with Progressive Limb Loading—Emphasis on Abdominals

Instructions: Patient position hook lying (knees 90°). Place pressure cuff under lumbar spine and inflate to 40 mm Hg. Begin each exercise with drawing-in maneuver to activate deep segmental muscles. Determine level at which patient can maintain pressure constant (stable pelvis) while performing either A, B, or C limb load activity. For endurance, decrease load and perform repetitive motion for 1 minute or longer. For strength, progress load.		**Progressive Limb Loading** →		
		A. Lift bent leg to 90° hip flexion	B. Slide heel to extend knee	C. Lift straight leg to 45°
Minimum external support	*Level 1: deep segmental muscle activation*	Draw in and hold 10 seconds		
Maximum external support ↓	*Level 2:*	Opposite LE on mat; bent leg fall out		
	Level 3: A, B, or C	Opposite LE is on table		
	Level 4: A, B, or C	Hold opposite LE @ 90° of hip flexion with UE		
	Level 5: A, B, or C	Hold opposite LE @ 90° of hip flexion (no UE assistance)		
Minimum external support	*Level 6: A, B, or C*	Bilateral LE movement		

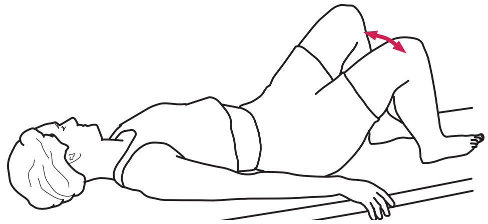

FIGURE 16.47 Bent-leg fall out. Level 2 limb loading for basic stabilization of the abdominal muscles in the supine position. This requires control to prevent pelvic rotation; stability is assisted by the opposite lower extremity while hook-lying. **VIDEO 16.17**

BOX 16.5 Instructions for use of Stabilizer™ for Stabilization Training with Leg Loading

Patient position: Supine, hook lying.

- Place the three-chamber pressure cell under the lumbar spine horizontally across low back area.
- Position the spine in neutral.
- Inflate the pressure cell to a baseline of 40 mm Hg.
- Draw in the abdominal wall without moving the spine or pelvis.
- Pressure should remain at 40 mm Hg (±10 mmHg) while performing the lower extremity loading exercises.

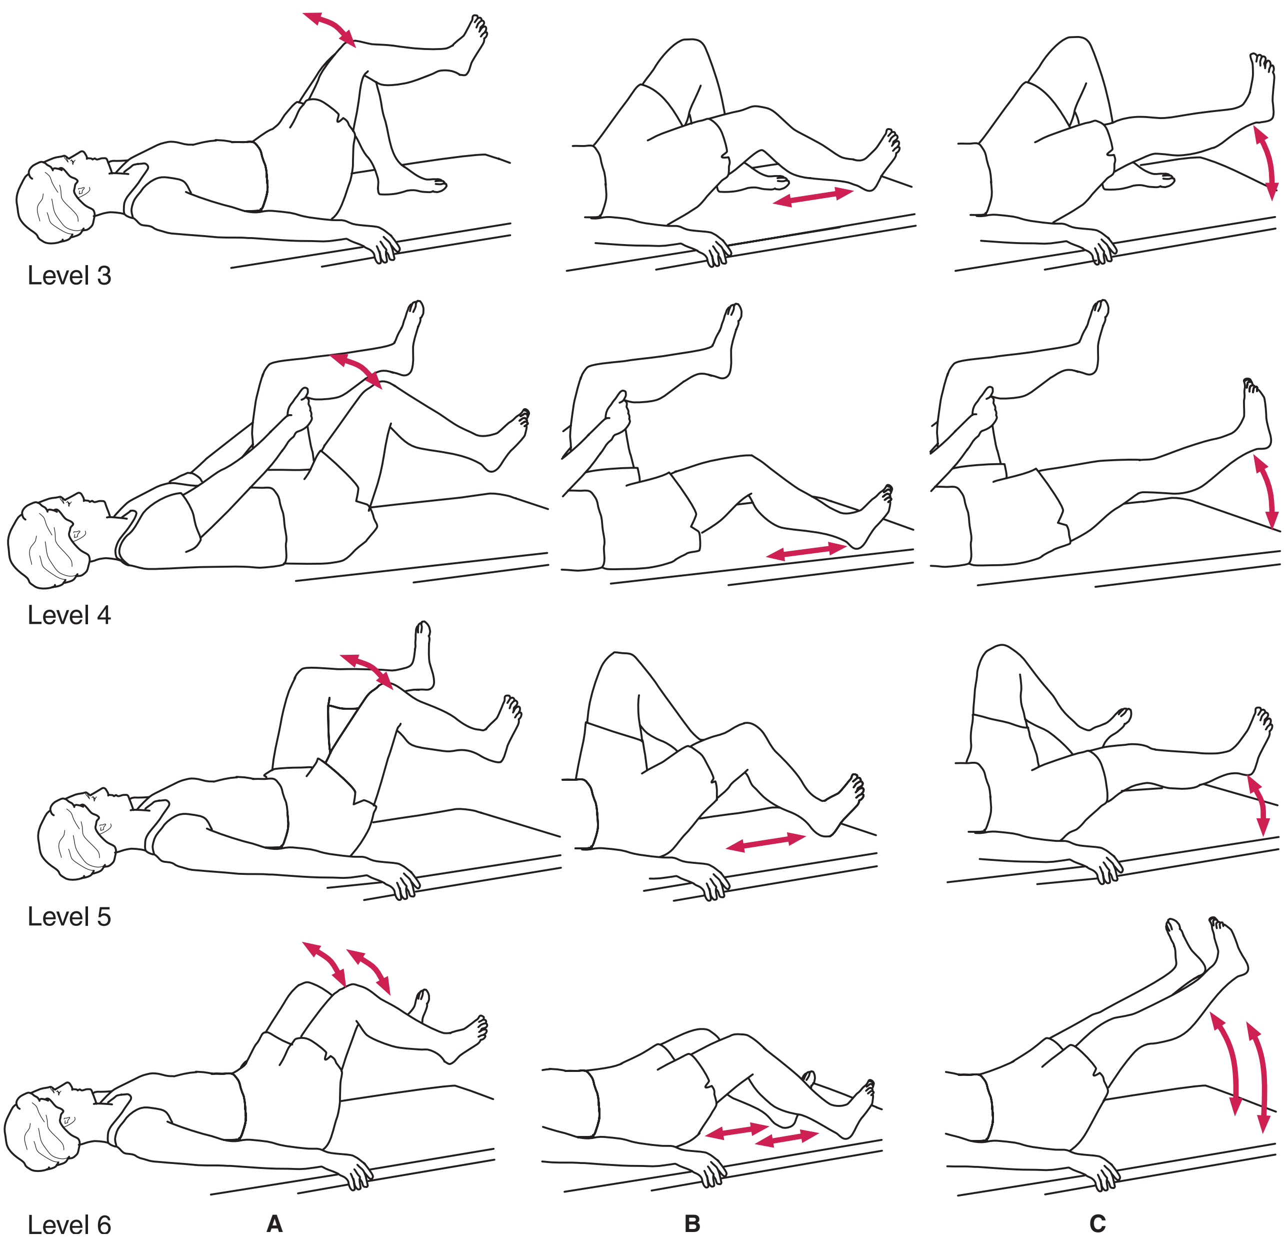

FIGURE 16.48 Limb loading for basic stabilization progression of the abdominal muscles in the supine position, levels 3 to 6. Level 3, stability assisted by opposite extremity in hook-lying position; level 4, stability assisted by patient holding opposite leg at 90°; level 5, stability challenged by patient actively holding opposite leg at 90°; level 6, stability challenged with both lower extremities moving. **(A)** Bent leg lift to 90°. **(B)** Heel slide to extend knee. **(C)** Straight-leg lift to 45°. **VIDEO 16.18**

TABLE 16.6 Basic Lumbar Stabilization with Progressive Limb Loading: Emphasis on Trunk Extensors

		Position	*Load*
Instructions: Patient position quadruped or prone. Patient assumes neutral spine in lumbar and cervical regions (keeping eyes focused toward floor or exercise mat), performs drawing-in maneuver, and moves extremities. Motions are repeated or alternated from side to side.	Lower intensity ↓	Quadruped position	Flex one upper extremity (UE)
			Extend one lower extremity (LE) by sliding it along the exercise mat
			Extend one LE and lift 6–8 inches off exercise mat
			Flex one UE and extend contralateral LE
	Greater intensity and spinal compression	Prone lying position—near end of range of motion, requiring greater control of neutral spine	Extend one LE
			Extend both LE
			Lift head, arms, and LE

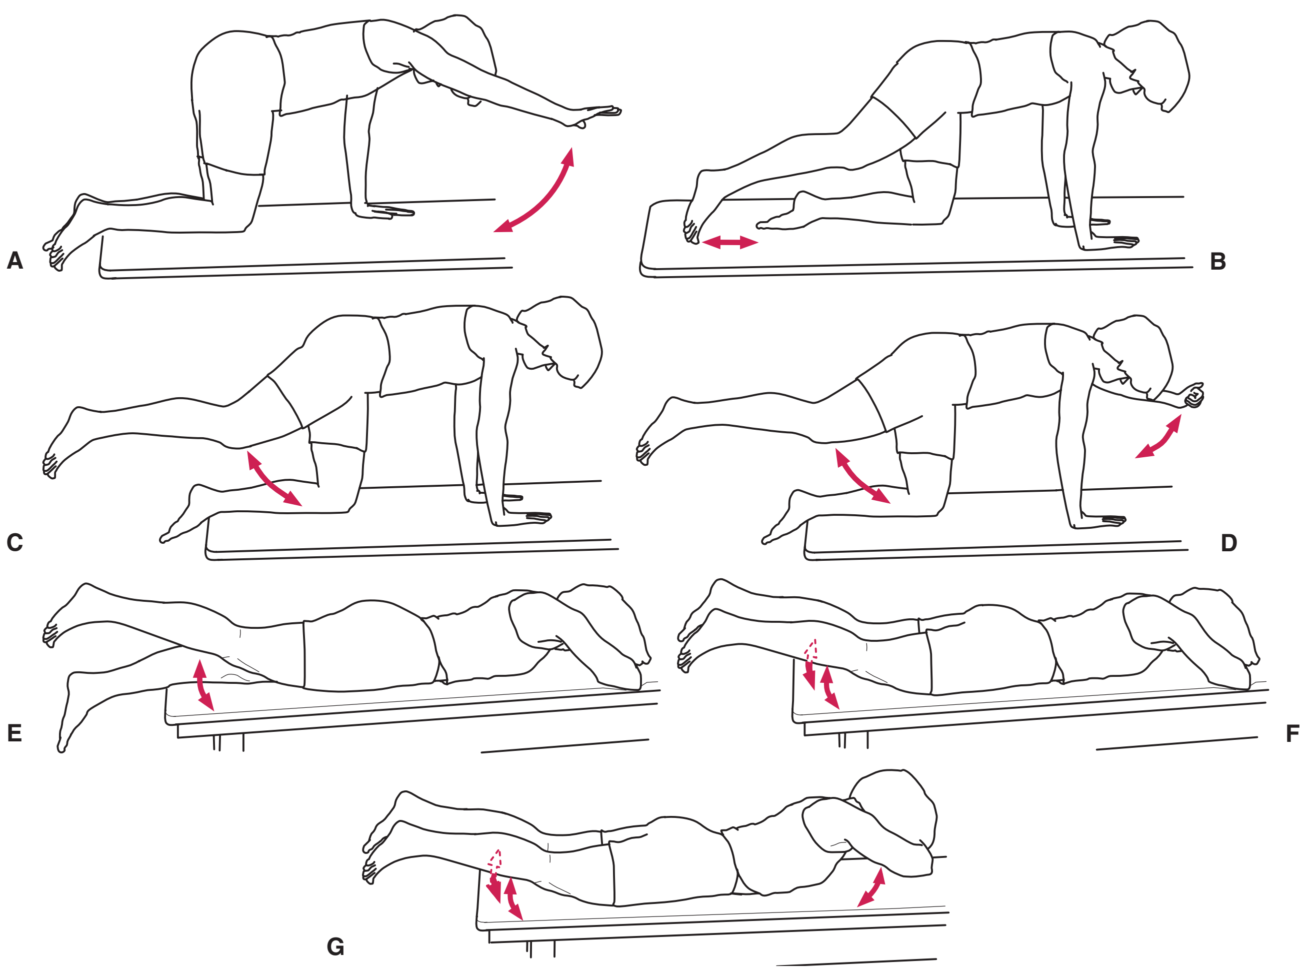

FIGURE 16.49 Limb loading for basic stabilization progression of the lumbar extensors. Begin in the quadruped position and progress the intensity by **(A)** flexing one UE; **(B)** extending one LE with a leg slide; **(C)** extending one LE by lifting it off the mat; **(D)** flexing one UE while extending contralateral LE and then alternate to opposite extremities. Progress to prone: **(E)** extending one LE; **(F)** extending both LE; and **(G)** lifting head, arms, and trunk. **VIDEO 16.19**

CLINICAL TIP

Performance of extremity loading in the prone position places a greater compressive load on the lumbar spine[5,39] and is not possible if there are hip flexion contractures; therefore, initiate extension exercises in the quadruped position, so the lumbar spine can be positioned more easily in neutral, and the patient can learn control.

If the patient cannot bear weight on the extremities or maintain balance in the quadruped position, use a padded stool or gym ball for additional support.

It is important to maintain the cervical spine in its neutral position during quadruped exercises. The patient should be able to align the head and focus the eyes on the floor. As the exercises progress, there is a greater challenge on co-activation of all of the stabilizing musculature.

NOTE: The exercise progressions described in Table 16.5 are adapted from several research studies that investigated the reliability, validity, and sensitivity to change one exercise level with abdominal muscle stabilizing ability using lower-limb loading.[16,17,29] The exercise progressions described in Table 16.6 are adapted from electromyography (EMG) studies that documented extensor activity with limb loading in the quadruped and prone-lying positions.[5,39]

Variations and Progressions in the Stabilization Exercise Program

For all exercises, reinforce the importance of first finding the neutral spine (cervical and lumbar regions), performing the drawing-in maneuver, and then maintaining the neutral spine while superimposing any extremity motions. It is critical to instruct the patient to stop the exercises (or decrease the intensity) as soon as loss of control of the stable spinal position is sensed. It is important not to progress the patient beyond what he or she is able to control in order to develop the proper muscle response. The emphasis is first on improving the static holding capacity (endurance) of the trunk muscles followed by strengthening. Endurance training of the trunk extensor muscles is related to decreased pain and improving function during the early stages of recovery in patients with subacute low back pain.[10]

- *Emphasis on muscle endurance.* Determine a level of exercise that the patient can perform for several repetitions while maintaining a stable spine in the neutral position. Have the patient exercise at that level with the goal of increasing the number of repetitions or the time. Once the patient can perform repetitions for 1 minute, add weights, decrease the repetitions, and emphasize strength. Progress to the next level of difficulty for muscular endurance.
- *Use of external props.* Use of the Stabilizer™ pressure biofeedback unit to help the patient learn control while doing the abdominal stabilization exercises was described earlier (see Box 16.5). For exercises in the quadruped position, if the patient has difficulty controlling the trunk rotation, use a prop, such as a dowel rod, placed along the spine. Have the patient attempt to keep it balanced while performing the arm and leg exercises (Fig. 16.50). It may be helpful to cue the patient not to shift his or her weight as the extremity is moved—this is difficult to do but is effective in bringing in the stabilizing trunk muscles.
- *Extremity loading.* Boxes 16.5 and 16.6 identify a progression of exercises in supine and quadruped/prone positions with extremity loading. Initially, have the patient do the motions repetitively; then progress to alternating the extremities or moving all four extremities simultaneously (Fig. 16.51). This requires the stabilizing musculature to adjust to the shifting loads. Motions begin in the sagittal plane and then progress to the transverse plane and diagonal patterns (unilateral and bilateral), in which movement away from the midline adds a rotational

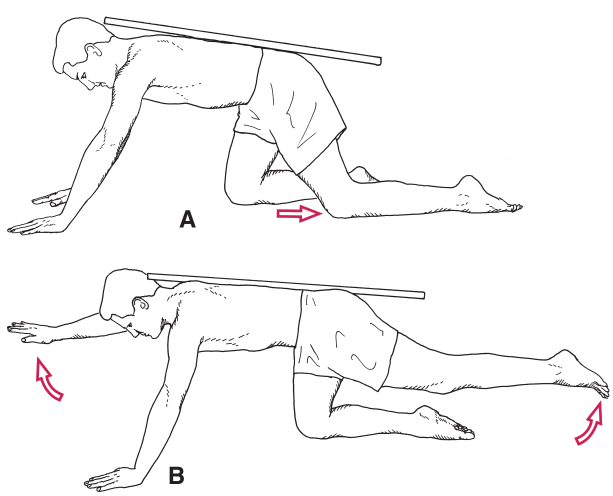

FIGURE 16.50 Balancing a rod on the back while doing quadruped exercises provides reinforcement that the trunk is not twisting. **(A)** Single leg slides. **(B)** Lifting the opposite arm and leg simultaneously, then alternating extremities.

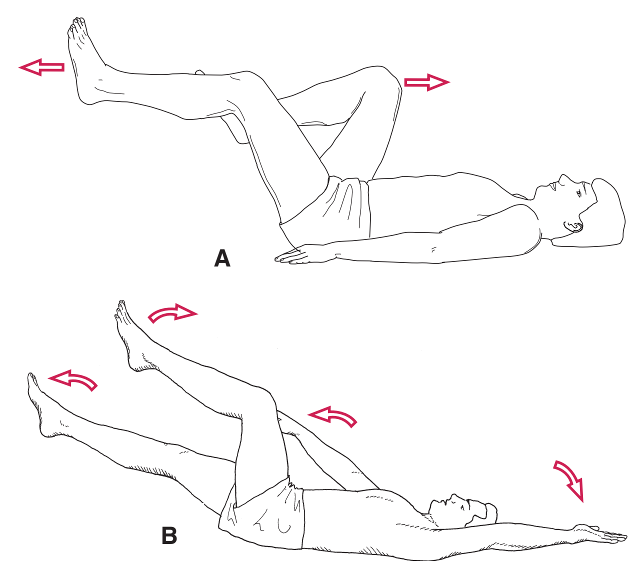

FIGURE 16.51 **(A)** Alternating LE motions with the "modified bicycle" or **(B)** reciprocal and alternating patterns using the UE and LE simultaneously require a strong controlling action in the abdominals.

component and increases the challenge to the stabilizing musculature.

- *External resistance.* Use weights, elastic resistance, or pulleys for strengthening. Several suggestions are illustrated in Figures 16.52, 16.53, and 16.54. Even though the extremities benefit from the exercises, the primary purpose is to improve performance in the stabilizing muscles of the trunk; therefore, when signs of fatigue occur, such as poor control of spinal stability (seen as movement of the pelvis or lumbar spine), reduce the intensity or stop the exercise and allow recovery.
- *Position changes.* Apply the extremity-loading exercises in the sitting (supported then unsupported), kneeling, and standing positions. Also, use modified bridging to challenge the stabilizing function of the trunk musculature. Exercises, such as wall slides and partial lunges and bridging with extremity motions, use the extremities and trunk during weight bearing and prepare the muscles for functional activities. These exercises are described in the final section under Functional Activities but also serve the purpose of challenging the stabilizing muscles.
- *Unstable surfaces.* Use a large gym ball, foam roller, or wobble board to challenge the patient's balance and develop the stabilizing musculature. With the ball, a variety of positions can be used, such as sitting upright on the ball with the feet on the floor (Fig. 16.55), lying supine with the trunk on the ball and feet on the floor (see Fig. 16.60 B) or with the feet on a low mat or wobble board. The foam roller can can be used with the patient supine (Fig. 16.56), kneeling, quadruped (with hands on one roller and knees on another), or standing. Use handheld weights or elastic or pulley resistance secured at various heights (see Fig. 16.54) to increase the challenge. **VIDEOS 16.20 and 16.21**

Quadratus Lumborum: Stabilization Exercises **VIDEO 16.22**

The quadratus lumborum has been identified as an important stabilizer of the spine in the frontal and transverse planes.[39] Strongest activation of this muscle occurs with the side propping (side plank) position. The external obliques are also activated in this position.[39]

Patient position and procedure: Begin side-lying. Have the patient prop up on the elbow and then lift the pelvis off the mat,

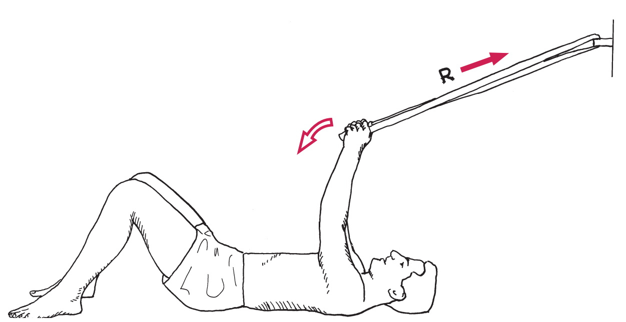

FIGURE 16.52 Developing the stabilizing action of the abdominal muscles by using pull-down activities against a resistive force from pulleys or elastic bands. This exercise can also be done sitting or standing to increase the challenge to the muscles in less stable positions.

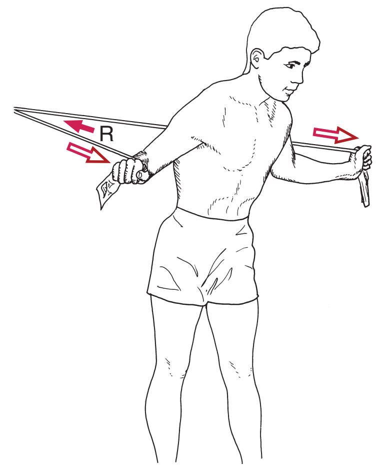

FIGURE 16.53 Using elastic resistance to train and strengthen the abdominal muscles in the upright position. The drawing-in maneuver to set the deep segmental stabilizing muscles precedes the movement of the arms forward against the resistance.

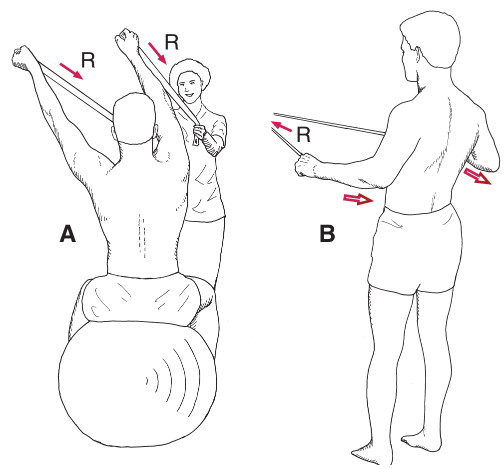

FIGURE 16.54 Using elastic resistance to train and strengthen the back extensor muscles to stabilize in the upright position **(A)** diagonal patterns while sitting on an unstable surface and **(B)** while standing.

FIGURE 16.55 Strength, balance, and coordination are required to maintain spinal stabilization while sitting on a gym ball and moving the extremities. This activity is progressed by adding weights to the extremities.

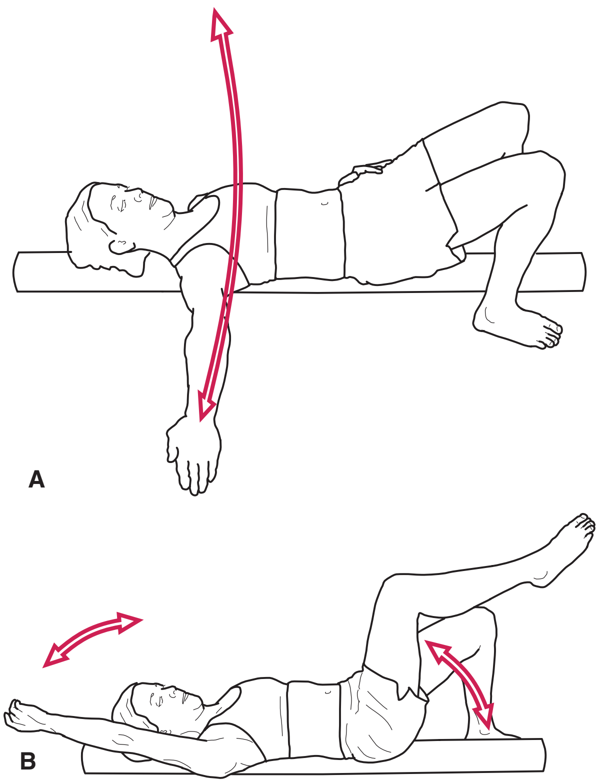

FIGURE 16.56 Activation of the stabilizing trunk muscles occurs to maintain balance on a foam roll while the extremities move in various planes: **(A)** shoulder horizontal abduction/adduction and **(B)** ipsilateral hip and shoulder flexion/extension are shown. Weights are added to increase the challenge.

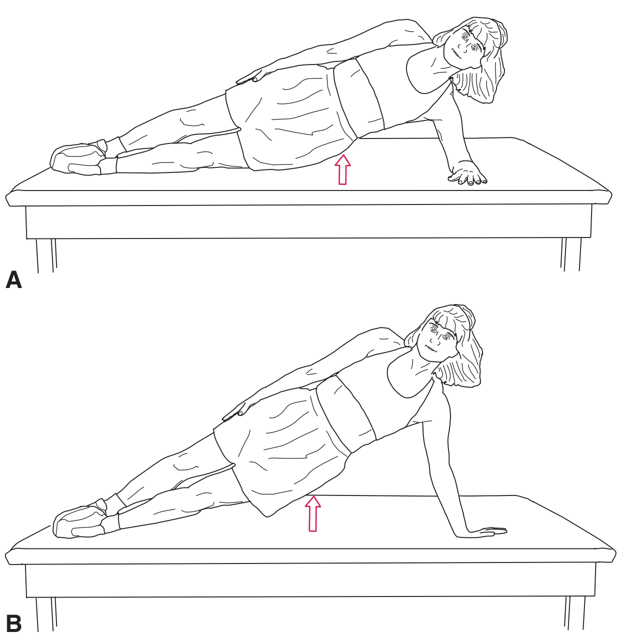

FIGURE 16.57 Quadratus lumborum stabilization training using side-propping (side plank) **(A)** on the elbow and knee and **(B)** on the hand and foot.

supporting the lower body with the lateral side of the knee on the downward side. The position can be maintained for an isometric hold or performed intermittently (Fig. 16.57 A). Progress by having the patient support the upper body with the hand (with the elbow extended) and lateral aspect of the foot on the downward side (Fig. 16.57 B). Arm and leg movements (without then with weights) are added to increase the challenge.

FOCUS ON EVIDENCE

Using ultrasound imaging, Teyhen and associates[61] demonstrated that the side support (side propping) exercise resulted in the greatest change in muscle thickness of the TrA and IO muscles with the least amount of lumbar loading compared to five other trunk exercises (abdominal crunch, drawing-in maneuver, quadruped opposite UE and LE lift, supine LE extender, and abdominal sit back).

Progression to Dynamic Exercises

When the patient has developed control, endurance, and strength in the stabilizing muscles in weight-bearing and nonweight-bearing positions, dynamic trunk strengthening exercises are initiated at a low-intensity (see following section). The emphasis is on control and safety.

As the patient returns to his or her instrumental activities of daily living (IADLs) and limited work activities, instruct him or her to incorporate the deep segmental activation and global stabilization techniques into the activities.

Isometric and Dynamic Exercises

Isometric exercises may be considered stabilizing exercises, as there is little or no movement of the spinal segments. They are included in this section with dynamic exercises, however, because of the method of application of the resistive force; that is, the resistive force is applied directly to the axial skeleton rather than through limb loading, as described in the spinal stabilization section. The decision to use the isometric exercises described in this section must be based on the goals of intervention. The exercises may be combined with the stabilization exercises in a home exercise program.

Dynamic exercises with spinal movement are introduced into the patient's exercise program when the patient demonstrates effective segmental and global stabilization techniques and has developed endurance in the stabilizing musculature. Dynamic exercises should not be a substitute for stabilization exercises. Because of the load imposed on the spine, they may exacerbate the patient's symptoms if introduced prior to effective stabilization and control. They are important in the total rehabilitation of the individual with neck, thoracic, or

low back pain, as dynamic muscle endurance and strength is required for many daily activities as well as manual labor and athletic performance.

Exercises for the Cervical Region

PRECAUTION: Use of external weights via a cable or pulley system applied directly to the head are contraindicated for cervical strength training due to the compressive loading on the spine and the potential loss of control during the exercise.

Isometric Exercises: Self-Resistance

The intensity of the isometric exercises can range from low to high, depending on the patient's symptoms and tolerance. *Patient position and procedure:* Sitting.

- *Flexion.* Have the patient place both hands on the forehead and press the forehead into the palms in a nodding fashion while not moving (Fig. 16.58 A).

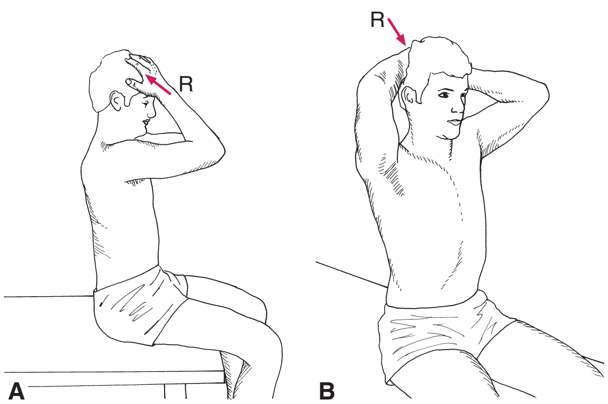

FIGURE 16.58 Self-resistance for isometric **(A)** cervical flexion and **(B)** axial extension.

- *Side bending.* Have the patient press one hand against the side of the head and attempt to side bend, as if trying to bring the ear toward the shoulder but not allowing motion.
- *Axial extension.* Have the patient press the back of the head into both hands, which are placed in the back, near the top of the head.
- *Rotation.* Have the patient press one hand against the region just superior and lateral to the eye and attempt to turn the head to look over the shoulder without allowing motion.

Isometric Resistance Activities

Patient position and procedure: Standing with a basketball-sized inflatable ball between the forehead and a wall. Have the patient keep the chin tucked and not go into a forward-head posture. The patient maintains the functional position while superimposing arm motions. Progress by adding weights to the arm motions. (See Fig. 16.46 C)

Dynamic Cervical Flexion

CLINICAL TIP

Often with faulty forward-head postures, the patient substitutes using the sternocleidomastoid (SCM) muscles to lift the head when getting up from the supine position rather than the overstretched, weak, deep cervical flexors. To correct this muscle imbalance, begin training capital flexion as described in the stabilization section (deep segmental muscle activation). For home exercise and when rising from a bed, emphasize "curling" the head and neck, not lifting the head up.

Patient position and procedure: Supine. If the patient cannot tuck the chin and curl the neck to lift the head off the mat, begin with the patient on a slant board or large wedge-shaped bolster under the thorax and head to reduce the effects of gravity (Fig. 16.59). Have the patient practice tucking the chin and curling the head up. Use assistance until the correct pattern is learned. Progress by decreasing the angle of the board or wedge and then adding manual resistance if the patient does not substitute with the SCM.

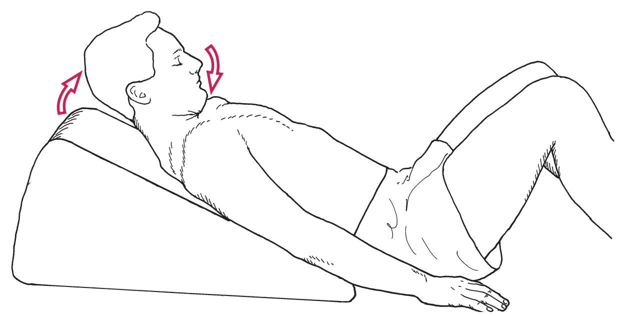

FIGURE 16.59 Training the short cervical flexors while de-emphasizing the sternocleidomastoid for cervical flexion to regain a balance in strength for anterior cervical stabilization.

Manual Resistance: Cervical Muscles

Patient position and procedures: Supine. Stand at the head end of the treatment table, supporting the patient's head for each exercise.

- Place one hand on the patient's head to resist opposite the motion. Do not resist against the mandible lest force be transmitted to the temporomandibular joint. Resistance is given to isolated muscle actions or to general ROMs, whichever best gains muscle balance and function.
- Isometric resistance can be applied with the head in any desired position before applying resistance. Avoid jerking the neck when applying or releasing the resistance by gradually building up the intensity, telling the patient to match your resistance, holding, and then gradually releasing and asking the patient to relax.

Intermediate and Advanced Training

As the patient progresses in the rehabilitation program, greater challenges to the musculature to stabilize and control motion are emphasized, especially for those individuals returning to work, sports, or recreational activities that place greater demands on the cervical structures.

Transitional Stabilization for the Cervical and Upper Thoracic Regions

- *Patient position and procedure:* Standing with a basketball-sized inflatable ball between the head and the wall. Have the patient roll the ball along the wall, using the head. This requires the patient to turn the body as he or she walks along.
- *Patient position and procedure:* Sitting on a large gym ball. Have the patient walk the feet forward so the ball rolls up the back and the thorax is resting on the ball (Fig. 16.60 A and B). The head and neck are maintained in neutral position, and the cervical flexors are emphasized. Have the patient then walk the ball farther, so it is under the head. The extensors are now emphasized (Fig. 16.60 C). The patient walks the feet forward and backward, alternating stabilization between the flexors and extensors. Progress to advanced training by adding arm motions and then arm motions with weights in each of the positions.

NOTE: This activity requires considerable strength in the cervical extensors to support the body weight and should be performed only with advanced training with patients who have been properly progressed to tolerate the resistance.

Functional Exercises

Design exercises that simulate patient-specific functional activities. Identify what activities stress that individual's neck and have the patient practice modifications of those activities with the spine kept in neutral position. Include pushing, pulling, reaching, and lifting (see the 'Functional Training' section later in this chapter). Challenge the patient with increased repetitions and weight and by using patterns that replicate functional demands.

Exercises for the Thoracic and Lumbar Regions

Alternating Isometric Contractions and Rhythmic Stabilization VIDEO 16.23

Patient positions and procedures: Begin with the patient supine in the most stable position (Fig. 16.61). Progress to sitting on a stable surface, sitting on an unstable surface such as a large gym ball, kneeling, and then standing. Sitting, kneeling, and standing require stabilizing action in the hip, knee, and ankle musculature, respectively, as well as the spinal muscles. Apply resistance directly against the patient's shoulders or pelvis, against a rod that is held by the patient (as in Fig. 16.61), or against the patient's outstretched arms.

- Have the patient find the neutral spine position and then activate the stabilizing muscles with the drawing-in maneuver prior to applying the resistive force. Then instruct the patient to "meet my resistance" while applying a force to stimulate isometric contractions. Apply the resistance in alternating directions at a controlled speed while the patient learns to maintain a steady position.
- Initially, provide verbal cues, such as "hold against my resistance, but do not overpower me. Feel your abdominal muscles contracting. Now, I'm pulling in the opposite direction. Match the resistance and feel your back muscles contracting."
- Progress by shifting the directions of resistance without the verbal cues and then by increasing the speed and force.
- Begin with alternating resistance in the sagittal plane; progress to side-to-side and then transverse plane resistance. Isometric resistance to trunk rotation (transverse plane resistance) has been shown to be the most effective

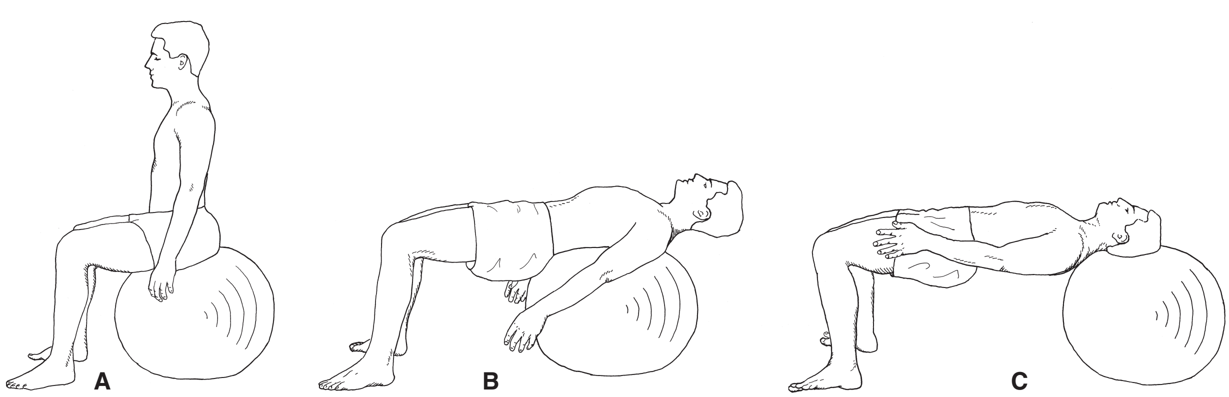

FIGURE 16.60 Advanced exercises for strengthening the cervical and upper thoracic flexors and extensors as stabilizers. Begin by **(A)** sitting on a large gym ball, then **(B)** walking forward while rolling the ball up the back. With the ball behind the mid-thoracic area, the cervical flexors must stabilize. Continue walking forward until the ball is **(C)** under the head; the cervical extensors now must stabilize. Walk back and forth between the two positions (B and C) to alternate control between the flexors and extensors. Progress by adding arm motions or arm motions with weights to increase resistance.

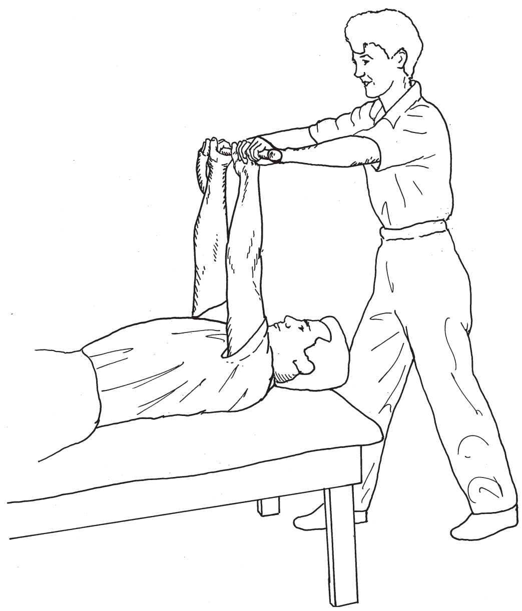

FIGURE 16.61 Alternating isometric resistance applied in the sagittal, frontal, and horizontal planes with the patient supine to stimulate the stabilizing function of the trunk musculature.

in stimulating the oblique abdominals, transversus abdominis, and deep spinal extensor muscles.[50]

- Alternating resistance to pelvic rotation can also be done by having the patient assume a modified bridge position. Apply resistance directly to the pelvis to stimulate rotation while the patient isometrically holds the pelvis and spine in a stable position.

Dynamic Strengthening: Abdominal Muscles

NOTE: Dynamic exercises of the trunk musculature are not initiated until late during the rehabilitation process and not until after the patient has learned to activate the drawing-in maneuver automatically for stabilization in all functional activities.

No one abdominal exercise challenges all of the abdominal muscles[39]; therefore, a variety of exercises should be included in the patient's exercise program to include the entire region.

FOCUS ON EVIDENCE

EMG studies have looked at abdominal muscle recruitment with various abdominal exercises.[4,34,39,64] In summary:

- Curl-ups (various types) recruit primarily the rectus abdominis, with low activity in the obliques, transversus abdominis, and psoas.
- Sit-ups (straight-leg and bent-knee) show high rectus and external oblique activity, high psoas activity, and high low-back compression. Heel press sit-ups increase psoas activity.
- Hanging-leg raises show high external oblique and high spinal compression.
- Supine single-leg lifts show negligible global abdominal muscle activity (opposite lower extremity provides stability). Primarily, these exercises are used early in the stabilization exercise routines to train the deep stabilizing muscles under progressive extremity loading.
- Supine-bilateral leg lifts show increased activity in the RA, EO, and IO during the first part of the range of hip flexion and increased load on the spine.
- Curl-ups on a labile surface doubled the activity of the rectus abdominis and increased the activity of the external obliques fourfold compared with curl-ups on a stable surface.[64]

Rectus abdominis. There is no clinically significant selective difference between the upper and lower rectus abdominis function.[34] Both portions contract strongly in all trunk curl-type and leg lift exercises.[34,39]

External obliques. External obliques contract strongest in sit-ups and diagonal sit-ups to the opposite side.[37]

Internal obliques. Internal obliques contract strongest in diagonal sit-ups to the same side and horizontal side propping (see Fig. 16.57).[39]

Transversus Abdominis. Use of the drawing-in maneuver prior to the abdominal crunch, abdominal sit-back, and lateral side propping activates increased muscle thickness in the transversus abdominis (demonstrated with ultrasound imaging).[61]

Trunk Flexion (Abdominals): Supine

Patient position and procedures: Supine or hook-lying with the lumbar spine neutral. McGill[39] suggested supporting the low back with the hands to maintain slight lordosis. The spine should not be allowed to go into an increased lordosis during the exercise—this indicates weakness of the abdominals and consequently lifting of the trunk occurs from hip flexor action only.[32] When training the abdominals, curl-up exercises should be performed at a slow, controlled rate to activate the stabilizing function of the abdominals.[65]

PRECAUTIONS: If a patient experiences pain or increased radicular symptoms with trunk flexion, these exercises should not be done. Use the stabilization exercises, as described in the previous section, with the spine maintained in a neutral position (slight lordosis).

Curl-ups. First, instruct the patient to perform the drawing-in maneuver to cause a stabilizing contraction of the abdominal muscles[61] (see section on 'Stabilization Training: Core Muscle Activation') and then lift the head. Progress by lifting the shoulders until the scapulae and thorax clear the mat, keeping the arms horizontal (Fig. 16.62). A full sit-up is not necessary, because once the thorax clears the mat, the rest of the motion is performed by the hip flexor muscles.

- Further progress the difficulty of the curl-up by having the patient change the arm position from horizontal to folded across the chest and then to behind the head; then by holding a weight or medicine ball. The weight is held with the shoulders at 90° flexion

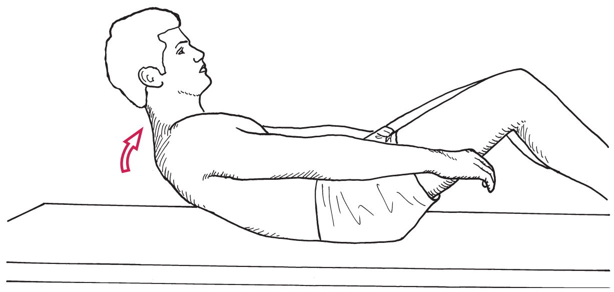

FIGURE 16.62 The curl-up exercise to strengthen the abdominal muscles. The thorax is flexed on the lumbar spine. The arms are shown in the position of least resistance. Progress by crossing the arms across the chest and then behind the head.

Curl-downs. If the patient is unable to perform the curl-up, begin with curl-downs by having the patient start in the hook-sitting or long-sitting position and lower the trunk only to the point at which he or she can maintain a flat low back and then return to the sitting position.

- Once the patient can curl-down full range, reverse and perform a curl-up.

Diagonal curl-ups. Have the patient reach one hand toward the outside of the opposite knee while curling up; then alternate. Reverse the muscle action by bringing one knee up toward the opposite shoulder; then repeat with the other knee. Diagonal exercises emphasize the oblique muscles.

Curl-ups on an unstable surface. Progress the above curl-up exercises on an unstable surface, such as a large gym ball (Fig. 16.63), foam roller, or a biomechanical ankle platform system (BAPS) board.

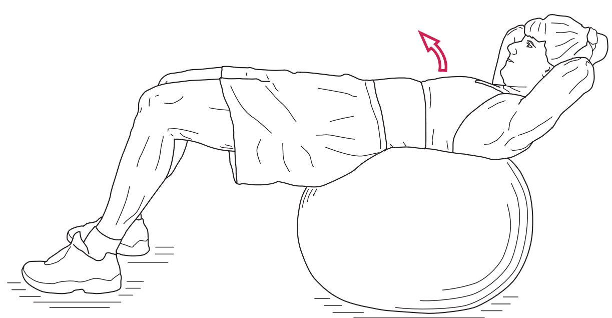

FIGURE 16.63 Curl-ups on an unstable surface. The unstable surface increases activity in the oblique and rectus abdominis muscles.

FOCUS ON EVIDENCE

Patients with chronic, unilateral low back pain have been shown to have impaired balance.[2] Using unstable surfaces, such as a gym ball (Fig. 16.63) or a balance board, while doing abdominal curl-up exercises has been shown to increase activity in the internal and external obliques and the rectus abdominis.[64] The presumption is that these muscles generate increased activity to maintain balance on the unstable surfaces.

Double knee-to-chest. To emphasize the lower rectus abdominis and oblique muscles, have the patient set a posterior pelvic tilt, bring both knees to the chest, and return. Progress the difficulty by decreasing the angle of hip and knee flexion (Fig. 16.64).

Pelvic lifts. Have the patient begin with the hips at 90° and the knees extended; then lift the buttocks upward off the mat (small motion). The feet move upward toward the ceiling (Fig. 16.65). The patient should not push against the mat with the hands.

Bilateral straight-leg raising. Have the patient begin with legs extended; then perform a posterior pelvic tilt followed by flexing both hips, keeping the knees extended. If the pelvis and spine cannot be kept stable, the knees should be flexed to a degree that allows control. If the hips are abducted before

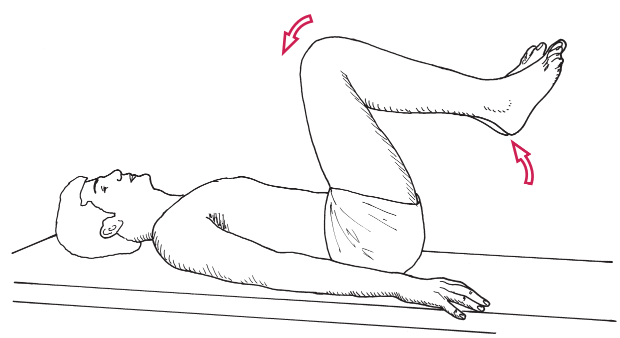

FIGURE 16.64 Strengthening the abdominal muscles by flexing the hip and pelvis on the lumbar spine. The legs are shown in the position for least resistance. Progress by decreasing the angle of hip flexion until the legs can be lifted with the knees extended, as in the pelvic lift.

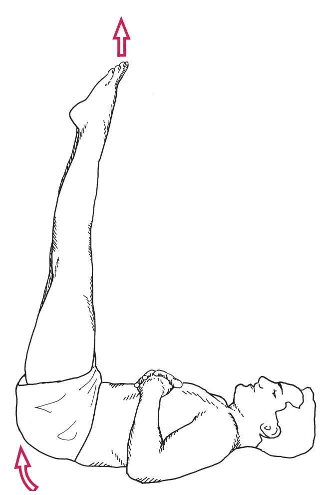

FIGURE 16.65 Pelvic lifts. Elevating the legs upward toward the ceiling by raising the buttocks off the floor emphasizes strengthening the lower abdominal muscles.

initiating this exercise, greater challenge is placed on the oblique abdominal muscles.

Bilateral straight-leg lowering. Bilateral straight-leg lowering can be performed if the bilateral SLR is difficult. Have the patient begin with the hips at 90° and knees extended; then, lower the extremities as far as possible while maintaining stability in the lumbar spine (should not increase the lordosis), followed by raising the legs back to 90°. See 'Precaution' under the bilateral SLR exercise.

PRECAUTIONS:

- The strong pull of the psoas major causes shear forces on the lumbar vertebrae. Also, the bilateral straight-leg raising and lowering exercises cause increased spinal compression loads.
- If there is any low-back pain or discomfort, especially with spinal hypermobility or instability, the bilateral straight-leg raising and lowering exercises should not be performed even if the abdominals are strong enough to maintain a posterior pelvic tilt.
- Be sure the patients avoid holding their breath (valsalva maneuver) as they may try to use their diaphragm to provide the stabilization.

Trunk Flexion (Abdominals): Sitting or Standing

Patient position and procedures: Sitting or standing. Pulleys or elastic material are secured at shoulder level behind the patient. Progress the resistance as the patient's abdominal strength increases.

- Have the patient hold the handles or ends of the elastic material with each hand and then flex the trunk, with emphasis on bringing the rib cage down toward the pubic bone and performing a posterior pelvic tilt (Fig. 16.66).
- Have the patient perform diagonal motions by bringing one arm down toward the opposite knee with emphasis on moving the rib cage down toward the opposite side of the pelvis. Repeat the diagonal motion in the opposite direction.

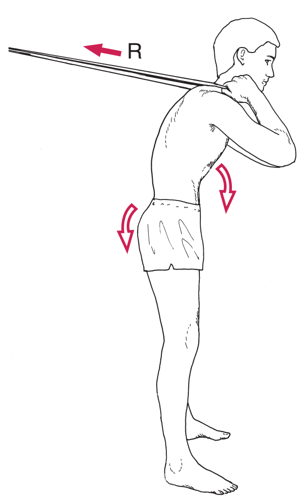

FIGURE 16.66 Standing trunk flexion against elastic material to strengthen the abdominal muscles. The patient performs a posterior pelvic tilt and then approximates the ribs toward the pubis.

Dynamic Strengthening: Erector Spinae and Multifidus Muscles

FOCUS ON EVIDENCE

Strengthening the extensor muscles and an improved extensor/flexor ratio of the trunk muscles have been found to be important in decreasing symptoms in patients with chronic low back pain (LBP).[58] Lee and associates[33] determined that the trunk extensor/flexor ratio is a sensitive parameter for predicting LBP. After following 67 asymptomatic individuals for 5 years, they found an increased incidence of LBP in those who had lower extensor strength than flexor muscle strength. Danneels and colleagues[13] demonstrated that intensive lumbar resistance training (isometric or dynamic) is necessary to develop paravertebral muscle strength and bulk. The following is a summary of specific exercise outcomes studies.

- Dynamic prone extension (prone arch), isometric trunk extension, and isometric leg extensions: high activity in both the multifidus and erector spinae[42]; stronger contractions when both lower extremities stabilized during trunk extension.[14]
- Quadruped and prone upper and lower extremity lifts: stronger contractions than bridging (including bridging with feet on gymnastic ball or shoulders on gymnastic ball).[14]
- Isolated training of multifidus: requires a low-intensity focus, as described in the stabilization section.[47]

Extension Exercises in Prone or Quadruped Position

Resistance can be applied to any of the following recumbent exercises by having the patient hold weights in the hands or by strapping weights around the patient's legs.

PRECAUTIONS: Extension exercises in the prone position are performed at the end of the ROM in spinal extension and therefore may not be appropriate for individuals with symptoms from conditions such as arthritis, spondylolisthesis, or nerve root compression. Patients with spondylosis or other flexion bias conditions or patients who develop symptoms under loaded conditions (e.g., with disc lesions) may experience increased symptoms and therefore should not do dynamic end-range extension exercises. If symptoms occur, modify the positioning toward more neutral spinal positions, such as the quadruped position, and emphasize stabilization with isometric holds rather than moving into full extension (see Figs. 16.49 A through D, 16.50, and 16.54).

Thoracic elevation. Begin with the arms at the sides, progress to behind the head or reaching overhead as strength improves. Have the patient tuck in the chin and lift the head and thorax. The lower extremities must be stabilized (Fig. 16.67).

Leg lifts. Initially, have the patient lift only one leg, alternate with the other leg, and, finally, lift both legs and extend

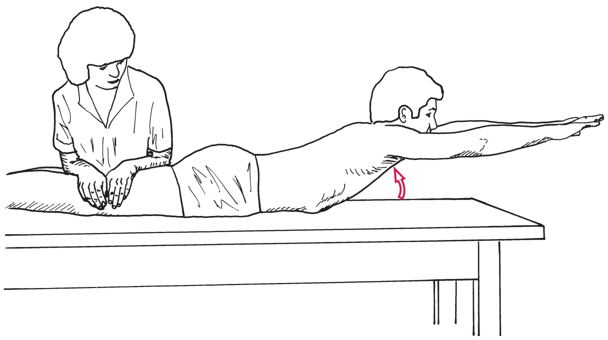

FIGURE 16.67 Strengthening the back extensors with the arms in position to provide maximal resistance. Additional resistance can be provided by holding weights in the hands.

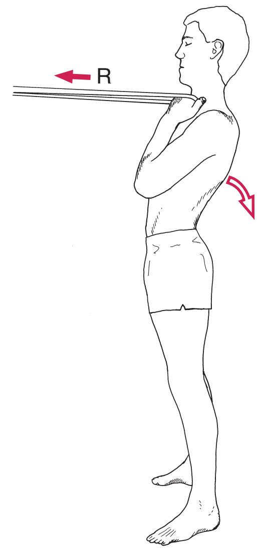

FIGURE 16.69 Using elastic resistance for concentric eccentric back extension.

the spine. (See Fig 16.28 E through G.) Stabilize the thorax by having the patient hold onto the side of the treatment table.

"Superman." Progress the extension exercises by having the patient lift both upper and lower extremities simultaneously (Fig. 16.68).

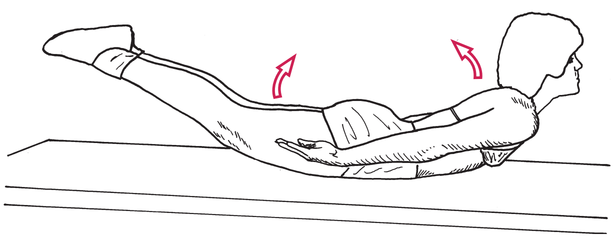

FIGURE 16.68 Strengthen the trunk and hip extensors by lifting the trunk and legs off the mat simultaneously. Greater resistance can be provided by abducting the shoulders to 90° or by elevating them to 180° ("Superman").

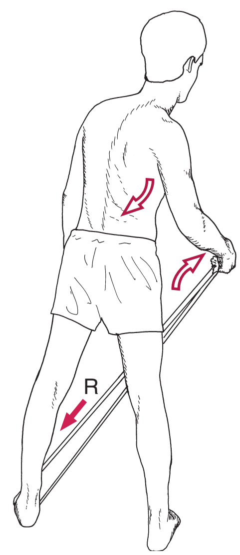

FIGURE 16.70 Rotation with extension strengthens the back extensors in functional patterns.

Variations. Patient positioned prone on a large gym ball; combine spinal extension with UE and/or LE resistance, similar to exercises described in the stabilization exercise section (see Fig. 16.46 B).

Extension Exercises Sitting or Standing

Elastic resistance or weighted pulleys. Secure pulleys or elastic resistance in front of the patient at shoulder level. Have the patient hold onto the ends of the material or handles and extend the spine (Fig. 16.69).

For trunk rotation, use a pulley or elastic resistance secured under the foot or to a stable object opposite the side being exercised. Have the patient pull against the resistance, extending and rotating the back. Change the angle of pull of the resistance to recreate functional patterns specific to the patient's needs (Fig. 16.70).

Trunk Side Bending (Lateral Abdominals, Erector Spinae, Quadratus Lumborum)

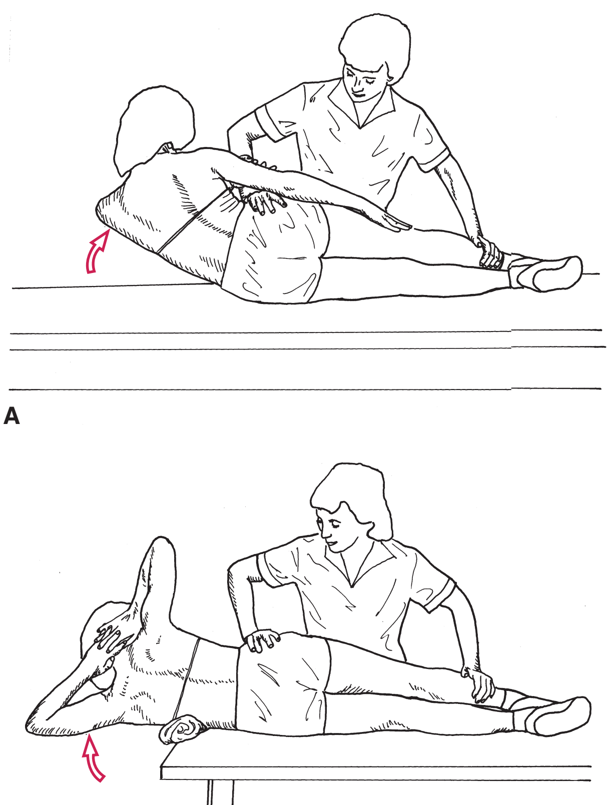
Trunk side-bending exercises are used for general strengthening of the muscles that side bend the trunk.

FOCUS ON EVIDENCE

McGill[39] identified the quadratus lumborum as one of the most important stabilizers of the spine and documented the isometric horizontal side support as an effective exercise to strengthen this muscle (see discussion in the 'Stabilization' section and Fig. 16.57).

Side-bending exercises are also used if there is scoliosis, although exercise alone has not been shown to halt or change the progression of a structural scoliosis curve. Exercise in conjunction with other methods of correction, such as bracing, is often employed.[8] When there is a lateral curve, the muscles on the convex side are usually stretched and weakened. The following exercises are described for use as strengthening exercises on the side of the convexity, although they may be used bilaterally for symmetrical strengthening. Stabilization exercises for spinal control, as previously described, may be beneficial for strengthening and conditioning when there is scoliosis.

- *Patient position and procedure:* Standing. Place elastic resistance under the foot or have the patient hold a weight in the hand on the side of the concavity; then have him or her side bend the trunk in the opposite direction.
- *Patient position and procedure:* Side-lying on the concave side of the curve with the apex at the edge of the table or mat so the thorax is lowered. If you have access to a split table with one end that can be lowered, begin with the apex of the curve at the bend of the table. Have the patient place the lower arm folded across the chest and upper arm along the side of the body and side bend the trunk up against gravity. Progress by having the patient clasp both hands behind the head (Fig. 16.71). Stabilization of the pelvis and lower extremities must be provided.



A

B

FIGURE 16.71 Antigravity strengthening of the lateral trunk musculature. **(A)** There is less resistance if the top arm is at the side and the bottom arm is folded across the chest. **(B)** Increase resistance by positioning the arms behind the head.

Cardiopulmonary Endurance

Goal. To develop cardiopulmonary fitness for overall endurance and well-being.

Aerobic conditioning exercises provide many benefits for the patient with spinal symptoms. The activity not only improves cardiopulmonary endurance but stimulates feelings of well-being and relief of symptoms. Chapter 7 describes cardiopulmonary conditioning principles and procedures. Specific precautions and suggestions for medical conditions are also explained. For patients recovering from spinal injuries, surgery, or postural dysfunction, aerobic exercises may be initiated once signs of inflammation no longer exist. Begin with low to moderate intensity and work with the patient to choose activities that do not place added stress on the recovering spinal structures. If a particular spinal bias has been identified (see Chapter 15), choose aerobic exercises that emphasize that spinal bias. A brief summary of the principles is reviewed in Box 16.6. Guidelines for safe application of common conditioning exercises when there are spinal impairments are described in this section.

BOX 16.6 Summary of Aerobic Conditioning Principles

1. Establish the target heart rate and maximum heart rate.
   - The maximum heart rate is generally 220 minus the individual's age or may be the symptom-limiting heart rate (the rate at which cardiovascular symptoms appear).
   - Target heart rate is between 60% and 80% of the maximum heart rate.
2. Perform warm-up exercises for 10 to 15 minutes, including active movements of the neck and trunk.
3. Individualize the program of exercise.
   - Select activities that emphasize the patient's spinal bias if necessary (see information in the text).
   - Not all people are at the same fitness level and therefore cannot perform the same exercises. Any one exercise has the potential to be detrimental if attempted by someone not able to execute it properly.
   - To avoid overuse syndromes to structures of the musculoskeletal system, appropriate equipment, such as correct footwear, should be used for biomechanical support with weight-bearing exercises.
4. Increase the pace of the activity to reach the target heart rate and maintain it for 20 to 30 minutes.
5. Cool-down for 5 to 10 minutes with slow, total body, repetitive motions and stretching activities.
6. Frequency of aerobic exercise should be three to five times per week.
7. Always stay within the tolerance of the individual. Overuse commonly occurs when there is an increase in time or effort without adequate rest (recovery) time between sessions. Increase repetitions or time by no more than 10% per week.[35] If pain begins while exercising, heed the warning and reduce the stress.

Common Aerobic Exercises and Effects on the Spine

Some aerobic exercises place the spine in end-range positions. They are reviewed so the reader understands why some activities may be inappropriate for patients with specific conditions. If modifications are possible, they should be considered.

Cycling

Road bikes place the thoracolumbar spine in flexion and the upper cervical spine in hyperextension. Use this exercise for patients who have a flexion bias in the lumbar region so long as there are no upper cervical symptoms. Modifications include using a bike that positions the body in a more upright posture, such as a mountain bike or hybrid bike. Many stationary bikes also position the individual in upright postures and therefore are less likely to precipitate cervical problems.

Walking and Running

The upright posture emphasizes normal spinal curves, and lumbar extension is emphasized with walking and running (terminal stance). Emphasize the importance of identifying the neutral spine, activating the drawing-in maneuver, and stabilizing the spine while walking or running. Because conscious control is not possible during the entire exercise time, coach the patient to check his or her posture and muscle control frequently, such as each time he or she crosses an intersection or passes another individual or if symptoms develop in the spinal region. Walking or running with the cervical spine in retraction (axial extension) and the scapulae comfortably adducted, along with a rhythmic arm swing, reinforces cervical stabilization. Easy access to treadmills, tracks, or roads and trails makes these activities popular. Running is a high-impact activity and may not be tolerated by individuals with intervertebral disc lesions or degenerative joint conditions.

Stair Climbing

Commercial devices that replicate stepping with various grades of resistance are used for strengthening and aerobic conditioning. Regular steps can also be used for aerobic conditioning. This activity requires pelvic control of the reciprocating lower extremities, because lifting the leg on one side emphasizes spinal flexion while the contralateral lower extremity and spine are extending. Coach the patient to maintain the neutral spine with the stabilizing muscles against the rotational forces.

Cross-Country Skiing and Ski Machines

Cross-country skiing, whether out in the cold or on a commercial machine, is a high-intensity aerobic activity. The kicking motion that accompanies the backward motion of the leg emphasizes spinal extension. It is important to coach the patient to maintain the neutral spine and contract the stabilizing abdominal muscles.

Swimming

Breast stroke. The breaststroke emphasizes extension in the cervical and lumbar spinal regions when taking a breath. Coach the patient not to extend the neck full range but to keep it neutral and lift the head out of the water as a "solid" unit with the thorax just enough to clear the mouth for breath.

Freestyle. The freestyle stroke may exacerbate cervical problems because of the repetitive cervical rotation while taking a breath; this stroke also emphasizes lumbar extension with the flutter kick. Teach the patient to breathe using a "log-roll" technique in which the whole body rolls toward one side while breathing and then rolls back to the face-down position for the stroke. This requires good spinal stabilization.

Backstroke. The backstroke emphasizes spinal extension via kicking the lower extremities and the arm motions.

Butterfly stroke. The butterfly stroke moves the spine through a full ROM; emphasis is placed on controlling the range with the stabilizing muscles.

Upper Body Ergometers

Ergometry machines provide upper extremity resistance and can also be used for aerobic training. Forward motions emphasize spinal flexion and shoulder girdle protraction; backward motions emphasize spinal extension and shoulder girdle retraction. Coach the patient to assume the neutral spinal posture and use the stabilizing muscles prior to and during the use of the ergometer to enhance postural responses. If the machine can be used standing, progression to the standing position stimulates a total body response.

Step Aerobics and Aerobic Dancing

Stepping is similar to using stairs or a stair machine except for the jumping and bouncing that is usually added to the more advanced step aerobics programs.

Dancing moves take on many forms, and classes are taught that address various fitness levels and age groups. If possible, review safe movement patterns and help the patient recognize the safe limits of his or her spinal range and abilities.

"Latest Popular Craze"

People like variety and may be attracted to charismatic and energetic figures who demonstrate "new" workout techniques and routines or new exercise machines. Patients may ask for advice as to the value of the activities and techniques. Knowledge and skill in analyzing the biomechanics of the activity and the forces that are imposed through the spine should be used to provide advice about exercise safety. End-of-range

postures and high-velocity stresses (such as vigorous kicking and ballistic motions) may be damaging to vulnerable tissues in the spine and should not be attempted by patients recovering from spinal problems.

Functional Activities

Goal. To progress to independence safely.

NOTE: Achieving the maximum level of independence underlies all the goals of therapeutic exercise. The patient develops segmental and global spinal stability; develops flexibility, muscle endurance, and strength; learns how exercise and posture correction relieve stress; and develops cardiopulmonary endurance—all to be able to function safely in daily activities, including work, recreation, and athletic pursuits.

Early Functional Training: Fundamental Techniques

Early functional training consists of teaching basic maneuvers needed for ADL, such as safely rolling over, moving from lying down to sitting (and reverse), and going from sitting to standing (and reverse). These techniques follow the early kinesthetic training instruction in which the patient learns to find his or her neutral spine and experiences the effect that simple arm and leg motions have on the spine, as well as early muscle performance training in which the patient learns how to activate the core musculature for segmental stabilization. If the examination reveals problems with basic ADL activities, the following are included in the early training program.

Rolling. Rolling with a neutral spine requires that the patient first find the neutral spine, perform the drawing-in maneuver, and then roll the trunk as a unit.

- It may be helpful to suggest that the patient "imagine a solid rod connecting the shoulders and pelvis so as not to twist" or suggest that he or she "roll like a log."
- Encourage the patient to use the arms and top leg to assist the roll.

Supine to sit/sit to lying down. Have the patient use the log roll maneuver (as described above) to roll from supine to side-lying while simultaneously flexing the hips and knees and pushing up with the arms.

- Help the patient focus on stabilizing the trunk with commands such as "push up your trunk as if it is a board; do not allow it to twist or bend."
- The reverse is practiced by coaching the patient to lower to the side-lying position as a unit first onto the elbow and then shoulder. Once down, the patient can roll to supine or prone-lying using the log-roll technique.

Sit to stand/stand to sit. The patient's level of function dictates how much assistance from the upper extremities is needed to accomplish "sit to stand" or "stand to sit." If the hip and knee extensors are not strong enough to elevate the body, the patient requires a chair with armrests, so there is some leverage for pushing up; alternatively, a firm seat or elevated seat may be necessary.

- To use the stable spine technique, instruct the patient to find the neutral spine by rolling the pelvis forward and backward, activate the drawing-in maneuver, and then bend forward at the hips while maintaining the neutral spine position.
- Help the patient focus on the hip motion while keeping the spine "solid like a board." The reverse is also practiced.

In and out of a car. Getting in and out of a car is often symptom-provoking for patients with low back or sacroiliac joint pain. Once sit-to-stand can be safely performed, have the patient practice the following.

- Approach the open car door and seat with the back toward the seat; stabilize the spine in its neutral position with the drawing-in maneuver; then bend at the hips and sit down.
- Once seated, flex both hips and knees and pivot the whole body around as a unit, maintaining a stable spine.
- When exiting a car, keep both knees together and pivot the legs and trunk outward as a unit. Once the feet are on the ground, bend at the hips and elevate the trunk as a unit.

Walking. For some patients, walking may provoke symptoms.

- Remind the patient to use the neutral spine and drawing-in maneuvers to stabilize the spine while walking.
- It is not possible to maintain conscious control for long, so remind the patient to check the spinal posture and reactivate the drawing-in maneuver whenever the symptoms recur.

Preparation for Functional Activities: Basic Exercise Techniques

Once the patient has learned to manage his or her symptoms and the symptoms of inflammation diminish, exercises are initiated that prepare the extremities and trunk for functional activities, such as safely lifting, carrying, pushing, pulling, and reaching in various directions. In the subacute or controlled motion phase of rehabilitation, emphasis is placed on strengthening the extremities in functional patterns while maintaining a stable spine. The patient should be able to perform IADLs and limited work activities at this stage. Evaluate the patient's performance and modify what he or she is doing to include safe spinal postures and correct stabilization. Use the activities in this section to prepare for or advance the patient's function.

Many of the strengthening exercises described in the extremity chapters are appropriate to use in preparation for functional training. With postural problems and recovery from back or neck injuries, it is critical to emphasize the neutral (functional) spinal posture before and during total

body exercises. Many of the stabilization and movement patterns described earlier in this chapter can also be progressed in intensity, repetition, speed, and coordination to prepare for return to functional activities.

Weight-Bearing Exercises

Modified Bridging Exercises

Modified bridging exercises require stabilization with the trunk flexor and extensor muscles in conjunction with strengthening the gluteus maximus and quadriceps muscles in preparation for lifting activities. The abdominals function with the gluteus maximus to control the pelvic tilt, and the lumbar extensors stabilize the spine against the pull of the gluteus maximus.

Patient position and procedures: Begin with the patient hook-lying. Have the patient concentrate on maintaining the neutral spinal position while raising and lowering the pelvis (flexing and extending at the hips) (see Fig. 20.28). Hold the bridge for isometric control.

- Alternate arm motions; progress by adding weights to the hands.
- Alternate lifting one foot and then the other by marching in place (Fig. 16.72 A); progress by extending the knee as each leg is lifted. When the patient tolerates greater resistance, add ankle weights and coordinate with arm motions (Fig. 16.72 B).
- Abduct and adduct the thighs without letting the pelvis sag. Progress by placing the feet on a stool, chair, or large gym ball and repeating the bridging activities, or by placing the large gym ball under the shoulder/neck region with feet on the floor.

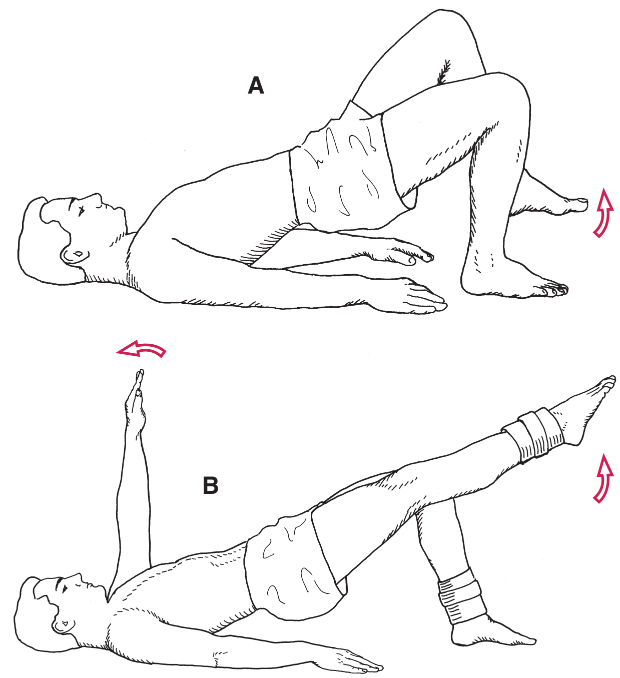


FIGURE 16.72 Holding a bridge to develop trunk control and gluteus maximus strength while superimposing extremity motions by **(A)** marching in place and **(B)** extending the extremities. Adding weights to the arms or legs requires greater strength and control.

Push-Ups with Trunk Stabilization

Push-ups use the body weight to strengthen the triceps and shoulder girdle musculature in preparation for pushing activities. The trunk musculature must stabilize against the pull of the shoulder girdle musculature as well as control the neutral spinal position as the body is raised and lowered.

Patient positions and procedures: Standing facing a wall or prone-lying with hands placed against the wall or floor in front of the shoulders. Remind the patient to find and maintain the neutral spinal position while performing the exercise.

- These exercises may begin as wall push-ups if the patient is not strong enough to push up from the floor.
- Prone-lying on the floor, the patient may push up with the pivot point being the knees or may perform full body push-ups with the pivot point being the feet.
- To challenge the patient on an unstable surface, he or she begins prone on a large gym ball. Have the patient walk forward with the hands on the floor until just the thighs are supported by the ball, maintain a stable spinal posture, and perform push-ups with the arms. To progress, walk out farther with the hands until just the legs are supported by the ball (Fig. 16.73).

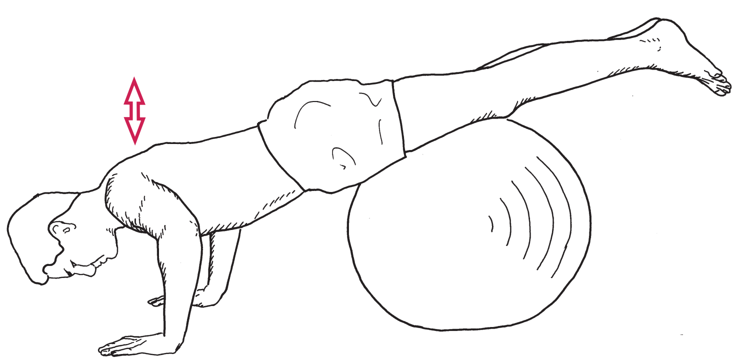

FIGURE 16.73 Push-up activities with the lower extremities balanced on a gym ball for strengthening the arms and developing trunk control.

Wall Slides

Wall slides develop strength in the hip and knee extensor muscles to prepare the lower extremities for squatting activities and training in safe body mechanics.

Patient position and procedure: Standing with the back to a wall and the spine held in its neutral position. Place a towel behind the back, so it slides easier along the wall. The exercise is more challenging if a large gym ball is placed between the back and the wall (Fig. 16.74). Have the patient slide his or her back down the wall into a partial squat and hold the position for isometric strengthening of the hip and knee extensors or move up and down for concentric/eccentric strengthening.

- Superimpose arm motions such as alternating or bilateral shoulder flexion/extension.
- Progress strengthening by incorporating single leg movements with marching steps or alternate knee extension.
- Use handheld weights to add resistance for upper and lower extremity strengthening.

Partial Lunges, Partial Squats, and Steps

Partial lunges and squats are described in Chapters 20 and 21. They are beneficial for strengthening total body movement in preparation for learning body mechanics. If necessary, begin by having the patient balance by holding onto the side of a treatment table or other stable object and then progress to balancing with a cane (see Fig. 20.32). Once able to perform multiple repetitions without holding on, add weights to the upper extremities for resistance.

- Add arm motions that are synchronized with the leg motions, such as reaching forward and downward to develop coordination and control.
- Progress to lunging onto an unstable surface and return upright.
- Add step-up/step-down activities, beginning with a low step and progressing the height.

Walking Against Resistance

Secure a weighted pulley or elastic resistance around the patient's pelvis with a belt, or the patient can hold the handles. Have the patient walk forward, backward, or diagonally against the resistive force. Emphasis is placed on spinal control (see Fig. 23.34).

Progress by having the patient push and pull weighted objects, such as a cart or a box on a table. Place emphasis on maintaining a stable spinal position while the extremities are loaded (see Figs. 17.58, 18.21 A, 23.18, and 23.36).

Transitional Stabilization Exercises

Exercises that cause movement into spinal flexion and then extension (and vice versa) challenge the patient to control the neutral spine position. The patient learns to stabilize the spine against alternating trunk and extremity motions.

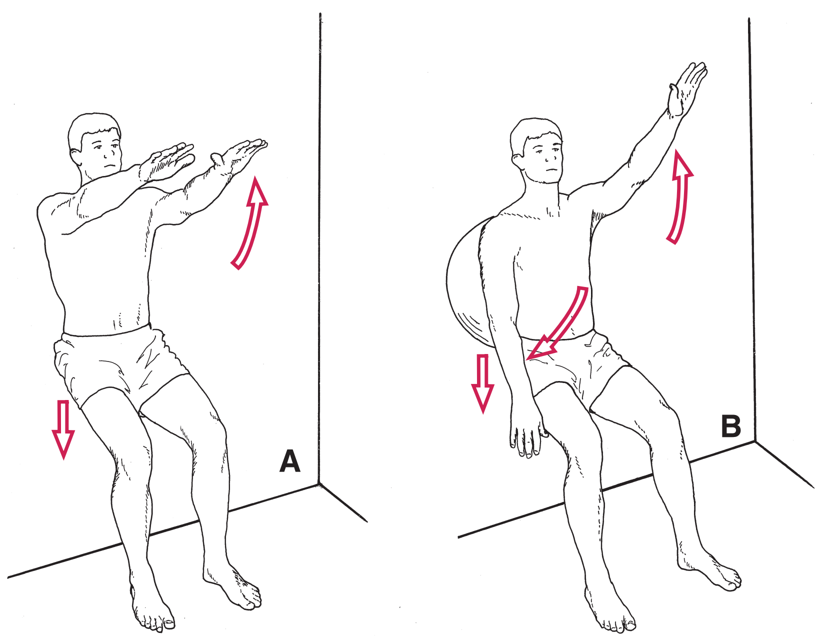

FIGURE 16.74 Wall slides/partial squats to develop LE strength and coordinate with trunk stability in preparation for training body mechanics. **(A)** The back sliding down a wall, with bilateral arm motion for added resistance. **(B)** Rolling a gym ball down the wall, with antagonistic arm motion to develop coordination.

Quadruped Forward/Backward Shifting

Patient position and procedure: Quadruped. Have the patient rock back to rest the buttocks on the heels; then shift the body forward onto the hands in the press-up position. The patient concentrates on controlling the pelvis in its neutral position rather than allowing full spinal flexion when shifting toward the heels or full spinal extension when shifting forward toward the press-up position.

Squatting and Reaching

Patient position and procedure: Begin standing. Have the patient reach downward while partially squatting. The tendency is for the spine to flex, so have the patient concentrate on maintaining a neutral spinal position with the spinal extensors. The patient then stands up and reaches overhead. This causes the spine to extend, so have the patient concentrate on using the trunk flexors to stabilize in the neutral position. Progress by lifting and reaching with weights while controlling the neutral posture of the spine.

Shifting Weight and Turning

Have the patient practice shifting weight forward/backward and side-to-side while maintaining the neutral spinal position and absorbing the forces with the hip and knee muscles. Practice turning using small steps and rotating at the hips rather than the back. Instruct the patient to imagine two rigid poles connecting each shoulder to each hip that do not allow the spine to twist. Even though some movement in the spine occurs, the activity helps the patient focus on a stable spine rather than rotating full range. Progress by using weights and having the patient lift, turn, and then place the weight at a new location.

Body Mechanics and Environmental Adaptations

Principles of Body Mechanics: Instruction and Training

When teaching safe body mechanics, it is advisable not to overwhelm the patient with too many instructions. Most people "know" they are to lift with their legs rather than their back, but they still have faulty techniques. Initiate training by suggesting that the patient find his or her neutral spine, perform the drawing-in maneuver, and then lift. Observe the technique they use and suggest modifications if needed. Squatting is often taught as the preferred method, yet not all patients are able to squat if they have impairments, such as knee pain or weakness. Under some circumstances, an individual may be more stable lifting with a lunge technique rather than the squat technique.

Lumbar Spine Position

The position of the lumbar spine, whether it is flexed, extended, or in mid-range, raises several issues. Of the three postures, lifting with a neutral spinal posture provides greater stability of the spine[18] and uses both the ligamentous and muscular system for stabilization and control.[57] After a back injury, the preferred lifting posture may have to be adapted, depending on the type of injury and the response of the tissues when stressed.[57]

Spinal flexion. When lifting with a flexed lumbar spine (posterior pelvic tilt), support for the spine is primarily from inert structures (ligaments, lumbodorsal fasciae, posterior anulus fibrosus, and facets); there is little muscle activity.

- Flexion occurs when stooping to the floor. Some have suggested that it may also be the posture of choice for a patient who has injured the back muscles, because the muscles are "quiet" when the spine is in flexion.[57]
- Lifting with the lumbar spine in flexion may pose some problems. When lifting slowly with a flexed spine, the load is maintained on the ligaments, and creep of the inert tissues occurs; this increases the chance of injury if the tissue is already weakened. In addition, with the muscles lengthened and relaxed, they may be at an unfavorable length-tension relationship to respond quickly with appropriate force to resist a sudden change in load. There is greater chance of ligamentous strain when a person lifts with a flexed spine.[28]

Spinal extension. When lifting with an extended (lordotic) lumbar spine, the muscles supporting the spine are more active than when flexed, which increases the compressive forces on the disc. Also, the facets are approximated (close-pack position). This posture relieves stress on the ligaments, but for an individual whose back muscles are in poor condition and fatigue quickly, this posture may jeopardize the spine when repeated lifts are performed, because the ligaments are not providing support.[57]

Load Position

Reinforce the concept of lifting and carrying objects as close to the center of gravity as possible.

- Have the patient practice carrying objects close to his or her center of gravity and draw attention to the feel of balance and control as well as less stress on the neck and back, compared to the feel when carrying objects in more stressful positions. Point out that, when lifting, the closer the object is held to the center of gravity, the less stress is placed on the supporting structures.
- Have the patient practice shifting the load from side-to-side and turning. Have the patient practice turning with hip rotation and minimal trunk rotation. The action should be directed by the legs while the spine is kept stable.

- Replicate the mechanics of the patient's job setting and practice safe mechanics.
- Teach the "golfer's lift" for picking up light objects, such as keys, pencils, and small toys. This is done by flexing the trunk forward over one hip while the other hip extends. It allows the patient to maintain a neutral spine and places the majority of the work on the LEs.

Environmental Adaptations

Ergonomic assessment and modification of the home and working environments are necessary to correct stresses as well as prevent future recurrence of symptoms.

Home, Work, and Driving Considerations

- Chairs and car seats should have lumbar support to maintain slight lordosis. Use a towel roll or lumbar pillow if necessary.
- Chair height should allow knees to flex to take tension off the hamstring muscles, support the thighs, and allow the feet to rest comfortably on the floor.
- Arm rests should be used if prolonged sitting is required in order to take the stress off shoulders and the cervical spine.
- Desk or table height should be adequate to keep the person from having to lean over the work.
- Work and driving habits should allow frequent changing of posture. If normally sedentary, the patient should get up and walk every hour.

Sleeping Environment

- The mattress needs to provide firm support to prevent any extreme stresses. If it is too soft, the patient sags and stresses ligaments; if it is too firm, some patients cannot relax.
- Pillows should be of a comfortable height and density to promote relaxation but should not place joints in an extreme position. Foam rubber pillows tend to cause increased tension in muscles because of the constant resistance they provide.
- Whether the person should sleep prone, side-lying, or supine is something that must be analyzed for each individual patient. Ideally, a comfortable posture is one that is in the mid-range and that does not place stress on any supporting structure. Pain that is experienced when waking up in the morning is often related to sleeping posture; if this is the case, listen carefully to the patient's description of postures when sleeping and see if it relates to the pain. Then, attempt to modify the sleep position accordingly. Remind the patient that it takes several weeks to change habits.

Intermediate to Advanced Exercise Techniques for Functional Training

As the patient learns spinal control while doing the exercises, repetitions are increased to develop muscular endurance, and resistance is added to develop strength. If coordination, agility, and balance are required, they are emphasized. By this stage, it is recognized that the individual already knows the basic spinal stabilization techniques and is habitually assuming the neutral spinal position and activating the drawing-in maneuver. Reinforce the importance of this when doing the following exercises. It is also recognized that the patient should be able to control greater spinal ROM without experiencing symptoms. Adapt the exercises to replicate return to work or sport-related activities. Examples follow.

Repetitive Lifting

The ability to do repetitive lifting throughout the workday is necessary for many jobs and may result in symptom recurrence. To prepare for returning to work, progressively increase the repetitions of lifting activities the patient must do to improve muscle endurance. Marras and Granta[36] demonstrated that with repetitive lifting (over a 5-hour period) subjects had a significant change in their lifting pattern and in the muscle recruitment patterns, so there was a decrease in spine stabilization (decreased compression) and an increase in anterior/posterior shear in the lumbar spine. To reduce the risk of recurrence of low-back disorders, a patient needs to learn to monitor these changes and be conscious of correcting faulty patterns. Help the patient modify and adapt the stable spine body mechanics that were initiated under basic techniques to replicate the type of lifting he or she will be doing at home or on the job. Include variations in the lifting tasks to prepare for unexpected situations.

Repetitive Reaching

Repetitive reaching requires that the patient learn to assume a comfortable stride and then practice shifting his or her weight forward and backward on the lower extremities rather than bending forward and backward with the spine. Preparatory exercises should include partial lunging forward, sideways, and backward. During practice, have the patient use a weight comparable to that in the real-life situation and go through the action on a repetitive basis, concentrating on spinal control and resting only when control is no longer possible.

Repetitive Pushing and Pulling

Repetitive pushing and pulling require strong upper extremities and a stable spine. Preparatory activities should include pushing and pulling against elastic resistance or pulley resistance set at heights that replicate the work environment. Progress to pushing and pulling a weighted cart or a weighted box across a table. Reinforce the importance of activating the spinal stabilizers.

Rotation or Turning

Turning with a load is a component of most work activity. A person may rotate the spine to reach around to place a load to the side or behind. Rotation may create an unstable situation or may be damaging to the spinal structures. Therefore, it is important to take the rotation out of turning. Have the patient practice a "stable spine turn," which requires motion and control in the hips or taking steps into the direction of the turn rather than twisting and rotating the back.

Transitional Movements

Most functional activities require transitional motions, such as reaching downward to pick up something (spinal flexion), then reaching overhead to place it on a high shelf (spinal extension). In sports activities, the activity may require moving quickly from a forward-bent position to an extended position with arms overhead (such as dribbling a basketball, then shooting). Set up drills that replicate the speed and movements of the desired outcome; have the patient practice moving through the patterns while attempting to maintain control of his or her functional spinal position and range.

Transfer of Training

Ideally, each patient is progressed through rehabilitation to the level of being able to transfer skills learned to closely related but new situations. Provide variable learning opportunities from simple to complex and then help the patient analyze successful adaptations to each new experience. (See Figure 1.8 and accompanying text in Chapter 1 for examples of how to vary tasks from simple to complex.)

Patient Education for Prevention

Education occurs on a continual basis. Before discharge, review the following relationships of posture and pain with the patient.

- When experiencing pain or the recurrence of symptoms, check posture. Avoid any one posture for prolonged periods.
- If sustained postures are necessary, take frequent breaks and perform appropriate ROM exercises at least every half hour. Finish all exercises by assuming a well-balanced posture.
- Avoid hyperextending the neck or being in a forward-head posture or forward-bent position for prolonged periods. Find ways to modify a task so it can be accomplished at eye level or with proper lumbar support.
- If in a tension-producing situation, perform conscious relaxation exercises.
- Use common sense and follow good safety habits.
- Review the home exercise program and explain how to safely progress and vary the exercises to maintain interest.
    - Teach flexibility, muscle endurance, and strengthening exercises appropriate for the patient to maintain ROM, muscle endurance, and strength.
    - Address any misconceptions the patient may have about exercise and management of the spine.
    - Teach the patient to safely progress the aerobic exercise program. Reinforce the importance of maintaining cardiopulmonary endurance and its effect on managing symptoms.

Independent Learning Activities

Critical Thinking and Discussion

1. Observe a homemaker or worker doing an activity that requires pushing, pulling, reaching, lifting, or some other repetitive pattern. Analyze what component motions are part of the total pattern and decide if strength, range, endurance, balance, or coordination (or a combination) is necessary in the upper extremities, lower extremities, and trunk. Decide what is necessary to make the spine safe while doing this activity and design an exercise program that encompasses all the components.
2. Go to a health club or exercise class and observe how individuals are performing the exercises. Note the activities that cause stress to the spine or pelvis. How would you modify each exercise? Consider safe use of the equipment, safe biomechanics, and appropriate instruction for the audience. Can you tell the purpose of each exercise (strength, stretch, endurance, balance)? Are the directions appropriately given for the level of participants?
3. What is the law in your state as it pertains to physical therapists performing manipulation and HVT? What are some situations in which you would perform a manipulation

rather than an HVT technique? What are some situations in which you would perform an HVT technique rather than a manipulation technique?

Laboratory Practice

1. With a laboratory partner practice the kinesthetic training techniques and deep segmental muscle activation techniques for the cervical spine and the lumbar spine until you become proficient at performing them and recognizing when they are done correctly. Then practice teaching them to a family member or friend and see how well they understand what they are to do.
2. Practice the progression of spinal stabilization exercises described in the muscle performance section. Start at the easiest level and progress the leg and arm movements until you feel you are at your maximum resistance for stabilization. After resting, time yourself for 1 minute, beginning at the most difficult level of movement. The idea is to keep the spine stable during the entire minute. If you begin to feel you are losing control, decrease the amount of extremity resistance (e.g., going from moving both lower extremities in a reciprocal pattern to moving just one extremity while the other is on the floor). This can also be done for 3 minutes. Were you able to meet the challenge yet keep the spine stable? Did you feel your stabilizing muscles "working"?
3. Practice doing wall slides, partial squats, and partial lunges with a stable spine. When you can do the squat comfortably with a stable spine, practice lifting a box from the floor to table height, then from the floor to shoulder height, then place it on a shelf at each height. Feel what is happening to your spine. Then repeat the maneuvers with a stable spine, and see if you can control the spinal position with the drawing-in maneuver. When you can do the lunge comfortably, practice lifting small objects from the floor with a lunging technique and stable spine. Finally, practice lifting objects from the floor and turning (using legs and hips to change direction, not spinal rotation) to place the objects on a table or shelf. Feel what is happening to the spine and repeat the activities with a stable spinal posture.
4. Review the indications and contraindications for spinal manipulation. Practice the cervical manipulations with your laboratory partner in both the supine and prone positions. In which position do you have better control (patient supine or prone)?
5. Several HVT techniques were discussed in this chapter. What are the contraindications for HVT in the spine? Practice three HVTs to improve thoracic flexion. How would you change the technique if your goal was to improve rotation to the left?

Case Studies

Review the cases described in Chapters 14 and 15 and modify your answers based on the information presented in this chapter.

CHAPTER

17

The Shoulder and Shoulder Girdle

CAROLYN KISNER, PT, MS ■ LYNN COLBY, PT, MS

JOHN D. BORSTAD, PT, PhD

The design of the shoulder girdle allows for mobility of the upper extremity. As a result, the hand can be placed almost anywhere within a sphere of movement, its range limited primarily by the length of the arm and the space taken up by the body. The combined mechanics of its joints and muscles provide for and control the mobility. When establishing a therapeutic exercise program for impaired function of the shoulder region, as with any other region of the body, the unique anatomical and kinesiological features must be taken into consideration as well as the state of pathology and functional limitations imposed by the impairments.

This chapter is divided into three major sections. The first section briefly reviews the structure and function of the shoulder girdle complex. The second section describes

common disorders and guidelines for conservative and post-surgical management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

Structure and Function of the Shoulder Girdle

The shoulder girdle has only one boney attachment to the axial skeleton (Fig. 17.1). The clavicle articulates with the sternum via the small sternoclavicular joint. As a result, considerable mobility is allowed in the upper extremity. Stability is provided by an intricate balance between the scapular and glenohumeral muscles and the structures of the joints in the shoulder girdle.

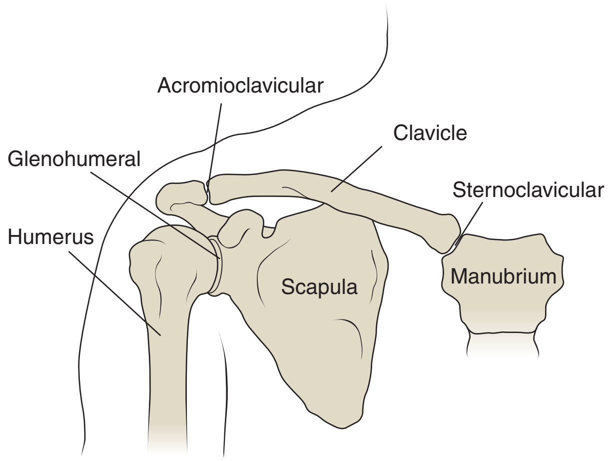

FIGURE 17.1 Bones and joints of the shoulder girdle complex.

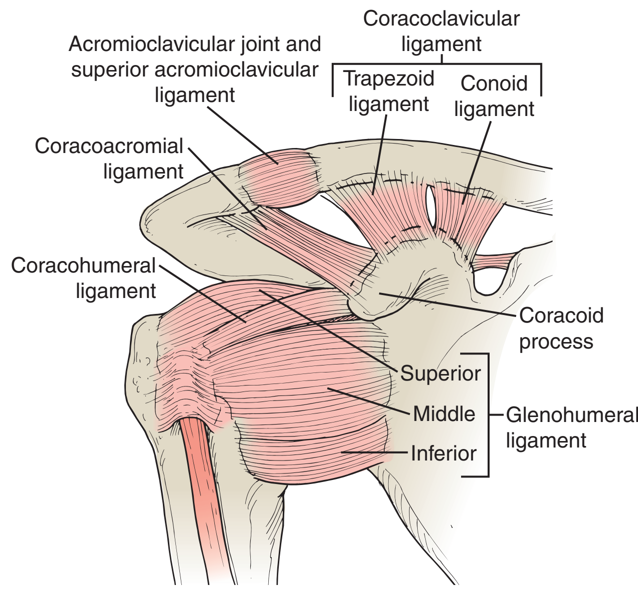

FIGURE 17.2 Ligaments of the glenohumeral (GH) and acromioclavicular (AC) joints.

Joints of the Shoulder Girdle Complex

Three synovial joints (glenohumeral, acromioclavicular, sternoclavicular) and two functional articulations (scapulothoracic, suprahumeral) make up the shoulder girdle complex.

Synovial Joints

Glenohumeral Joint

The glenohumeral (GH) joint is an incongruous, ball-and-socket (spheroidal) triaxial joint with a lax joint capsule. It is supported by the tendons of the rotator cuff and the glenohumeral (superior, middle, inferior) and coracohumeral ligaments (Fig. 17.2). The concave boney partner, the glenoid fossa, is located on the superior-lateral margin of the scapula. It faces anteriorly, laterally, and upward, which provides some stability to the joint. A fibrocartilagenous lip, the glenoid labrum, deepens the fossa for greater congruity and serves as the attachment site for the capsule. The convex boney partner is the head of the humerus. Only a small portion of the head comes in contact with the fossa at any one time, allowing for considerable humeral movement and potential instability.[156]

Arthrokinematics

According to the convex-concave theory of joint motion (see Chapter 5), with motions of the humerus (physiological motions), the convex head rolls in the same direction and slides in the opposite direction in the glenoid fossa (Box 17.1).

FOCUS ON EVIDENCE

Of interest and apparent contradiction to this theory, one study reported that, through the mid-range of the arc of

BOX 17.1 Summary of Joint Arthrokinematics of the GH Joint

Physiological Motion of the Humerus	Roll	Slide
Flexion	Spin (minimal roll and slide)	
Horizontal adduction	Anterior	Posterior
Internal rotation at 0° Abduction	Anterior	Posterior
Extension	Spin (minimal roll and slide)	
Horizontal abduction	Posterior	Anterior
External rotation at 0° Abduction	Posterior	Anterior
Abduction	Superior	Inferior

passive motion, there is minimal displacement of the humeral head. However, beyond mid-range, the overall displacement of the head in normal joints is anterior with shoulder flexion and posterior with shoulder extension.[77] This cadaveric study demonstrated that the integrity of the capsular ligamentous system influenced the displacement, and both hyper- and hypomobility of the capsule changed the overall displacement of the humeral head with passive range of motion (ROM). While these results appear to contradict the convex-concave theory of arthrokinematics, this study and many similar studies of glenohumeral kinematics report the motion of the estimated center of the humeral head and not the humeral-glenoid contact points. This distinction should be clear when interpreting the results and clinical application of experimental studies.

In another study, Howel and associates[94] measured humeral head displacement in normal and unstable shoulders using radiographs. These investigators reported posterior displacement of the humeral head during end-range horizontal abduction with the humerus at 90° and in full external rotation in normal subjects, yet anterior displacement in subjects with anterior instability. These studies support the importance of joint mobility testing to examine restricted accessory motions to determine if interventions with joint mobilization techniques should be used and determine the direction of the mobilization force, rather than using the convex-concave rule to determine the direction of mobilizations.

Stability

Static and dynamic restraints provide joint stability (Table 17.1).[33,48,183,224,227] The structural relationship of the boney anatomy, ligaments, and glenoid labrum and the adhesive and cohesive forces in the joint provide static stability. The tendons of the rotator cuff blend with the ligaments and glenoid labrum at their sites of attachment, so when the muscles contract, they provide dynamic stability by tightening the static restraints (Fig. 17.3). The coordinated response of the muscles of the cuff and tension in the ligaments provide varying degrees of support depending on the position and motion of the humerus.[172,183,208] In addition, the long head of the biceps and the long head of the triceps brachii reinforce the capsule with their attachments and provide superior and inferior shoulder joint support respectively, when functioning with elbow motions.[109] The long head of the biceps, in particular, stabilizes against humeral elevation[109] and contributes to anterior stability of the glenohumeral joint by resisting torsional forces when the shoulder is abducted and externally rotated.[11,172] Neuromuscular control, including movement awareness and motor response, underlies coordination of the dynamic restraints.[224,227]

TABLE 17.1 Static and Dynamic Stabilizers of the Scapula and Glenohumeral Joint

Description	Static Stabilizers	Muscular Stabilizers
Scapula		
Weight of upper extremity creates downward rotation and protraction moment on the scapula	▪ Cohesive forces of subscapular bursa, SC, and AC joint ligaments ▪ Scapulothoracic fascia	Scapulothoracic musculature, especially upper, middle, and lower trapezius, serratus anterior, levator scapula, and rhomboids
Glenohumeral joint		
In dependent position: if scapula is in normal alignment, weight of arm creates an inferior translation moment on the humerus	▪ Superior capsule, superior GH ligament, and coracohumeral ligament are taut ▪ Adhesive and cohesive forces of synovial fluid and negative joint pressure hold surfaces together ▪ Slight upward inclination of glenoid and labrum deepens fossa and improves congruency; acts as inferior barrier	Rotator cuff, deltoid, long head of biceps brachii, pectoralis major, latissimus dorsi, and teres major
When the humerus is elevating and the scapula is rotating upward	▪ Tension placed on static restraints by the rotator cuff ▪ Glenohumeral ligaments limit excessive translations of humeral head	▪ Rotator cuff and deltoid; elbow action brings in two-joint muscle support ▪ Long head of biceps stabilizes against humeral elevation

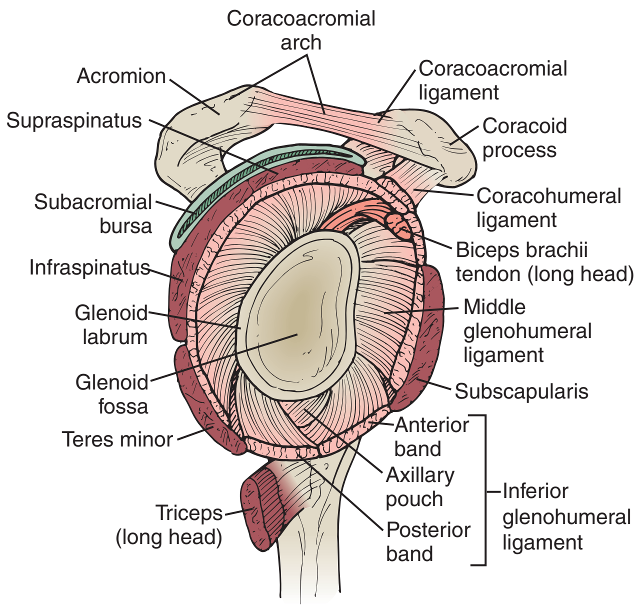

FIGURE 17.3 Lateral aspect of the glenoid fossa (interior view), showing attachments of the glenoid labrum, capsule, and ligaments as well as their relationship to the rotator cuff and long head of the biceps brachii musculature.

Acromioclavicular Joint

The acromioclavicular (AC) joint is a plane, triaxial joint that may or may not have a disk. The weak capsule is reinforced by the superior and inferior AC ligaments (see Fig. 17.2). The convex boney partner is a facet on the lateral end of the clavicle. The concave boney partner is a facet on the acromion of the scapula.

Arthrokinematics

With motions of the scapula, the acromial surface slides in the same direction in which the scapula moves, because the surface is concave. Motions affecting this joint include upward rotation (the scapula turns so the glenoid fossa rotates upward), downward rotation, winging of the vertebral border, and tipping of the inferior angle.

Stability

The AC ligaments are supported by the strong coracoclavicular ligament. No muscles directly cross this joint for dynamic support.

Sternoclavicular Joint

The sternoclavicular (SC) joint is an incongruent, triaxial, saddle-shaped joint with a disk. The joint is supported by the anterior and posterior SC ligaments and the interclavicular and costoclavicular ligaments (Fig. 17.4). The medial end of the clavicle is convex superior to inferior and concave anterior to posterior. The joint disk attaches to the upper end. The superior-lateral portion of the manubrium and first costal cartilage is concave superior to inferior and convex anterior to posterior.

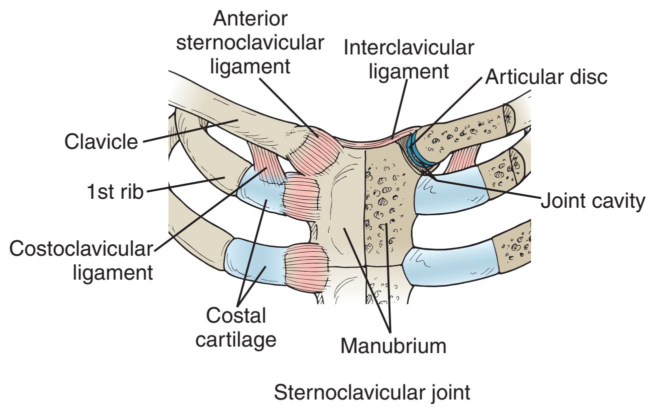

FIGURE 17.4 Ligaments of the sternoclavicular (SC) joint.

Arthrokinematics

The motions of the clavicle occur as a result of the scapular motions of elevation, depression, protraction (abduction), and retraction (adduction) (Box 17.2). Rotation of the clavicle occurs as an accessory motion when the humerus is elevated above the horizontal position and the scapula upwardly rotates; it cannot occur as an isolated voluntary motion.

Stability

The ligaments crossing the joint provide static stability. There are no muscles crossing the joint for dynamic stability.[45]

Functional Articulations

Scapulothoracic Articulation

Normally, there is considerable soft tissue flexibility, allowing the scapula to slide along the thorax and participate in all upper extremity motions.

Motions of the Scapula

- *Elevation, depression, protraction, and retraction*: These motions are seen with clavicular motions at the SC joint (Fig. 17.5 A and B). Elevation and depression occur in the frontal plane as the scapula moves upward and downward, respectively; protraction/retraction occur in the transverse plane as the scapula moves away from or toward the spinal column. They are also component motions when the humerus moves.

BOX 17.2 Summary of Arthrokinematics of the SC Joint

Physiological Motion of the Clavicle	Roll	Slide
Protraction	Anterior	Anterior
Retraction	Posterior	Posterior
Elevation	Superior	Inferior
Depression	Inferior	Superior

- *Upward and downward rotation:* These motions are seen with clavicular motions at the SC joint and rotation at the AC joint and occur concurrently in various planes with motions of the humerus (Fig. 17.5 C). Upward rotation (along with posterior tilting and external rotation of the scapula) are component motions that occur with full shoulder ROM of elevation (flexion, scapular plane abduction, and frontal-plane abduction of the humerus).[64,133]
- *Internal and external rotation and tilting (tipping):* These motions are seen with motion at the AC joint concurrently with motions of the humerus (Fig. 17.5 D). Internal and external rotations are transverse plane motions in which the medial border lifts away from (wings) or approximates the rib cage, respectively. Anterior tilting of the scapula occurs in conjunction with internal rotation and extension of the humerus when reaching the hand behind the back, while posterior tilting occurs during humeral elevation.[64,133]

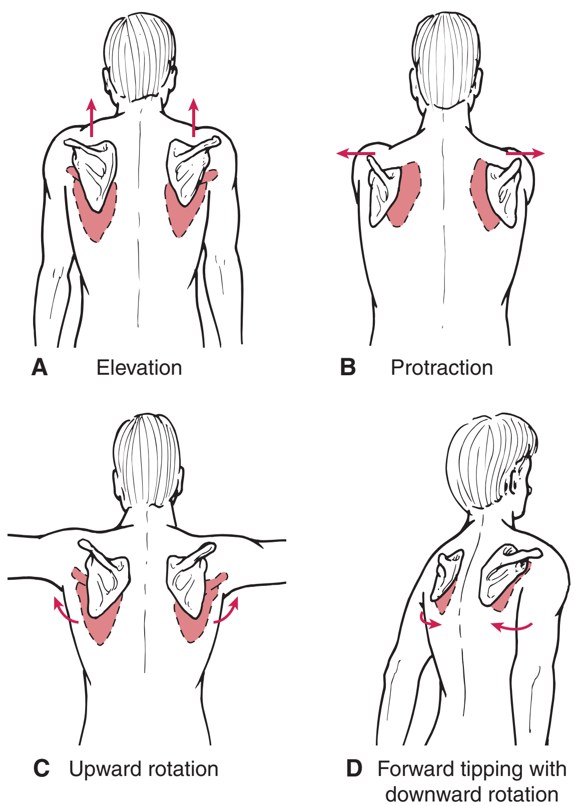

FIGURE 17.5 Scapular motions. **(A)** Elevation occurs with clavicular elevation at the SC joint when shrugging. **(B)** Protraction (abduction) occurs with clavicular abduction at the SC joint when reaching forward. **(C)** Upward rotation occurs with clavicular rotation at the SC and AC joints when flexing and abducting the shoulder. **(D)** Forward tilting (along with downward rotation) occurs at the AC joint when extending and internally rotating the shoulder.

Scapular Stability

Postural relationship. In the dependent position, the scapula is stabilized primarily through a balance of forces. The weight of the arm creates a downward rotation, protraction, and forward tilting moment on the scapula. These moments are balanced by the support of the upper trapezius, serratus anterior, rhomboids, and middle trapezius[120,184] (see Table 17.1).

Active arm motions. With active arm motions, the muscles of the scapula function in synchrony to stabilize and control the position of the scapula, so the scapulohumeral muscles can maintain an effective length-tension relationship as they function to stabilize and move the humerus. Without the positional control of the scapula, the efficiency of the humeral muscles decreases. The upper and lower trapezius along with the serratus anterior upwardly rotate the scapula whenever the arm elevates, and the serratus anterior protracts the scapula on the thorax to align the scapula during flexion or pushing activities. During arm extension or during pulling activities, the rhomboids function to downwardly rotate and retract the scapula in synchrony with the latissimus dorsi, teres major, and rotator cuff muscles. These stabilizing muscles also eccentrically control acceleration of upward rotation and protraction of the scapula.[158]

Faulty posture. A slouched posture significantly alters scapular kinematics. Specifically, sitting or standing with increased thoracic kyphosis, significantly decreases posterior tilting and external rotation of the scapula during elevation of the arm.[64] Furthermore, with faulty scapular alignment, muscle length and strength imbalances occur not only in the scapular muscles but also in the humeral muscles, altering the mechanics of the glenohumeral joint. A forward tilt of the scapula (seen with a forward head posture and increased thoracic kyphosis) is associated with decreased flexibility in thepectoralis minor, levator scapulae, and scalenus muscles and weakness in the serratus anterior or trapezius muscles. This scapular posture also changes the posture of the humerus in the glenoid, which assumes a relatively abducted and internally rotated position with respect to the scapula (Fig. 17.6). The glenohumeral internal rotators may become less flexible, and external rotators may weaken, affecting the mechanics of the joint.

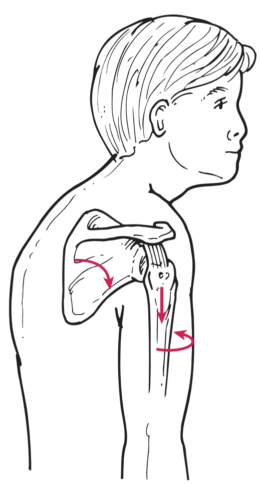

FIGURE 17.6 Faulty forward head, thoracic kyphosis, and shoulder girdle posture result in a forward tilt and downward rotation of the scapula with relative abduction and internal rotation of the humerus when the arm is in a dependent position.

FOCUS ON EVIDENCE

A study by Borstad and Ludewig,[18] which looked at the effect of pectoralis minor resting length on scapular kinematics in subjects without shoulder pain, documented that those individuals with a short pectoralis minor ($n = 25$) had greater scapular internal rotation (protraction) and less posterior tilting during arm elevation in flexion, abduction, and scapular plane than those with a longer pectoralis minor ($n = 25$), thus providing evidence for altered pectoralis minor muscle length and altered scapular movement. In a related study by the same author,[19] a correlation between the postural impairments of increased thoracic kyphosis, scapular internal rotation and forward tipping, and decreased pectoralis minor length was found to be significant, further supporting the relationship between muscle length and posture.

Suprahumeral (Subacromial) Space

The coracoacromial arch, composed of the acromion and coracoacromial ligament, overlies the subacromial/subdeltoid bursa, the supraspinatus tendon, and a portion of the muscle (Fig. 17.7).[120] These structures allow for and participate in normal shoulder function. Compromise of this space from faulty muscle function, faulty postural relationships, faulty joint mechanics, injury to the soft tissue in this region, or structural anomalies of the acromion lead to impingement syndromes.[18,28,32,106,112,118,132,238] After a rotator cuff tear, the bursa may communicate with the glenohumeral joint cavity.[48]

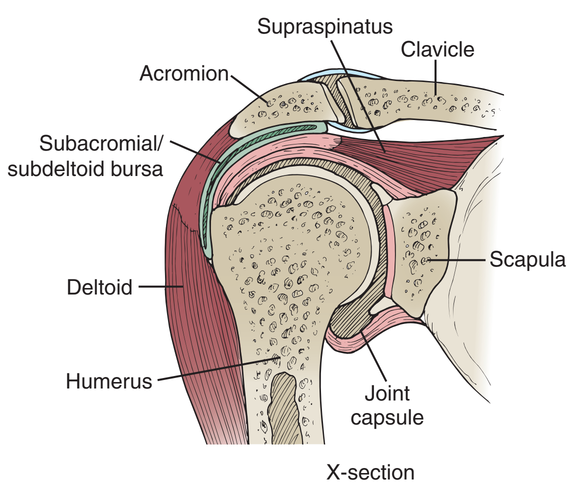

FIGURE 17.7 The supraspinatus and subacromial/subdeltoid bursa lie in the suprahumeral space.

Shoulder Girdle Function

Scapulohumeral Rhythm

Motion of the scapula, synchronous with motions of the humerus, allows for 150° to 180° of shoulder ROM into flexion or abduction with elevation. The ratio has considerable variation among individuals but is commonly accepted to be 2:1 (2° of glenohumeral motion to 1° of scapular rotation) overall motion. During the setting phase (0° to 30° abduction, 0° to 60° flexion), motion is primarily at the glenohumeral joint, whereas the scapula seeks a stable position. During the mid-range of humeral motion, the scapula has greater motion, approaching a 1:1 ratio with the humerus; later in the range, the glenohumeral joint again dominates the motion.[43,120,191]

- Early studies analyzed only upward rotation of the scapula. More recent three-dimensional research demonstrated component scapular motions to be upward rotation, posterior tilting, and scapular external rotation with full shoulder elevation (flexion, scapular plane abduction, and frontal-plane abduction of the humerus).[106,133]
- During humeral elevation, the synchronous motion of the scapula allows the muscles moving the humerus to maintain an effective length-tension relationship throughout the activity and helps maintain congruency between the humeral head and fossa while decreasing shear forces.[43,120,191]
- The upper and lower trapezius and the serratus anterior muscles cause the upward rotation of the scapula. Weakness or complete paralysis of these muscles results in the scapula being rotated downward by the contracting deltoid and supraspinatus as abduction or flexion is attempted. These two muscles then reach active insufficiency, and functional elevation of the arm cannot be reached, even though there may be normal passive ROM and normal strength in the shoulder abductor and flexor muscles.[191]
- During elevation of the humerus, the pectoralis minor is lengthened as the scapula upwardly rotates, retracts, and tips posteriorly. Restricted scapular movement during humeral elevation from a shortened pectoralis minor results in patterns similar to those seen in patients with impingement symptoms and could be a risk factor for development of the syndrome.[18]

Clavicular Elevation and Rotation with Humeral Motion

It is commonly accepted that initially the first 30° of upward rotation of the scapula occurs with elevation of the clavicle at the SC joint. Then, as the coracoclavicular ligament becomes taut, the clavicle rotates 38° to 55° about its longitudinal axis, which elevates its acromial end (because it is crank-shaped). This motion allows the scapula to rotate an additional 30° at the AC joint.[120] Loss of any of these functional components decreases the amount of scapular rotation and thus the ROM of the upper extremity.

FOCUS ON EVIDENCE

A three-dimensional study[119] of clavicular motion during humeral flexion, scapular plane elevation of the arm, and abduction to 115° using surface electromagnetic sensors on 30 asymptomatic subjects and 9 individuals with shoulder pathology documented 11° to 15° of clavicular elevation, 15° to 29° of retraction, and 15° to 31° of posterior long axis rotation, showing similar patterns but different ranges from previously

reported studies. Ranges of clavicular motion above 115° were not reliable, owing to movement of the clavicle under the skin.

External Rotation of the Humerus with Elevation

During elevation of the arm, the humerus externally rotates; this allows the greater tubercle of the humerus to clear the coracoacromial arch. Weak infraspinatus and teres minor muscles or inadequate external rotation may result in impingement of the soft tissues in the suprahumeral space, causing pain, inflammation, and eventually loss of function.

FOCUS ON EVIDENCE

An *in vivo* study of elevation in flexion, in the plane of the scapula, and in abduction demonstrated approximately 55° external rotation in all planes.[193] During abduction, external rotation occurred up to 125° followed by some internal rotation; during forward flexion, external rotation occurred until 50°, then plateaued. Lastly, external rotation occurred again from 110° to 160°. During elevation in the scapular plane, external rotation occurred throughout.

Deltoid–Short Rotator Cuff and Supraspinatus Mechanisms

Most of the force of the deltoid muscle causes upward translation of the humerus; if unopposed, it leads to impingement of the soft tissues in the suprahumeral space between the humeral head and the coracoacromial arch.

- The combined effect of the short rotator muscles (infraspinatus, teres minor, subscapularis) produces stabilizing compression and downward translation of the humerus in the glenoid.
- The combined actions of the deltoid and short rotators result in a balance of forces that elevate the humerus and control the humeral head.
- The supraspinatus muscle has a significant stabilizing, compressive, and slight upward translation effect on the humerus during arm elevation. It functions with the deltoid in humeral elevation.
- Interruption of the coordinated function of these mechanisms may lead to tissue microtrauma and shoulder complex dysfunction.

Referred Pain and Nerve Injury

For a detailed description of referred pain patterns, peripheral nerve injuries in the shoulder, thoracic outlet syndrome, and complex regional pain syndromes (including reflex sympathetic dystrophy) and their management, see Chapter 13.

Common Sources of Referred Pain in the Shoulder Region

Cervical Spine

- Vertebral joints between C3 and C4 or between C4 and C5
- Nerve roots C4 or C5

Referred Pain from Related Tissues

- Dermatome C4 is over the trapezius to the tip of the shoulder.
- Dermatome C5 is over the deltoid region and lateral arm.
- Diaphragm: pain perceived in the upper trapezius region.
- Heart: pain perceived in the axilla and left pectoral region.
- Gallbladder irritation: pain perceived at the tip of shoulder and posterior scapular region.

Nerve Disorders in the Shoulder Girdle Region

Brachial plexus in the thoracic outlet. Common sites for compression are the scalene triangle and the costoclavicular space and under the coracoid process and pectoralis minor muscle.[117]

Suprascapular nerve in the suprascapular notch. This injury occurs from direct compression or from nerve stretch, such as when carrying a heavy book bag over the shoulder.

Radial nerve in the axilla. Compression occurs from continual pressure, such as when leaning on axillary crutches.

Management of Shoulder Disorders and Surgeries

To make sound clinical decisions when managing patients with shoulder disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, functional limitations, and possible disabilities. In this section, common pathologies and surgeries are presented and are related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[2] (Table 17.2). Conservative and postoperative management of these conditions are described in this section.

Joint Hypomobility: Nonoperative Management

Glenohumeral Joint

Restricted mobility of the glenohumeral joint may occur as a result of pathology, such as rheumatoid arthritis or osteoarthritis; from prolonged immobilization; or from unknown causes (idiopathic frozen shoulder). Associated

TABLE 17.2 Shoulder Pathologies/Surgical Procedures and Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Patterns and Associated Impairments[2]
■ Abnormal posture (protracted scapula, kyphosis, forward head)	■ Pattern 4B—Impaired posture
■ Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) ■ Synovitis ■ Postimmobilization arthritis (stiff shoulder) ■ Idiopathic frozen shoulder ■ Adhesive capsulitis ■ Joint instability, subluxation, dislocation (nontraumatic/recurrent) ■ Rotator cuff syndrome and allied disorders ■ Labral lesion	■ Pattern 4D—Impaired joint mobility, motor function, muscle performance, and range of motion (ROM) associated with connective tissue dysfunction
■ Arthritis—acute stage ■ Acute impingement syndrome (tendonitis, bursitis) ■ Acute capsulitis ■ Acute rotator cuff tear ■ Traumatic shoulder dislocation	■ Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
■ Fractures (proximal humerus, clavicle, scapula)	■ Pattern 4G—Impaired joint mobility, muscle performance, and ROM associated with fracture
■ Total shoulder arthroplasty ■ Hemiarthroplasty ■ Reverse total shoulder arthroplasty ■ Resurfacing and interposition arthroplasties	■ Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
■ Subacromial decompression procedures (bursectomy, acromioplasty, distal clavicular resection) ■ Rotator cuff repair ■ Capsulorrhaphy (capsular shift) ■ Electrothermally assisted arthroscopic capsulorrhaphy ■ Capsulolabral reconstruction ■ Fracture stabilization with internal fixation ■ Joint débridement ■ Synovectomy ■ Arthrodesis	■ Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with boney or soft tissue surgery

impairments in muscle performance and connective tissue mobility may also be present in the cervical and shoulder girdle region.

Related Pathologies and Etiology of Symptoms

Rheumatoid arthritis and osteoarthritis. These disorders follow the clinical picture described in Chapter 11.

Traumatic arthritis. This disorder occurs in response to a fall or blow to the shoulder or to microtrauma from faulty mechanics or overuse.

Postimmobilization arthritis or stiff shoulder. This disorder occurs as a result of lack of movement or as a secondary effect from conditions such as heart disease, stroke, or diabetes mellitus.

Idiopathic frozen shoulder. This disorder, which is also called *adhesive capsulitis* or *periarthritis,* is characterized by the development of dense adhesions, capsular thickening, and capsular restrictions, especially in the dependent folds of the capsule, rather than arthritic changes in the cartilage and bone, as seen with rheumatoid arthritis or osteoarthritis. The onset is insidious and usually occurs between the ages of 40 and 60 years; there is no known cause (primary frozen shoulder), although problems already mentioned in which there is a period of pain and/or restricted motion, such as with rheumatoid arthritis, osteoarthritis, trauma, or immobilization, may lead to a frozen shoulder (secondary frozen shoulder). With primary frozen shoulder, the pathogenesis may be a provoking chronic inflammation in musculotendinous or synovial tissue, such as the rotator cuff, biceps tendon,

or joint capsule.[45,74,104,145,148] Faulty posture and muscle strength imbalances may be consistent with this, predisposing the individual to impingement and overuse syndromes.[1]

Clinical Signs and Symptoms

Glenohumeral joint arthritis. The following characteristics are associated with the various types of glenohumeral (GH) joint arthritis that lead to hypomobility.

- *Acute phase.* Pain and muscle guarding limit motion, usually external rotation and abduction. Pain is frequently experienced radiating below the elbow and may disturb sleep. Owing to the depth of the capsule, joint swelling is not detected, although tenderness can be elicited by palpating in the fornix immediately below the edge of the acromion process between the attachments of the posterior and middle deltoid.
- *Subacute phase*. Capsular tightness begins to develop. Limited motion is detected, consistent with a capsular pattern (external rotation and abduction are most limited, and internal rotation and flexion are least limited). Often, the patient feels pain as the end of the limited range is reached. Joint-play testing reveals limited joint play. If the patient can be treated as the acute condition begins to subside by gradually increasing shoulder motion and activity, the complication of joint and soft tissue contractures can usually be minimized.[139,145]
- *Chronic phase.* Progressive restriction of the GH joint capsule magnifies the signs of limited motion in a capsular pattern and decreased joint play. There is significant loss of function with an inability to reach overhead, outward, or behind the back. Aching is usually localized to the deltoid region.

Idiopathic frozen shoulder. This clinical entity progresses through a series of four stages following a classic continuum.*

- **Stage 1**. Characterized by a gradual onset of pain that increases with movement and is present at night. Loss of external rotation motion with intact rotator cuff strength is common. The duration of this stage is usually less than 3 months.
- **Stage 2** (Often referred to as the *"Freezing" Stage).* Characterized by persistent and more intense pain even at rest. Motion is limited in all directions and cannot be fully restored with an intra-articular injection. This stage is typically between 3 and 9 months.
- **Stage 3** (*"Frozen" Stage).* Characterized by pain only with movement, significant adhesions, and limited GH motions, with substitute motions in the scapula. Atrophy of the deltoid, rotator cuff, biceps, and triceps brachii muscles may be noted. This stage is between 9 and 15 months.
- **Stage 4** (*"Thawing" Stage).* Characterized by minimal pain and no synovitis but significant capsular restrictions from adhesions. Motion may gradually improve during this stage. This stage lasts from 15 to 24 months or longer. Some patients never regain normal ROM.

Some references indicate that spontaneous recovery occurs, on average, 2 years from onset,[74] although others have reported long-term limitations without spontaneous recovery.[177] Inappropriately aggressive therapy at the wrong time may prolong the symptoms.[16] Management guidelines are progressed based on the continuum of stages[104] and are the same as for acute (maximum protection during stages 1 and 2), subacute (controlled motion during stage 3), and chronic (return to function during stage 4) joint pathology described in this section.

Common Structural and Functional Impairments

- Night pain and disturbed sleep during acute flares
- Pain on motion and often at rest during acute flares
- Mobility: decreased joint play and ROM, usually limiting external rotation and abduction with some limitation of internal rotation and elevation in flexion
- Posture: possible faulty postural compensations with protracted and anteriorly tilted scapula, rounded shoulders, and elevated and protected shoulder
- Decreased arm swing during gait
- Muscle performance: general muscle weakness and poor endurance in the glenohumeral muscles with overuse of the scapular muscles leading to pain in the trapezius, levator scapulae, and posterior cervical muscles
- Substitution for limited glenohumeral motion with increased scapular motion, especially elevation.

Common Activity Limitations and Participation Restrictions (Functional Limitations and Disabilities)

- Inability to reach overhead, behind head, out to the side, and behind back; thus, having difficulty dressing (putting on a jacket or coat or in the case of women, fastening undergarments behind their back), reaching hand into back pocket of pants (to retrieve wallet), reaching out a car window (to use an ATM machine), self-grooming (combing hair, brushing teeth, washing face), and bringing eating utensils to the mouth
- Difficulty lifting weighted objects, such as dishes into a cupboard
- Limited ability to sustain repetitive activities

Glenohumeral Joint Hypomobility: Management—Protection Phase

See 'General Guidelines for Management When Symptoms are Acute' in Chapter 10 and Box 10.1.

Control Pain, Edema, and Muscle Guarding

- The joint may be immobilized in a sling to provide rest and minimize pain.
- Intermittent periods of passive or assisted motion within the pain free/protected ROM and gentle joint oscillation

*45,74,104,144,145,148,174,214

techniques are initiated as soon as the patient tolerates movement in order to minimize adhesion formation.

- Gentle soft tissue mobilization to the cervical and periscapular muscles may improve patient comfort and minimize guarding, as may cervical range of motion and/or cervical grade I or II passive intervertebral mobilizations/manipulations.

Maintain Soft Tissue and Joint Integrity and Mobility

PRECAUTION: If there is increased pain or irritability in the joint after use of the following techniques, either the dosage was too strong or the techniques should be modified by decreasing the range of passive movement or delaying joint glides.

CONTRAINDICATION: If there are mechanical restrictions causing limited motion, appropriate tissue stretching should be initiated only *after* the inflammation subsides.

- *Passive range of motion* (PROM) in all ranges of pain-free motion (see Chapter 3). As pain decreases, the patient is progressed to active ROM with or without assistance, using activities such as rolling a small ball or sliding a rag on a smooth table top in flexion, abduction, and circular motions. Be sure the patient is taught proper mechanics and avoids faulty patterns, such as scapular elevation or a slumped posture.
- *Passive joint distraction and glides, grade I and II* with the joint placed in a pain-free position (see Chapter 5).
- *Pendulum (Codman's) exercises* are techniques that use the effects of gravity to distract the humerus from the glenoid fossa.[33,36] They help relieve pain through gentle traction and oscillating movements (grade II) and provide early motion of joint structures and synovial fluid. No weight is used during this phase of treatment (see Fig. 17.22).

CLINICAL TIP

Many patients perform pendulum exercises incorrectly by utilizing the GH muscles and performing large motions; the technique must be taught as small, gentle pendular motions initiated with body swaying.[116]

- *Gentle muscle setting* to all muscle groups of the shoulder and adjacent regions, including cervical and elbow muscles because of their close association with the shoulder girdle. Instructions are given to the patient to gently contract a group of muscles while slight manual resistance is applied—just enough to stimulate a muscle contraction without provoking pain. The emphasis is on rhythmic contracting and relaxing of the muscles to help stimulate blood flow and prevent circulatory stasis.

Maintain Integrity and Function of Associated Regions

- Complex regional pain syndrome type I (reflex sympathetic dystrophy) is a potential complication after shoulder injury or immobility. Therefore, additional exercises, such as having the patient repetitively squeeze a ball or other soft object, may be given for the hand.
- The patient is educated on the importance of keeping the joints distal to the shoulder complex as active and mobile as possible. The patient or family member is taught to perform ROM exercises of the elbow, forearm, wrist, and fingers several times each day while the shoulder is immobilized. If tolerated, active or gentle resistive ROM is preferred to passive ROM for a greater effect on circulation and muscle integrity.
- If edema is noted in the hand, instruct the patient to elevate the hand above the level of the heart whenever possible.
- Cervical ROM (active and/or passive), intervertebral joint mobilizations, and soft tissue mobilization should also be considered.

CLINICAL TIP

For conditions in which there is potentially a prolonged acute/inflammatory stage, such as with rheumatoid arthritis and during Stages I or II of idiopathic frozen shoulder, it is critical to teach the patient active-assistive exercises to maintain muscle and joint integrity and as much mobility as possible without exacerbating the symptoms.

GH Joint Hypomobility: Management—Controlled Motion Phase

When symptoms are subacute, follow the guidelines as described in Chapter 10, Box 10.2, emphasizing joint mobility, neuromuscular control, and instructions to the patient for self-care.

Control Pain, Edema, and Joint Effusion

- *Functional activities.* It is important to carefully monitor activities. If the joint is immobilized, the amount of time the shoulder is free to move each day is progressively increased.
- *Range of motion.* ROM for glenohumeral and scapula motions is progressed up to the point of pain. The patient is instructed in the use of self-assistive ROM techniques, such as the wand exercises or hand slides on a table.

PRECAUTION: With increased pain or decreased motion after these techniques, the activity may be too intense or the patient may be using faulty mechanics. Reassess the technique and modify it by restricting the joint to a safer range of motion, correcting faulty movements, or altering the intensity, frequency, and/or duration of the technique.

Progressively Increase Joint and Soft Tissue Mobility

- *Passive joint mobilization techniques.* Grade III sustained or grade III and IV oscillations that focus on the restricted capsular tissue at the end of the available ROM are used to increase joint capsule mobility[100,150,211] (see Box 17.1 and

Figs. 5.15 through 5.20 in Chapter 5). End-of-range techniques include rotating the humerus and then applying either a grade III distraction or a grade III glide to stretch the restrictive capsular tissue or adhesions (see Figs. 5.17, 5.21, and 17.20).

- Use a grade I distraction with all gliding techniques. If the joint is highly irritable and gliding in the direction of restriction is not tolerated, glide in the opposite direction. As pain and irritability decrease, begin to glide in the direction of restriction.[100]

FOCUS ON EVIDENCE

Evidence supporting joint mobilization techniques is limited. A multiple-subject case study, using seven subjects with adhesive capsulitis of the glenohumeral joint (mean disease duration 8.4 months, range 3 to 12 months) treated with end-range mobilization techniques twice a week for 3 months, showed increased active and passive range and increased capacity of the joint capsule at the end of treatment and at the 9-month follow-up. No control groups were used; therefore, the natural course of the disease could not be excluded as the explanation for improvement.[211]

A follow-up study by the same author randomly assigned 100 subjects with stage II adhesive capsulitis to a group receiving high-grade mobilization techniques (end-range stretching using Maitland grade III or IV) or a group receiving low-grade mobilization techniques (Maitland grade I or II in nonstressful positions). After 3 months of treatment, both groups exhibited clinically significant improvement, with the group receiving the high-grade mobilization techniques showing greater improvement than the low-grade mobilization group. Because there was no control group, natural progression could not be ruled out.[212]

A study exploring the effect of the direction of joint mobilization demonstrated that a posterior glide was more effective than an anterior glide to increase glenohumeral external rotation range of motion. Patients with stage II to IV primary adhesive capsulitis received distraction plus grade III sustained mobilizations, held for at least 1 minute, with treatment duration of 15 minutes, for 6 treatment sessions. Anterior mobilizations were progressed by placing the humerus at end-range abduction and external rotation, while posterior mobilizations were progressed by placing the humerus at end-range flexion and external rotation. At the end of the sixth visit, subjects in the anterior mobilization group ($n = 10$) had an increase in external rotation ROM of 3.0°, while those in the posterior mobilization group ($n = 8$) had an increase of 31.3°, a difference that was statistically significant.[99]

PRECAUTION: Carefully monitor the joint reaction to the mobilization stretches; if irritability increases, grade III or IV techniques should not be undertaken until the chronic stage of healing.

- *Self-mobilization techniques.* The following self-mobilization techniques may be used for a home program.
  - CAUDAL GLIDE. *Patient position and procedure:* Sitting on a firm surface and grasping the fingers under the edge. The patient then leans the trunk away from the stabilized arm (Fig. 17.8).
  - ANTERIOR GLIDE. *Patient position and procedure:* Sitting with both arms behind the body or lying supine supported on a solid surface. The patient then leans the body weight between the arms (Fig. 17.9).

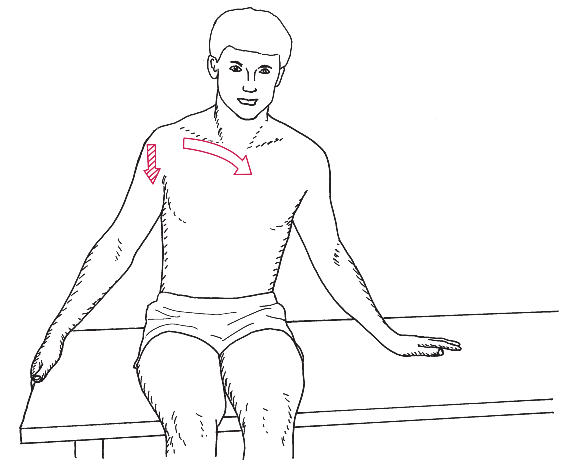

FIGURE 17.8 Self-mobilization. Caudal glide of the humerus occurs as the person leans away from the fixed arm.

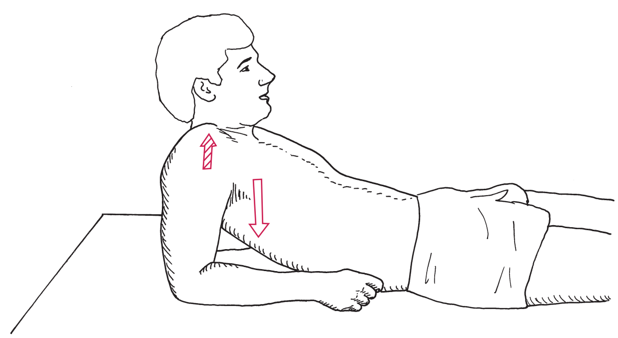

FIGURE 17.9 Self-mobilization. Anterior glide of the humerus occurs as the person leans between the fixed arms.

  - POSTERIOR GLIDE. *Patient position and procedure:* Prone, propped up on both elbows. The body weight shifts downward between the arms (Fig. 17.10).
- *Manual stretching.* Manual stretching techniques are used to increase mobility in shortened muscles and related connective tissue.
- *Self-stretching exercises.* As the joint reaction becomes predictable and the patient begins to tolerate stretching, self-stretching techniques are taught (see Figs. 17.24 through 17.29 in the exercise section).

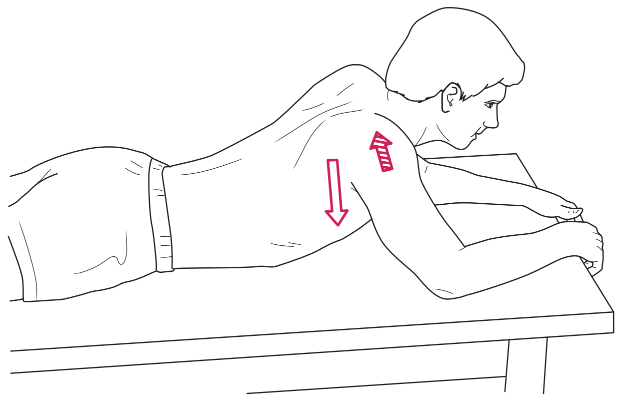

FIGURE 17.10 Self-mobilization. Posterior glide of the humerus occurs as the person shifts his weight downward between the fixed arms.

Inhibit Muscle Spasm and Correct Faulty Mechanics

Muscle spasm may lead to a faulty deltoid-rotator cuff mechanism and scapulohumeral rhythm when the patient attempts arm elevation (Fig. 17.11). The head of the humerus may be positioned cranially in the joint, making it difficult and/or painful to elevate the arm because the greater tuberosity impinges on the coracoacromial arch. In this case, repositioning the head of the humerus with a caudal glide is necessary before proceeding with any other form of shoulder exercise. The patient also needs to learn to avoid "hiking the shoulder"

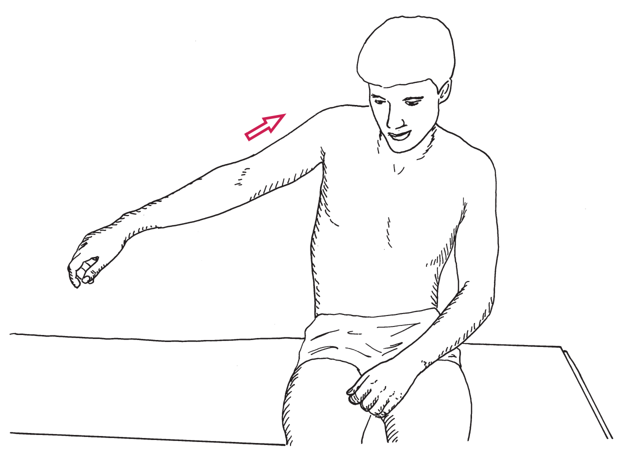

FIGURE 17.11 Poor mechanics with the patient hiking the shoulder while trying to abduct it, thus failing to upwardly rotate the scapula and elevating rather than depressing the humeral head.

when at rest or when elevating the arm. The following techniques may address these problems and faulty mechanics. See also 'Mobilization with Movement Techniques' in the next section.

- Gentle joint oscillation techniques to help decrease the muscle spasm (grade I or II).
- Sustained caudal glide joint techniques to reposition the humeral head in the glenoid fossa.
- Protected weight bearing, such as leaning hands against a wall or on a table, stimulates co-contraction of the rotator cuff and scapular stabilizing muscles and improves synovial fluid movement through hyaline cartilage compression. Techniques are progressed by gentle rocking forward/backward and side-to-side, moving from bilateral to unilateral, increasing the angle of the joint, or adding perturbations.
- GH internal/external rotation strengthening to facilitate stabilization of the humeral head (see Fig. 17.52).
- Movement retraining to minimize the substitution pattern of scapular elevation can be initiated by providing the visual feedback of a mirror or the tactile feedback of the opposite hand placed on the ipsilateral upper trapezius.

Improve Joint Tracking

Mobilization with movement (MWM) techniques may assist with retraining muscle function for proper tracking of the humeral head.[137]

- *Shoulder MWM for painful restriction of shoulder external rotation* (Fig. 17.12).
  - *Patient position:* Supine lying with folded towel under the scapula; the elbow is near the side and flexed to 90°. A cane is held in both hands.

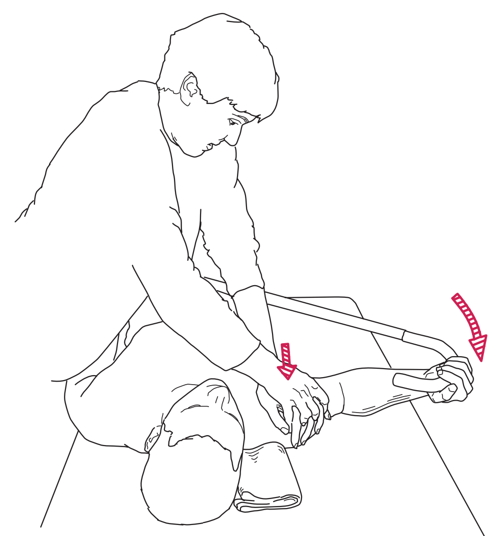

FIGURE 17.12 Mobilization with movement (MWM) to improve external rotation. A posterolateral glide is applied to the humeral head while the patient pushes the arm into the end-range of external rotation with a cane.

  - *Therapist position and procedure:* Stand on the opposite side of the bed facing the patient and reach across the patient's torso to cup the anteromedial aspect of the head of the humerus with reinforced hands. Apply a pain-free graded posterolateral glide of the humeral head on the glenoid. Instruct the patient to use the cane to push the affected arm into the previously restricted range of external rotation. Sustain the movement for 10 seconds and repeat in sets of 5 to 10. It is important to maintain the elbow near the side of the trunk and

ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function.

- *Shoulder MWM for painful restriction of internal rotation* and inability to reach the hand behind the back (Fig. 17.13).
  - *Patient position:* Standing with a towel draped over the unaffected upper trapezius and affected hand at current range of maximum pain-free position behind back. The patient's hand on the affected side grasps the towel behind the back.

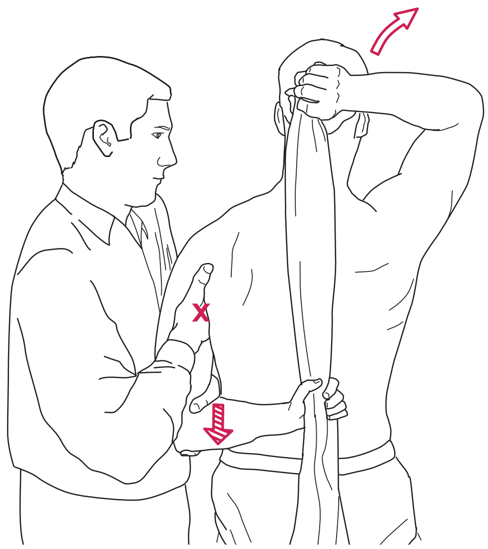

FIGURE 17.13 MWM to improve internal rotation. An inferior glide is applied to the humerus while the patient pulls the hand up the back with a towel.

  - *Therapist position and procedure:* Stand facing the patient's affected side. Place the hand closest to the patient's back high up in the axilla with the palm facing outward to stabilize the scapula with an upward and inward pressure. With the hand closest to the patient's abdomen, hook the thumb in the cubital fossa and grasp the lower humerus to provide an inferior glide. Your abdomen is in contact with the patient's elbow to provide an adduction force to the arm. Have the patient pull on the towel with the unaffected hand to draw the affected hand up the back while the mobilization force is being applied in an inferior direction. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of glide as needed to achieve pain-free function. Maximal glide should be applied to achieve end-range loading.
- *Shoulder MWM for painful arc or impingement signs.* If impingement signs are present in addition to the capsular restrictions, the MWM active elevation technique may be appropriate. (See Fig. 17.17 and description in the impingement section.)

Improve Muscle Performance

- Faulty postures or shoulder girdle mechanics, such as scapula elevation or protraction or excessive trunk movement, displayed when moving the upper extremity in various functional patterns should first be identified and corrected. Manual techniques, stretches, and strengthening exercises are initiated to correct muscle length or strength imbalances, followed by an emphasis on developing active control of weak musculature. As the patient learns to activate the weak muscles, progress to strengthening in functional patterns.
- Because faulty postures or shoulder girdle mechanics may be impacted by impaired trunk strength or control, an emphasis on trunk stability should also be considered. Exercises to manage faulty spinal posture are described in Chapter 16, with active cervical retraction and thoracic extension especially important for shoulder function.
- After proper mechanics are restored, the patient should perform active ROM of all shoulder motions daily and return to functional activities to the extent tolerated.

GH Joint Hypomobility: Management—Return to Function Phase

For joint impairments in the chronic stage, follow the guidelines described in Chapter 10, Box 10.4.

Progressively Increase Flexibility and Strength

- Stretching and strengthening exercises are progressed as the joint tissue tolerates. The patient should be actively involved in self-stretching and strengthening by this time, so emphasis during treatment is on maintaining correct mechanics, safe progressions, and exercise strategies for return to function. Progressions may include increasing resistance and repetitions, performing exercises through multiple planes, adding perturbations, and incorporating regional muscle groups (such as the trunk) into dynamic exercises.
- If capsular tissue is still restricting ROM, vigorous manual stretching and joint mobilization techniques are applied.

Prepare for Functional Demands

If the patient is involved in repetitive heavy lifting, pushing, pulling, carrying, or reaching, exercises are progressed to replicate these demands. See the last section of this chapter and Chapter 23 for suggestions.

GH Joint Management: Postmanipulation Under Anesthesia

Occasionally, no progress is made, and the physician chooses to perform manipulation under anesthesia. Following this procedure, there is an inflammatory reaction and the joint is treated as an acute lesion. If possible, joint mobility and passive ROM techniques are initiated while the patient is still in the recovery room. Surgical intervention with incision of the dependent capsular fold may be used if the adhesions are not broken with the manipulation.

Postoperative treatment is the same with the following considerations.[148]

- The arm is kept elevated overhead in abduction and external rotation during the inflammatory reaction stage; treatment principles progress as with any joint lesion.
- Therapeutic exercises are initiated the same day while the patient is still in the recovery room, with emphasis on internal and external rotation in the 90° (or higher) abducted position.
- Joint mobilization procedures are used, particularly a caudal glide, to prevent readherence of the inferior capsular fold.
- When sleeping, the patient may be required to position the arm in abduction for up to 3 weeks after manipulation.

Acromioclavicular and Sternoclavicular Joints

Related Pathologies and Etiology of Symptoms

Overuse syndromes. Overuse syndromes of the AC joint may be from repeated stressful movement of the joint with the arm at waist level, such as with grinding, packing assembly, and construction work,[75] or repeated diagonal extension, adduction, and internal rotation motions, as when spiking a volleyball or serving in tennis. The AC joint is susceptible to overuse syndromes in conjunction with arthritis or following a traumatic injury.

Subluxation or dislocation. Subluxation or dislocation of either joint usually is caused by falling against the shoulder or against an outstretched arm. At the AC joint, the distal end of the clavicle often displaces posteriorly and superiorly on the acromion, and the ligaments supporting the AC joint may rupture.[147] Clavicular fractures may also result from a fall or other high force events such as a motor vehicle accident.[147] After trauma and associated overstretching of the capsules and ligaments of either joint, hypermobility is usually permanent because there are almost no muscles that provide direct stability to these joints.

Hypomobility. Decreased clavicular mobility may occur with SC joint osteoarthritis and may contribute to a thoracic outlet syndrome (TOS) with a compromise of space for the neuromuscular bundle as it courses between the clavicle and first rib (described in Chapter 13).

Common Structural and Functional Impairments

- Pain localized to the involved joint or ligament.
- Painful arc toward the end-range of shoulder elevation.
- Pain with shoulder horizontal adduction or abduction.
- Hypermobility in the joints if trauma or overuse is involved.
- Hypomobility in the joints if sustained posture, arthritis, or immobility is involved.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Limited ability to sustain repeated forceful movements of the arm, such as with grinding, packing, assembly, and construction work.[75]
- Inability to reach overhead or perform repetitive overhead activities without pain.

Nonoperative Management of AC or SC Joint Strain or Hypermobility

- Minimize joint loading by supporting the weight of the arm with a sling.
- Cross-fiber massage to the capsule or ligaments.
- Maintain ROM of the glenohumeral joint and scapulothoracic articulation.
- Instruction in self-application of cross-fiber massage if joint symptoms occur after excessive activity.
- Increase strength of shoulder complex, trunk, and legs.
- Gradually return to functional activities

Nonoperative Management of AC or SC Joint Hypomobility

Joint mobilization techniques are used to increase joint mobility (see Figs. 5.22 through 5.24).

Glenohumeral Joint Surgery and Postoperative Management

Severe deterioration of one or both surfaces of the GH joint or an acute or nonunion fracture of the proximal humerus often must be managed with surgical intervention. Underlying pathologies that cause advanced joint destruction include late-stage osteoarthritis (OA), rheumatoid arthritis (RA), traumatic arthritis, cuff tear arthropathy, and osteonecrosis (avascular necrosis) of the head of the humerus as the result of a fracture of the anatomical neck of the humerus or long-term use of steroids for systemic disease.

The most common surgical procedure used to treat advanced shoulder joint pathology is *glenohumeral arthroplasty*, often simply referred to as *shoulder arthroplasty*.[38] In rare situations, *arthrodesis* (surgical ankylosis) of the GH joint may have to be selected as an alternative to arthroplasty or as a salvage procedure.[126]

The goals of these surgical procedures and the postoperative rehabilitation program are to: (1) relieve pain, (2) improve shoulder mobility or stability, and (3) restore or improve strength and functional use of the upper extremity. The extent to which these goals are achieved is predicated on the patient's participation in postoperative rehabilitation; the distinguishing features and severity of the underlying pathology; the prosthetic design and surgical techniques; the integrity of the rotator cuff mechanism and other soft tissues; and the age, overall health, and anticipated activity level of the patient.[38,126,182,189]

Glenohumeral Arthroplasty

Arthroplasty of the GH joint falls into several categories, the most common of which are *total shoulder arthroplasty (TSA)*,[126,141,182,189] in which the glenoid and humeral surfaces are replaced (Fig. 17.14), and *hemireplacement arthroplasty (hemiarthroplasty)*, in which one surface, the humeral head, is replaced.[6,63,126,143,182,239] *Reverse total shoulder arthroplasty (rTSA)* is another type of arthroplasty, typically used when the rotator cuff integrity is compromised.[42,129,216] Other categories of shoulder arthroplasty include interpositional and resurfacing arthroplasties, which involve less extensive removal of bone.[126,182,189,206]

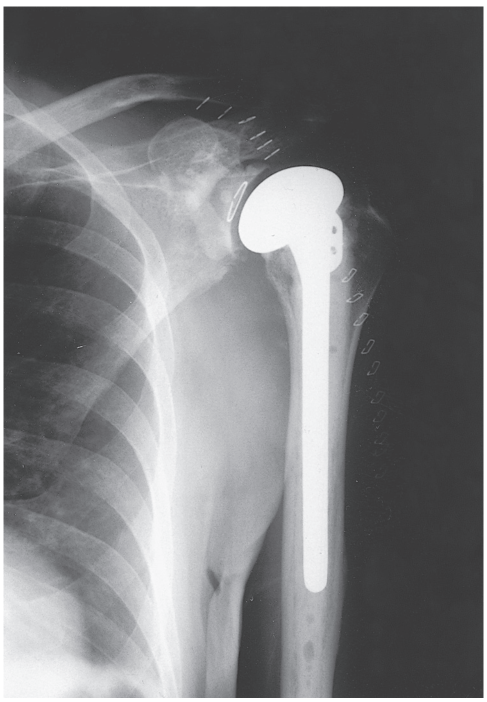

FIGURE 17.14 Postoperative anterior-posterior view of the shoulder showing a Neer II type of cemented humeral prosthesis and a nonmetal backed polyethylene glenoid. *(From Tovin, BJ, Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice.* Philadelphia, FA Davis, 2001, p 266, with permission.*)*

Indications for Surgery

The following structural and functional impairments associated with these pathologies are widely accepted indications for GH arthroplasty.*

- The primary indication is persistent and incapacitating pain (at rest or with activity) secondary to GH joint destruction.
- Secondary indications include loss of shoulder mobility or stability and/or upper extremity strength leading to inability to perform functional tasks with the involved upper extremity.

Procedures

Background

Implant design, materials, and fixation. Since the pioneering work of Neer during the 1960s and 1970s[141,143] and many other investigators,[29] prosthetic designs and surgical techniques for replacing the shoulder joint have continued to evolve. The designs of current-day TSA hardware, composed of a high-density polyethylene glenoid component (usually all plastic) and a modular inert metal humeral component, closely approximate the biomechanical characteristics of the human shoulder.[232] The exception to this is the rTSA, the design of which reverses the ball and socket location of the native shoulder. Specifically, the glenoid fossa is replaced with a convex, "glenospherical" component attached to a glenoid base and the humeral head with a stemmed cup.[213] Fixation of the prosthetic components is achieved with a press fit, bioingrowth, or cement. The type of fixation selected by the surgeon depends on the component (glenoid or humeral), the underlying pathology, and the quality of the bone stock. Cement fixation is most often necessary in patients with osteoporosis.*

The designs of total shoulder replacements, ranging from *unconstrained* to *semiconstrained* to *constrained,* provide varying amounts of mobility and stability to the GH joint. Box 17.3 summarizes the characteristics of each of these designs.[38,125,126,180,182,189,206]

NOTE: The description of constrained designs is included in Box 17.3 for historical purposes and for a comparison with less constrained designs. Because of the high rate of complications that occurs with constrained designs, these implant systems are rarely, if ever, used today.[38,126]

Selection of procedure. Controversy exists over the specific criteria for selection of TSA versus rTSA versus hemiarthroplasty, but in general, it depends on the etiology and severity of the joint deterioration and the condition of the periarticular soft tissues, particularly the rotator cuff mechanism.[126,190] Several examples that follow underscore the complexity of the clinical decision-making process involved in the choice of operative procedure and prosthetic design.

In patients with late-stage primary OA, the GH joint typically exhibits loss or thinning of the articular cartilage of the head of the humerus and the posterior portion of the glenoid fossa. The rotator cuff is intact in approximately 90% to 95% of these patients, making them good candidates for either TSA or hemiarthroplasty.[38,125,161,180,182,189] However, opinions vary on whether selection of an unconstrained TSA yields results that are better than or equal to those of hemiarthroplasty for shoulders with these characteristics.[38,126,157,182,192]

Chronic synovitis, associated with RA and other types of synovium-based arthritis, tends to erode periarticular soft tissues in addition to the articular surfaces of a joint. As a consequence, a full-thickness tear of a rotator cuff tendon (typically the supraspinatus) develops in 25% to 40% of these

[*] 38,125,126,197,232

BOX 17.3 Designs of Prosthetic Implants for Total Shoulder Arthroplasty

Unconstrained
- Anatomical design with a small, shallow glenoid component combined with a stemmed humeral component
- The most frequently used prosthetic design
- Provides the greatest freedom of shoulder motion but no inherent stability
- Indicated when the rotator cuff mechanism is intact or can be repaired to provide dynamic stability to the GH joint

Semiconstrained
- A larger glenoid component that is hooded or cup-shaped
- Some degree of joint stability inherent in the design
- Indicated when erosion of the glenoid fossa can be compensated for by reaming the fossa and rotator cuff function; although deficient preoperatively, can be improved by repair

Reversed Ball and Socket
- Small humeral socket that slides on a larger ball-shaped glenoid component
- Couples some degree of stability with mobility for rotator cuff-deficient shoulders that cannot be repaired
- Provides an alternative to standard, semiconstrained total shoulder arthroplasty (TSA) and hemiarthroplasty

Constrained
- Fixed fulcrum, ball-in-socket designs with congruency of the glenoid and humeral components
- Greatest amount of inherent joint stability but less mobility than less constrained designs
- Once thought to be an alternative to hemiarthroplasty for the selected patient with a deficient rotator cuff or cuff tear arthropathy or chronic/recurrent GH joint dislocation after a previous TSR
- Rarely used today owing to high rate of loosening or failure of the components

patients and a rupture of the biceps tendon in an even greater percentage.[63,180,189,197,206] If the soft tissues can be repaired and their functions improved, a semiconstrained TSA that may include bone grafting at the glenoid to improve prosthetic fixation may be indicated. If an effective cuff repair cannot be achieved, an rTSA is usually indicated. When there is insufficient bone stock for fixation of a glenoid implant, hemiarthroplasty is usually the procedure of choice.[63,126,180,182,190,197,206]

Hemiarthroplasty is often used when the articular surface and underlying bone of the humeral head have deteriorated, but the glenoid fossa is reasonably intact, as seen with osteonecrosis of the head of the humerus.[38,126,189] A patient with severe, chronic pain and loss of function as the result of a massive, irreparable cuff tear and subsequent development of a *cuff tear arthropathy* typically is a candidate for rTSA. (First used by Neer, the term "cuff tear arthropathy" refers to deterioration and eventual collapse of the head of the humerus, an infrequent but debilitating long-term result of a primary, massive, and irreparable tear of the rotator cuff.)[126,180,221,239]

Chronic deficiency of the rotator cuff mechanism leads to superior migration of the head of the humerus in the glenoid fossa. If a glenoid component is inserted under these conditions, the superior migration creates an incongruous articulation that accentuates the risk of loosening and premature wear of the glenoid implant.[37,82,180] The rTSA was developed to overcome this complication by eliminating translation between the glenosphere and humeral articular surface. Other features of the rTSA include reduced forces on the glenoid component, inherent stability owing to the congruency of the components, and increased deltoid moment arms. One limitation of the rTSA design is a decrease in glenohumeral range of motion.[23,129,213]

Operative Procedures

TSA, rTSA, and hemiarthroplasty are open surgical procedures performed with the patient in a semi-reclining position. These operative procedures involve the following components*: (1) anterior approach using a deltopectoral incision that extends from the AC joint to the deltoid insertion for adequate surgical exposure; (2) release (tenotomy) of the subscapularis tendon from its proximal attachment on the lesser tuberosity; (3) anterior capsulotomy; (4) exposure of the humeral head for a humeral osteotomy; and (5) preparation of the humeral canal for insertion of the prosthetic implant. The glenoid fossa is débrided and for a TSA is precisely contoured, so the glenoid implant can be placed flush within the fossa. The subscapularis is then reattached and may be lengthened (medial advancement or Z-plasty) if external rotation is limited.

Reconstruction and balancing of soft tissues is critical for optimal function after TSA, rTSA, and hemiarthroplasty. "Balancing" refers to the intraoperative lengthening or tightening of soft tissues to restore as near-normal resting tension in the tissues as possible, particularly in the rotator cuff, biceps, and deltoid muscle-tendon units.

Concomitant procedures that may be necessary during shoulder arthroplasty include:

- Repair of a deficient rotator cuff if the quality of the cuff tissue is sufficient.
- Capsular plication and tightening for chronic subluxation or dislocation (usually posterior) of the GH joint.
- Anterior acromioplasty for a history of impingement syndrome.
- Bone graft of the glenoid if bone stock is insufficient for fixation of the glenoid implant.

After implantation of the prosthetic component(s) and repair of soft tissues but before closure of the skin incision, the shoulder is passively moved through all planes of motion to visually evaluate the stability of the prosthetic joint and the integrity of the repaired soft tissues. This determines the

*6,38,63,126,182,189

anatomical ROM possible after surgery and how aggressive the postoperative program can be.[38,126]

Complications

Although the incidence of intraoperative and postoperative complications after current-day arthroplasty is low, even a single complication can adversely affect the functional outcome. The incidence of complications after TSA tends to be higher in patients with a deficient rotator cuff mechanism, osteoporosis, and a preoperative history of chronic GH joint instability.[81] Aside from medical complications, such as infection or a deep vein thrombosis, complications specific to shoulder arthroplasty are noted in Box 17.4.[37,81]

Postoperative Management

NOTE: Effective patient education and close communication among the therapist, surgeon, and patient are the basis of an effective and safe rehabilitation program. Postoperative management is individualized to address the specific surgical procedures used and to meet the unique needs of each patient.

Special Considerations

Integrity of the rotator cuff. Regardless of the underlying cause of late-stage glenohumeral arthritis, the goals, components, and rate of progression of a rehabilitation program after TSA or hemiarthroplasty are influenced by the pre- and postoperative integrity of the rotator cuff mechanism. The rehabilitation program for a patient with an intact rotator cuff prior to shoulder arthroplasty can be progressed more rapidly than the program for a patient with coexisting rotator cuff deficiency requiring a concomitant cuff-tendon repair at the time of shoulder arthroplasty.

If the rotator cuff was intact prior to surgery, the emphasis of postoperative rehabilitation is to restore shoulder mobility and functional use of the arm as soon as possible while protecting soft tissues as they heal. In contrast, with a tenuous repair, or a preoperative history of recurrent GH dislocation, rehabilitation must place greater emphasis on improving or maintaining joint stability for functional use of the arm than on increasing shoulder mobility.[47,52,57,103,126]

Intraoperative ROM. Goals for safe, stable postoperative ROM are based on intraoperative ROM measurements taken prior to closing the surgical incision. For a patient with an unconstrained TSA and sufficient postoperative shoulder stability (static and dynamic), the goal at the conclusion of rehabilitation is to achieve active ROM equal to intraoperative ROM—ideally, 140° to 150° of shoulder elevation and 45° to 50° of external rotation.[47,126] For a patient with more constrained TSA, a deficient rotator cuff mechanism, or capsuloligamentous laxity, intraoperative ROM is typically less, and postoperative goals focus more on developing dynamic stability and less on shoulder mobility. Following rTSA, ROM is limited to 0° to 20° external rotation and 90° to 120° elevation for 3 months.[23,129]

Posture. If the postural changes associated with aging[108] (increased thoracic kyphosis and scapular protraction) are present, it is important to emphasize an erect sitting or standing posture during elevation of the arm and to incorporate spinal extension and scapular retraction exercises into the postoperative program.

Immobilization and Postoperative Positioning

At the close of the surgical procedure, the operated arm is placed in some type of shoulder immobilizer, usually a sling or sometimes a splint, to protect reattached and repaired soft tissues and for comfort.[6,38,126,180,189,208] Early postoperative positioning that protects the operated shoulder is detailed in Box 17.5.

Initially, the sling or splint is removed only for exercise and bathing. A patient who did not require repair of the rotator cuff is weaned from the sling during the day as quickly as possible to prevent postoperative stiffness. However, a patient who has undergone a cuff repair or other soft tissue reconstruction may need to wear a sling or splint while out in crowded areas or during sleep for approximately 4 to 6 weeks to protect the repaired tissues until sufficient healing has occurred.[24,27,38,47,52,53,103,126,198]

A patient who has undergone rTSA wears a shoulder immobilizer (sling and swathe) continuously for at least 3 to 4 weeks following surgery except for daily personal hygiene and periodic PROM (pendulum exercises) during the day.[129]

Exercise Progression

The guidelines for progression of exercises during each phase of rehabilitation after TSA, rTSA, or hemiarthroplasty presented in this section are drawn from the limited number of published protocols available, all of which are based on

BOX 17.4 Complications Specific to Glenohumeral Arthroplasty

Intraoperative Complications

- Insufficient lengthening of a tight subscapularis muscle-tendon unit
- Intraoperative damage to the axillary or suprascapular nerves, affecting the deltoid and supraspinatus/infraspinatus muscles, respectively
- Fracture of the humerus

Soft Tissue-Related Postoperative Complications

- Re-tearing a repaired rotator cuff mechanism
- Postoperative disruption of the repaired subscapularis
- Chronic instability or dislocation of the GH joint
- Incidence of dislocation is higher after rTSA than TSA
- Progressive erosion of the articular surface of the glenoid fossa (after hemiarthroplasty)

Implant-Related Postoperative Complications

- After TSA mechanical (aseptic) loosening, premature wear, or fracture of the polyethylene glenoid implant
  - Most often seen in a rotator cuff-deficient shoulder
  - Due to excessive stresses at the bone–prosthesis interface
  - Low incidence with unconstrained designs but higher with early-generation constrained designs
- Loosening of the humeral prosthesis after hemiarthroplasy

BOX 17.5 Positioning After Shoulder Arthroplasty: Early Postoperative (Maximum Protection) Phase

Supine

- Arm immobilized in sling that is worn continuously
  - Elbow flexed to 90°
  - Forearm and hand resting on abdomen
- Arm supported at the elbow on a folded blanket or pillow slightly away from the side and anterior to the midline of the trunk
  - Forward flexion (10° to 20°), slight abduction, and internal rotation of the shoulder
  - Head of bed elevated about 30°

Sitting

- Arm supported in sling or resting on a pillow in the patient's lap or on the armrest of a chair

With Tenuous Rotator Cuff Repair

- In some cases, if a sling does not provide adequate protection of a repaired cuff, an abduction splint must be worn

clinical experience rather than evidence from controlled studies and none of which has been shown to be more effective than another.* Almost all of these protocols are time-based, with few criteria reported for advancing a patient from one phase of rehabilitation to the next.

Recently, however, several resources have suggested such criteria.[23,39,52,213,221] It is important to note that these criteria and suggested timelines for progression of exercises and functional activities must be adapted to each patient based on periodic evaluations of the patient's status and ongoing communication between the therapist and the surgeon.

NOTE: The exercise guidelines in this section are for patients *without* preoperative rotator cuff deficiency and who *did not* undergo a cuff repair during TSA or hemiarthroplasty. For patients with a poor quality rotator cuff mechanism or who underwent rTSA, modifications in guidelines are noted. A comparison of postoperative exercise guidelines and precautions following TSA versus rTSA are summarized in Table 17.3.

*24,27,39,47,52,102,103,108,126,198,221

TABLE 17.3 Comparison of Exercise Guidelines and Precautions Following Total Shoulder Arthroplasty and Reverse Total Shoulder Arthroplasty

	Total Shoulder Arthroplasty (Intact Rotator Cuff)	Reverse Total Shoulder Arthroplasty
Progression of rehab	Phase 1: postop weeks 0–4 Phase 2: postop weeks 4–12 Phase 3: postop weeks 12+	Phase 1: postop weeks 0–6 Phase 2: postop weeks 6–12 or 16 Phase 3: postop weeks 12+ or 16+
Immobilization	■ No immobilizer unless rotator cuff repaired ■ Sling worn for comfort when shoulder unsupported and when in crowded, public areas or during sleep for about 4 weeks ■ Sling removed for exercise soon after surgery as directed by surgeon	■ Abduction splint (shoulder in scapular plane) ■ Worn 24 hours/day for first 3–4 or up to 6 weeks ■ Removed for pendulum exercises 3–4 times/day and personal hygiene
ROM restrictions	*Limit from 0–4 weeks:* ■ Elevation of the arm: up to 120° ■ External rotation up to 30° (arm at side) *Limit for 4–6 weeks:* ■ No GH extension past neutral *After 6–12 weeks* ■ Combined adduction, internal rotation, extension permitted	*Limit for 12 weeks or more:* ■ No GH extension or internal rotation past neutral ■ No combined GH extension, adduction, internal rotation ■ 0°–20° external rotation and up to 90°–120° arm elevation in scapular plane
ROM exercises, stretching, and joint mobilization	*During Phase 1:* ■ Grade I /II joint oscillations ■ AROM: scapula and distal extremity joints only ■ Pendulum exercises ■ PROM→A-AROM GH joint —Perform in *supine* (0–3 weeks) —Progress to A-AROM in sitting and standing ■ AROM of GH joint by 4–6 weeks ■ No *active* internal rotation for at least 6 weeks (protect subscapularis repair)	*During Phase 1* (when immobilizer can be removed): ■ Grade I /II joint oscillations ■ AROM: scapula and distal extremity joints only ■ Pendulum exercises ■ PROM only of GH joint ■ Observe ROM restrictions

Continued

TABLE 17.3 Comparison of Exercise Guidelines and Precautions Following Total Shoulder Arthroplasty and Reverse Total Shoulder Arthroplasty—cont'd

	Total Shoulder Arthroplasty (Intact Rotator Cuff)	Reverse Total Shoulder Arthroplasty
	During Phase 2: ▪ Continue AROM ▪ Gradually increase GH rotation ▪ Gentle stretching after 6–8 weeks, if needed *During Phase 3:* ▪ Progress end-range self-stretching	*During Phase 2:* ▪ Increase PROM while observing motion restrictions ▪ A-AROM→AROM of GH joint —Begin in supine; progress to sitting, standing —Gradually increase internal rotation past neutral *During Phase 3:* ▪ Gentle stretching, if needed within motion restrictions
Resistance exercises	*During Phase 1:* ▪ Only light, NWB isometrics of ST and deltoid muscles with shoulder in scapular plane *During Phase 2:* ▪ Emphasis on improving function of rotator cuff and ST muscles ▪ Submaximal isometrics of GH muscles combined with light weight bearing through UE ▪ Delay resisted rotation for several weeks (to protect repaired rotator cuff) ▪ Progress to low-resistance dynamic strengthening of elbow and wrist; ST and GH joints if mechanics during AROM allow *During Phase 3* ▪ Progress PRE in functional patterns ▪ Progress closed-chain stabilization exercises	*During Phase 1:* ▪ Only light, NWB isometrics of ST and deltoid muscles with shoulder in scapular plane *During Phase 2:* ▪ Emphasis on improving function of deltoid and ST muscles ▪ Submaximal isometrics (NWB only) of GH and ST muscles ▪ Delay resisted rotation for several weeks (to protect repaired subscapularis and teres minor, if preserved) ▪ Progress to low-resistance, dynamic strengthening of elbow and wrist; ST and GH joints if mechanics during AROM allow —NWB positions only (through week 12) *During Phase 3* ▪ Begin closed-chain stabilization exercises ▪ Progress UE PRE in functional patterns
ADLs precautions	*For first 4 to 6 weeks* ▪ Observe ROM restrictions: —Do not reach behind the back or into hip pocket —When supine, support arm on pillow to avoid GH extension past neutral —Light ADL permitted with *elbow at waist level* (writing, eating, washing face) ▪ Do not lean on involved arm (rising from or sitting down in chair) ▪ Lifting limit: 1 lb (cup of coffee or glass of water) *From 6–12 weeks* ▪ Limit *unilateral* lifting to 3 lb *After 12 weeks* ▪ Ultimate *bilateral* lifting limit: 10–15 lb ▪ Gradual return to light functional activities	*For first 12 weeks:* ▪ Observe ROM restrictions during functional activities —Do not reach behind the back or into hip pocket —When supine, support arm on pillow to avoid GH extension past neutral ▪ By 5–7 *weeks* light ADL permitted with elbow at waist level (writing, eating, washing face) ▪ Do not lean on involved arm (rising from or sitting down in chair ▪ Restrict lifting with operated arm for 12–16 weeks (no heavier than cup of coffee or glass of water) *After 12–16 weeks* ▪ Limit *unilateral* lifting to 6 lb ▪ Ultimate *bilateral* lifting limit: 10–15 lb ▪ Gradual return to light functional activities

A-AROM=Active-assistive ROM; AROM= Active ROM; ADL= Activities of daily living; GH=Glenohumeral, NWB= Nonweight-bearing, ST=Scapulothoracic, UE=upper extremity

CLINICAL TIP

Remember, regardless of implant design, pain relief is the primary goal of shoulder arthroplasty, with improvement in functional mobility a secondary goal. Although improvements in surgical techniques and implant technology now allow more accelerated progression of postoperative rehabilitation than several decades ago, it is still important to proceed judiciously during each phase of rehabilitation to avoid damage to the healing soft tissues, implant loosening, or excessive muscle fatigue or irritation.

Exercise: Maximum Protection Phase

The maximum protection phase of rehabilitation following TSA begins on the first postoperative day and extends for 4 to 6 weeks. The emphasis of this first phase is patient education, pain control, and initiation of ROM exercises to prevent adhesions and restore shoulder mobility as early as possible to the ranges achieved during surgery. Early motion is permissible after uncemented and cemented shoulder arthroplasty.

While the patient is hospitalized (usually for 3 to 4 days after surgery), patient education includes reviewing early postoperative precautions and teaching the initial exercises in the patient's home program. Precautions during the first 4 to 6 weeks after TSA, when protection of soft tissues is crucial, are summarized in Box 17.6. A patient's adherence to these precautions is of the utmost importance during this phase of rehabilitation.

Goals and interventions. The first phase of rehabilitation includes the following.[24,27,39,47,52,53,102,103,126,198]

- ***Control pain and inflammation.***
  - Use of a sling or splint for comfort.
  - Use of prescribed analgesic and anti-inflammatory medication.
  - Use of cryotherapy, especially after exercise.
- ***Maintain mobility of adjacent joints.***
  - Active movements of the spine and scapula (while wearing the shoulder sling and after it can be removed for exercise) to maintain motion and minimize muscle guarding and spasm. Incorporate "shoulder rolls" by elevating, retracting, and then relaxing the scapulae to reinforce an erect posture of the trunk. Emphasize active scapular retraction and spinal extension.
  - Active ROM of the hand, wrist, and elbow when the arm can be removed from the sling.
- ***Restore shoulder mobility.***
  - Passive or therapist-assisted shoulder motions *within the safe ROM limits determined during surgery.* With the patient lying supine and the arm slightly away from the side of the trunk on a folded towel and the elbow flexed, perform elevation of the arm in the plane of the

BOX 17.6 Precautions for the Maximum Protection Phase of Rehabilitation Following Shoulder Arthroplasty

Exercise

- Short but frequent exercise sessions (four or five times per day).
- Low number of repetitions per exercise.
- Only *passive* or *assisted* shoulder ROM exercises and only within the "safe" limits of ranges noted during surgery. *Absolutely no end-range stretching.*
  - Passive external rotation to neutral after rTSA or to less than 30° after TSA to avoid excessive stress to the surgically repaired subscapularis muscle.
  - During passive or assisted shoulder rotation with the patient lying supine, position the humerus slightly anterior to the midline of the body (by placing the arm on a folded towel) to avoid excessive stress to the anterior capsule and suture line.
  - No hyperextension or horizontal abduction (beyond neutral) of the shoulder to avoid stress to the anterior capsule.
  - No combined extension, adduction, and internal rotation
  - If an overhead rope-pulley system is used for assisted elevation of the arm, initially *have the patient face the doorway and pulley apparatus,* so shoulder elevation occurs only within a limited range.
- Maintain an erect trunk during passive or assisted elevation of the arm while sitting or standing to avoid subacromial impingement of soft tissues.
- In most instances, no active (unassisted), antigravity, dynamic shoulder exercises, particularly resisted internal rotation.
- No resistance (strengthening) exercises.
- In general, a more gradual progression of exercises following rTSA and for a patient with a severely damaged and repaired or irreparable rotator cuff mechanism who underwent TSA than for a patient with a preoperatively intact cuff.

Activities of Daily Living

- Limit activities to those that can be performed with the elbow at waist level, such as eating or writing.
- Avoid reaching behind the back to tuck in a shirt, reach into a back pocket, or following toileting.
- Avoid weight bearing (leaning) on the operated extremity, such as pushing during transfers or when moving in bed, especially the first few weeks after surgery.
- Avoid lifting objects with the operated arm.
- Support the arm in a sling during extended periods of standing or walking.
- Wear the sling while sleeping or outside in crowded areas.
- No driving for 4 to 6 weeks.

scapula to tolerance, external rotation to no more than 30° to 45°, and internal rotation until the forearm rests on the chest.

- Pendulum (Codman's) exercises. Encourage the patient to periodically remove the sling and gently swing the arm during ambulation at home.
- Later during this phase, progress to *supine self-assisted* shoulder ROM (elevation and rotation) by assisting with the sound hand and later using a wand or dowel rod. Add horizontal abduction to neutral and adduction across the chest holding a wand.
- Self-assisted shoulder ROM with a wand *in sitting or standing* by performing "gear shift" exercises (see Fig. 17.23), resting the arm on a table and sliding it forward (see Fig. 17.25), or use of an overhead rope-pulley system to lessen the weight of the arm. Remind the patient to maintain an erect trunk when performing assisted shoulder motions while seated or standing.
- Self-assisted reaching movements (to the nose, forehead, or over the head as comfort allows) to simulate functional movements.
- For some patients, transition to *active* (unassisted) shoulder ROM is often possible by 4 weeks.
- Functional activities with the elbow at waist level, such as hand to face and writing, are permissible.

- ***Minimize muscle inhibition, guarding, and atrophy.***
  - Gentle muscle-setting of shoulder musculature (excluding the internal rotators) with the elbow flexed and the shoulder in the plane of the scapula or neutral. Teach these exercises prior to discharge from the hospital by having the patient practice isometric contractions of the muscles of the *sound* shoulder. Postpone setting exercises (light isometrics) of the operated shoulder until about 4 to 6 weeks after surgery.
  - Scapular stabilization exercises in nonweight-bearing positions. Target the serratus anterior and trapezius muscles.

NOTE: For a patient who underwent TSA with repair of a large tear or rupture of a rotator cuff tendon, it may not be permissible to begin ROM exercises immediately after surgery. When the sling or splint can be removed for exercise, perform only passive or assisted ROM throughout the first phase of rehabilitation. The range of shoulder elevation and external rotation initially permitted may be less than for shoulders that did not require cuff repair. Postpone active (unassisted), antigravity ROM and light isometrics until the second phase (approximately 6 weeks postoperatively, when repaired soft tissues are reasonably well healed).

Following rTSA, patients have a lifting limit of 1 lb or less for 6 weeks, and external rotation and elevation ROM are limited to 0° to 20° and 90° to 120°, respectively, for 3 months.[23,129] In addition, shoulder hyperextension, lifting, and supporting of body weight with the involved shoulder are all precautions following rTSA.[23] (Refer to Table 17.3 for additional precautions after rTSA.)

Criteria to progress. Criteria to advance to the second phase of rehabilitation following TSA are:

- ROM: At least 90° of passive elevation, at least 45° degrees of external rotation, and 70° of internal rotation in the plane of the scapula with minimal pain[221] or *almost* full, passive shoulder motion based on intraoperative measurements with little to no pain.[39,103]
- No pain during resisted, isometric internal rotation of the subscapularis.[39]
- Ability to perform most waist-level activities of daily living (ADLs) without pain.[103]
- For rTSA, criteria include tolerance of assisted ROM and demonstration of the ability to isometrically activate the deltoid and periscapular musculature while the joint is positioned in the scapular plane.[23]

Exercise: Moderate Protection/Controlled Motion Phase

Although suggested timelines vary from one resource to another, the moderate protection/controlled motion phase of rehabilitation, which typically begins at about 4 to 6 weeks postoperatively and extends to at least 12 to 16 weeks, focuses on gradually establishing active (unassisted) control, dynamic stability, and strength of the shoulder while continuing to increase ROM.[24,27,47,52,102,103,126,198,221]

PRECAUTIONS: During this phase of rehabilitation, although it is safe to place increasing stresses (stretching or resistance) on periarticular soft tissues, it is important to do so gradually so as not to irritate these tissues, which are continuing to heal. Therefore, continue with short but frequent exercise sessions (preceded by application of heat and followed by cold) and avoid vigorous stretching or resistance exercises or overuse of the involved shoulder during functional activities.

Goals and interventions. The goals and exercises for this phase of rehabilitation are as follows.

- ***Continue to increase ROM of the shoulder.***
  - Transition from passive or assisted ROM to *low-intensity, pain-free* stretching in all anatomical and diagonal planes of motion to achieve intraoperative ROM.
  - Gentle joint mobilization techniques for specific capsular restrictions.
  - In addition to therapist-assisted stretching, teach the patient how to perform gentle self-stretching exercises to increase elevation, internal/external rotation, extension, and horizontal adduction/abduction. Suggestions are pictured in the 'Exercise Techniques' section of this chapter.
- ***Develop active control and dynamic stability and improve muscle performance (strength and endurance) of the shoulder.***
  - Continue or gradually transition to *active* shoulder ROM exercises, initiating antigravity abduction when the patient can perform the movement without elevating the scapula.

- Scapular and GH joint stabilization exercises (alternating isometrics and rhythmic stabilization) progressing from nonweight-bearing to light weight-bearing positions.

NOTE: For patients who have had an rTSA, maintain nonweight-bearing precautions for up to 12 weeks postoperatively.[23]

- Pain-free, low-intensity (submaximal) resisted isometrics of shoulder muscles, particularly the rotator cuff including the subscapularis or any other repaired muscle-tendon units.
- Dynamic resistance exercises for the scapula and shoulder musculature (between 0° and 90° of shoulder elevation) using light weights or light-grade elastic resistance. Begin in the supine position to support and stabilize the scapula and progress to the sitting position.
- Upper extremity endurance training with stationary ergometer or a portable reciprocal exerciser on a table. Emphasize progressive repetitions to increase muscular and cardiopulmonary endurance.

Criteria to progress. To advance to the final phase of rehabilitation, a patient should meet the following criteria.

- Full, passive ROM of the shoulder (based on intraoperative ranges)[39,103] or at least 130° to 140° of pain-free, passive or assisted shoulder flexion and 120° of abduction.[221]
- In the plane of the scapula, at least 60° pain-free, passive external rotation and 70° internal rotation.[221]
- Active (unassisted), antigravity elevation of the arm to at least 100° to 120° in the plane of the scapula while maintaining joint stability and using appropriate shoulder mechanics, particularly no scapula elevation prior to elevating the arm.[221]
- 4/5 strength of rotator cuff and deltoid muscles.[52,103]
- rTSA patients should have documented improvements in function and increasing strength of the deltoid and periscapular muscles prior to progressing to the next phase.[23]

Exercise: Minimum Protection/Return to Function Phase

The minimum protection/return to functional activity phase usually begins around 12 to 16 weeks postoperatively (depending on rotator cuff tissue quality and function) and typically extends for several more months.[52,103,221] Pain-free strengthening of the shoulder girdle for dynamic stability and functional use of the upper extremity for progressively more demanding tasks are the primary focuses of this phase. For optimal results, the home exercise program may need to be continued for 6 months or longer, and functional and recreational activities may need to be modified.

Goals and interventions. Goals and activities for the final phase of rehabilitation include the following.[24,27,39,52,53,102,103,221]

- ***Continue to improve or maintain shoulder mobility.***
  - End-range self-stretching.
  - Grade III joint mobilization and self-mobilization, if appropriate.[24,27,39,103]
- ***Continue to improve neuromuscular control and muscle performance of the shoulder.***
  - Pain-free, low-load, high-repetition progressive resistive exercise (PRE) of shoulder musculature in anatomical and diagonal planes and in patterns of movement that replicate functional tasks throughout the available ROM. Position the patient in a variety of gravity-resisted positions.
  - Closed-chain, resisted shoulder exercises, gradually increasing the amount of weight bearing through the upper extremity.
  - Use of the involved upper extremity for lifting, carrying, pushing, or pulling activities against increasing loads.
- ***Return to most functional activities.***
  - Use of the operated upper extremity for progressively more advanced functional activities.
  - Recreational activities, such as swimming and golf are possible.
  - Modification of high-demand, high-impact work-related or recreational activities to avoid imposing excessive forces on the GH joint that could lead to loosening or premature wear of prosthetic implants.

NOTE: For the patient whose rotator cuff was irreparable or continues to be significantly deficient because of a tenuous repair and who has limited but pain-free shoulder ROM, modification of the environment and use of assistive devices may be necessary for independence in functional activities.

Outcomes

Over the past 30 years, as patient selection criteria, prosthetic designs, and surgical techniques have been refined, postoperative outcomes after shoulder arthroplasty have improved. Numerous resources suggest that outcomes after TSA, rTSA, or hemiarthroplasty are influenced by many factors, including the type and severity of the underlying pathology, the status of soft tissues (especially the rotator cuff mechanism and subscapularis), the type and quality of the surgical procedure(s) performed, and patient-related factors, such as participation in a postoperative rehabilitation program.[34,38,221] The outcomes most often measured in follow-up studies are pain relief, quality of life, passive and active shoulder ROM, and the ability to perform functional activities.

Despite the emphasis in numerous resources that a patient's participation in postoperative rehabilitation is crucial for successful outcomes, there are no studies to support this opinion, because all patients undergoing shoulder arthroplasty are given some form of postoperative exercise instruction. Furthermore, published protocols are routinely modified to meet the needs of individual patients and consequently have not been compared to determine if one protocol yields better outcomes than another.[221]

Pain relief. A decrease in pain is the most dramatic result of glenohumeral arthroplasty. Almost all patients—regardless of the underlying pathology, the type of arthroplasty, or the design of the prosthetic implants—report complete or

substantial relief of shoulder pain and improved functional use of the arm.*

The extent of pain relief has been shown to be associated with the underlying cause(s) of glenohumeral arthritis. Neer and associates,[141] Matsen,[125] and more recently, Norris and Iannotti[153] reported that 90% of patients with primary OA or osteonecrosis had complete or near-complete pain relief after TSA. Similar results have been reported for patients with OA who underwent hemiarthroplasty.[115,126,143] Patients with RA or other synovium-based diseases also report substantial pain relief after TSA or hemiarthroplasty, although not quite to the extent reported by patients with OA or osteonecrosis.[38,180,206] However, in a sample of 191 patients after rTSA, Wall and colleagues report statistically significant improvements in pain as measured by the Constant score regardless of patient diagnosis.[216]

Whether TSA is more effective than hemiarthroplasty for pain relief has also been studied. In a prospective follow-up study over a mean of 4.3 years when patients with OA having TSA were compared to those having hemiarthroplasty, postoperative pain scores were reported to be similar in the two groups, with patients in the TSA group demonstrating more improvement because of a higher level of pain preoperatively.[157] In another study, patients with OA were randomly assigned to undergo either TSA or hemiarthroplasty and were evaluated postoperatively over a 24-month period. Results of this study indicated that both groups of patients reported significant pain relief and improvements in other quality-of-life parameters, with no significant differences between the TSA and hemiarthroplasty groups.[115] Whether TSA versus hemiarthroplasty is more effective for pain relief in patients with RA has not been clearly established.[126,206]

ROM and functional use of the upper extremity. Despite the emphasis placed on improving ROM and use of the arm for functional activities during rehabilitation after shoulder arthroplasty, improvements in these outcomes are less predictable than pain relief, with the functional status improving more consistently than ROM.† In general, patients with primary OA or osteonecrosis demonstrate greater improvement in active ROM (forward elevation and shoulder rotation) than patients with RA, in part because of a higher incidence of cuff deficiency associated with RA or the use of more constrained prosthetic designs.[180,206,221] For example, in patients with OA or osteonecrosis, the mean active forward elevation of the shoulder (reported in reviews of a number of studies) changed from 105° to 161°. In patients with RA, means ranged from 75° to 105°.[192,221]

Significant improvement in functional status has been reported for patients with OA or osteonecrosis. Although functional improvement after arthroplasty has been reported for patients with RA, many studies used nonstandardized measurement tools, making it difficult to compare their results with those of other studies.[221] Following rTSA, patients with primary rotator cuff arthropathy, primary OA with rotator cuff tear, and those with a massive rotator cuff tear had better functional and clinical outcomes than patients with posttraumatic arthritis or revision arthroplasty.[216] Regardless of the underlying pathology, resources agree that a well-functioning rotator cuff mechanism is the basis for significant postoperative gains in active ROM and functional abilities.[38,189,221]

Painful Shoulder Syndromes (Rotator Cuff Disease and Impingement Syndromes): Nonoperative Management

Mechanical compression and irritation of the soft tissues (rotator cuff and subacromial bursa) in the suprahumeral space (see Fig. 17.7) is called *impingement syndrome* and is the most common cause of shoulder pain.[83,112,121] Various etiological factors have been identified and therefore, have led to several classification systems, which are summarized in Box 17.7.

Related Pathologies and Etiology of Symptoms

The cause of impingement is multifactoral, involving both structural and mechanical impairments. Impingement syndrome is often used as the diagnosis when the patient's signs and symptoms are related to pain with overhead reaching, a painful arc mid-range, and positive impingement tests. Other test results may more specifically identify the tissue involved, the faulty mechanics associated with the condition, or the degree of instability or injury. Symptoms that derive from impingement are usually brought on with excessive or repetitive overhead activities that load the shoulder joint, particularly in the mid-range. Impingement syndromes are generally classified as *intrinsic or extrinsic*, with extrinsic further classified as *primary, secondary, and internal*.

Other types of musculotendinous strain in the shoulder region occur as the result of overuse or trauma, such as in the anterior pectoral region from racket sports or in the long head of the triceps and serratus anterior from impact trauma, such as holding onto a steering wheel in an automobile accident.

Intrinsic Impingement: Rotator Cuff Disease

Intrinsic factors are those that compromise the integrity of the musculotendinous structures and include vascular changes in the rotator cuff tendons, tissue tension overload, and collagen disorientation and degeneration.[65,136] These factors typically involve the articular side of the tendons and may progress to articular-side rotator cuff tears, seen most often in those older than 40 years of age.[80]

BOX 17.7 Categories of Painful Shoulder Syndromes

Impingement syndromes and other painful shoulder conditions have varying etiologic factors and therefore can be categorized in several ways.

Based on Degree or Stage of Pathology of the Rotator Cuff (Neer's Classification of Rotator Cuff Disease)[140]
- *Stage I.* Edema, hemorrhage (patient usually <25 years of age)
- *Stage II.* Tendonitis/bursitis and fibrosis (patient usually 25 to 40 years of age)
- *Stage III.* Bone spurs and tendon rupture (patient usually >40 years of age)

Based on Impaired Tissue[45]
- Supraspinatus tendonitis
- Infraspinatus tendonitis
- Bicipital tendonitis
- Superior glenoid labrum
- Subdeltoid (subacromial) bursitis
- Other musculotendinous strains (specific to type of injury or trauma)
  - Anterior—from overuse with racket sports (pectoralis minor, subscapularis, coracobrachialis, short head of biceps strain)
  - Inferior—from motor vehicle trauma (long head of triceps, serratus anterior strain)

Based on Mechanical Disruption and Direction of Instability or Subluxation
- Multidirectional instability from lax capsule with or without impingement
- Unidirectional instability (anterior, posterior, or inferior) with or without impingement
  - Traumatic injury with tears of capsule and/or labrum
  - Insidious (atraumatic) onset from repetitive microtrauma
  - Inherent laxity

Based on Progressive Microtrauma (Jobe's classification)[98]
- *Group 1.* Pure impingement (usually in an older recreational athlete with partial undersurface rotator cuff tear and subacromial bursitis)
- *Group 2.* Impingement associated with labral and/or capsular injury, instability, and secondary impingement
- *Group 3.* Hyperelastic soft tissues resulting in anterior or multidirectional instability and impingement (usually attenuated but intact labrum, undersurface rotator cuff tear)
- *Group 4.* Anterior instability without associated impingement (result of trauma; results in partial or complete dislocation)

Based on Degree and Frequency
- Instability → subluxation → dislocation
- Acute, recurrent, fixed

Extrinsic Impingement: Mechanical Compression of Tissues

Extrinsic impingement is believed to occur as a result of mechanical wear of the rotator cuff against the anteroinferior one-third of the acromion in the suprahumeral space during elevation activities of the humerus (Fig. 17.15). Encroachment may be the result of anatomical or biomechanical factors that decrease the dimensions of the suprahumeral space. Extrinsic impingement can also occur at the posterior aspect of the supraspinatus tendon, mainly in athletes who throw repetitively.

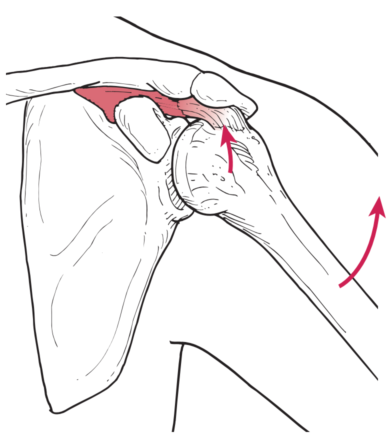

FIGURE 17.15 Decrease in the suprahumeral space during repetitive elevation activities leads to symptoms of impingement.

Primary extrinsic impingement. Primary extrinsic impingement can result from anatomical or biomechanical factors. Anatomical factors that may cause primary extrinsic impingement include structural variations in the acromion or humeral head, hypertrophic degenerative changes of the AC joint, or other trophic changes in the coracoacromial arch or humeral head. All of these factors decrease the suprahumeral space and often have to be dealt with surgically.[65,92,170,238] Biomechanical factors include altered orientation of the clavicle or scapula during movement, or increased anterosuperior humeral head translations as may occur with a tight posterior GH capsule.[77]

Neer[142] first suggested that the size and shape of the structures that make up the coricoacromial arch are related to rotator cuff impingement. In later studies, variations of the acromion were identified and classified into three shapes: type I (flat), type II (curved), and type III (hooked) (Fig. 17.16).[15] Rotator cuff pathology is often associated with types II and III—but not type I—acromial shapes.[1,135,238]

Secondary extrinsic impingement. Secondary impingement is used to describe mechanical compression of the suprahumeral tissues due to hypermobility or instability of the GH joint and increased translation of the humeral head. This instability may be multidirectional or unidirectional and can occur with compromised static restraints (GH ligaments)

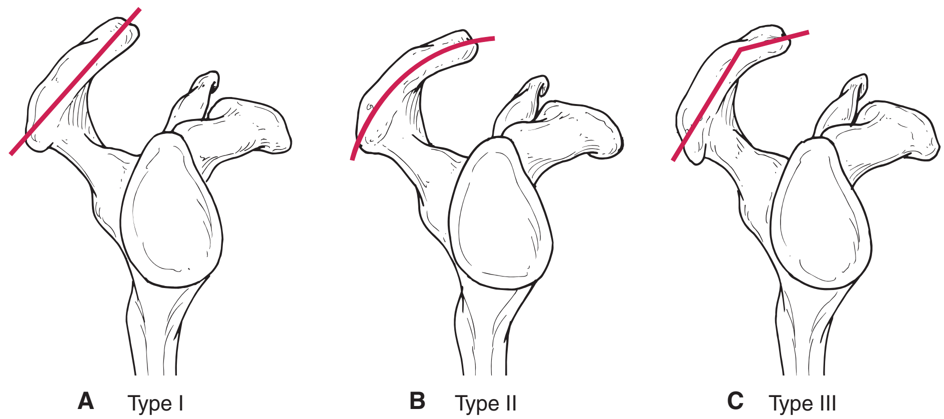

FIGURE 17.16 Classifications of the acromion by shape: **(A)** type I (flat); **(B)** type II (curved); **(C)** type III (hooked).

or with dynamic rotator cuff insufficiency (force imbalances or fatigue).

- ***Multidirectional instability.*** Some individuals have physiologically increased connective tissue extensibility, causing excessive joint mobility. In the GH joint, this increased extensibility allows larger than normal humeral head translations in all directions.[156,181] Many individuals, particularly those involved in overhead activities, develop laxity of the capsule from continually subjecting the joint to stretch forces.[65,98] A hypermobile GH joint may be supported satisfactorily by strong rotator cuff muscles; but with muscle fatigue, poor humeral head stabilization leads to faulty humeral mechanics, trauma, and inflammation of the suprahumeral tissues.[98,134] With multidirectional instability, the mechanical impingement of tissue in the suprahumeral space is, therefore, a secondary effect of the increased humeral head translations.[65]
- ***Unidirectional instability with or without impingement.*** Unidirectional instability (anterior, posterior, or inferior) may be the result of physiological laxity of the connective tissues, but is often the result of trauma and usually involves rotator cuff tears. The tears can be classified as acute, chronic, degenerative, or partial- or full-thickness tears. Often, there is damage to the glenoid labrum and tearing of some of the supporting ligaments.

Internal extrinsic impingement. Internal impingement is a relatively recent type of extrinsic impingement that occurs in a position of elevation, horizontal abduction, and maximum external rotation, primarily in throwing athletes. This position and a posterior-superior shift of the humeral head on the glenoid results in a mechanical entrapment of the posterior supraspinatus tendon between the humeral head and the labrum. Internal impingement is associated with a combination of posterior GH capsule tightness and scapula kinematic alterations.[111,138]

Tendonitis/Bursitis

Neer categorizes tendonitis/bursitis as a stage II impingement syndrome (see Box 17.7).[140] The following sections describe specific pathological diagnoses and presenting signs and symptoms.

Supraspinatus tendonitis. With supraspinatus tendonitis, the lesion is usually near the musculotendinous junction, resulting in a painful arc with overhead reaching. There is also pain with impingement tests and pain on palpation of the tendon just inferior to the anterior aspect of the acromion when the patient's hand is placed behind the back. It is difficult to differentiate tendonitis from subdeltoid bursitis because of the anatomical proximity of these two structures.

Infraspinatus tendonitis. With infraspinatus tendonitis, the lesion is usually near the musculotendinous junction, resulting in a painful arc with overhead, forward, or cross body motions. It may present as a deceleration (eccentric) injury due to overload during repetitive or forceful throwing activities. Pain occurs with palpation of the tendon just inferior to the posterior corner of the acromion when the patient horizontally adducts and externally rotates the humerus.

Bicipital tendonitis. With bicipital tendonitis, the lesion involves the long tendon in the bicipital groove beneath or just distal to the transverse humeral ligament. Swelling in the boney groove is restrictive and compounds and perpetuates the problem. Pain occurs with Speed's test and on palpation of the bicipital groove.[123] Rupture or dislocation of this humeral depressor may escalate impingement of tissues in the suprahumeral space.[140,149]

Bursitis (subdeltoid or subacromial). When acute, the symptoms of bursitis are the same as those seen with supraspinatus tendonitis. Once the inflammation is under control, there are no symptoms with resisted motions.

Other Impaired Musculotendinous Tissues

The following are examples of other musculotendinous problems in the shoulder region.

- The pectoralis minor, short head of the biceps, and coracobrachialis are subject to microtrauma, particularly in racquet sports requiring a controlled backward, then a rapid forward

swinging of the arm. The scapular stabilizers, particularly the retractors, are also susceptible to microtrauma, as they function to control forward motion of the scapula.[114]

- The long head of the triceps and scapular stabilizers may be injured in motor vehicle accidents, as the driver holds firmly to the steering wheel on impact.
- Injury, overuse, or repetitive trauma can occur in any muscle being subjected to stress.[152] Pain occurs when the involved muscle is lengthened or when contracting against resistance. Palpating the site of the lesion causes the familiar pain.

Insidious (Atraumatic) Onset

Neer has identified rotator cuff tears as a stage III impingement syndrome, a condition that typically occurs in persons over age 40 after repetitive microtrauma to the rotator cuff or long head of the biceps.[140] With aging, the distal portion of the supraspinatus tendon is particularly vulnerable to impingement or stress from overuse strain. With degenerative changes, calcification and eventual tendon rupture may occur.[65,146,155] Chronic ischemia caused from tension on the tendon and decreased healing in the elderly are possible explanations, although Neer stated that, in his experience, 95% of tears are initiated by impingement wear rather than by impaired circulation or trauma.[140]

Common Structural and Functional Impairments

Various impairments have been reported to be common in impingement syndromes; however, it is not known if they are the cause or effect of the faulty mechanics.[33,118,121,158,218] A thorough examination of the cervical spine and shoulder girdle is necessary to differentiate signs and symptoms related to primary and secondary impingements or other causes of shoulder pain.[22,51,123] Common impairments associated with rotator cuff disease and impingement syndromes are summarized in Box 17.8.

Impaired Posture and Muscle Imbalances

Increased thoracic kyphosis, forward head, and protracted and forward-tilted scapula are often identified as related to impingement syndrome. Faulty scapular alignment may be one factor in decreasing the suprahumeral space and therefore leading to irritation of the rotator cuff tendons with overhead activities.[118] Faulty upper quadrant posture leads to an imbalance in the length and strength of the scapular and GH musculature and decreases the effectiveness of the dynamic and passive stabilizing structures of the GH joint.[227]

Typically with increased thoracic kyphosis, the scapula is protracted and tilted forward, and the GH joint is in an internally rotated posture. With this posture, the pectoralis minor, levator scapulae, and shoulder internal rotators are tight; and the external rotators of the shoulder and upward rotators of the scapula may test weak and have poor muscular endurance. When reaching overhead, faulty scapular and humeral mechanics may result in alterations of scapular alignment and in the muscular control of the shoulder complex.

BOX 17.8 Summary of Common Impairments with Rotator Cuff Disease and Impingement Syndromes

All, some, or none of the following may be present:

- Pain at the musculotendinous junction of the involved muscle with palpation, with resisted muscle contraction, and when stretched
- Positive impingement sign (forced internal rotation at 90° of flexion) and painful arc
- Impaired posture: thoracic kyphosis, forward head, and forward (anterior) tipped scapula with decreased thoracic mobility
- Muscle imbalances: hypomobile pectoralis major and minor, levator scapulae, and internal rotators of the GH joint; weak serratus anterior and lateral rotators
- Hypomobile posterior GH joint capsule
- Hypomobile cervical and/or thoracic spine mobility, especially with secondary impingement.
- Faulty kinematics during humeral elevation: decreased posterior tipping of scapula related to weak serratus anterior; scapular elevation and overuse of upper trapezius; and altered scapulohumeral rhythm
- With a complete rotator cuff tear, inability to abduct the humerus against gravity
- When acute, pain referred to the C5 and C6 reference zones

FOCUS ON EVIDENCE

In a study that examined the kinematics of 52 subjects (26 without shoulder impairment and 26 with shoulder impingement), Ludewig and Cook[118] documented delayed upward rotation of the scapula during the 31° to 60° range of humeral elevation, incomplete posterior tilting of the scapula, and excessive scapular elevation in individuals with impingement compared to those without shoulder impairments. This mechanical alteration may contribute to decreased clearance under the anterior acromion. The investigation also documented decreased activation of the lower serratus anterior and overuse of the upper trapezius with scapular elevation, which was suggested as a possible compensation for the weak posterior tilting action of the serratus anterior.

Decreased Thoracic ROM

Thoracic extension is a component motion that is needed for full overhead reaching. Incomplete thoracic extension decreases the functional range of humeral elevation.

CLINICAL TIP

Full overhead shoulder movement is more difficult when there is increased thoracic kyphosis and forward head posture. This relationship can be used as an educational tool with a patient to demonstrate the importance of spinal posture.

First, have your patient reach overhead while in a slouched posture; then, have him assume "good posture" and reach overhead again and note the difference in ROM. Reinforce the importance of spinal posture in the management and prevention of shoulder problems.

Rotator Cuff Overuse and Fatigue

If the rotator cuff musculature or long head of the biceps fatigue from overuse, they no longer provide the dynamic stabilizing, compressive, and translational forces that support the joint and control the normal joint mechanics. This is thought to be a precipitating factor in secondary impingement syndromes when capsular laxity is present and increased muscular stability is necessary for stability.[159] The tissues in the subacromial space may then become impinged as a result of faulty mechanics. There is also a relationship between muscle fatigue and joint position sense in the shoulder that may play a role in impaired performance in repetitive overhead activities.[35]

Muscle Weakness Secondary to Neuropathy

Muscle weakness may be related to nerve involvement. Long thoracic nerve palsy has been identified as a cause of faulty scapular mechanics, resulting from serratus anterior muscle weakness, leading to impingement in the suprahumeral region.[184]

Hypomobile Posterior GH Joint Capsule

Tightness in the posterior GH joint capsule compromises the normal arthrokinematics and increases forces on the head of the humerus against the anterior capsule,[77] as demonstrated by increased anterior translation in the humeral head when there is a tight posterior capsule.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- When acute, pain may interfere with sleep, particularly when rolling onto the involved shoulder.
- Pain with overhead reaching, pushing, or pulling.
- Difficulty lifting loads.
- Inability to sustain repetitive shoulder activities (such as reaching, lifting, throwing, pushing, pulling, or swinging the arm).
- Difficulty with dressing, particularly putting a shirt on over the head.

Management: Painful Shoulder Syndromes

NOTE: Even though symptoms may be "chronic" in terms of long standing or recurring, if there is inflammation, the initial treatment priority is to get the inflammation under control.

Management: Protection Phase

Control Inflammation and Promote Healing

- Modalities and low-intensity cross-fiber massage are applied to the site of the lesion. While applying the modalities, position the extremity to maximally expose the involved region.[46,49]
- Support the arm in a sling for rest.

Patient Education

The environment and habits that provoke the symptoms must be modified or avoided completely during this stage. The patient should be informed about the mechanics of the irritation and given guidelines for anticipated recovery with compliance.

Maintain Integrity and Mobility of the Soft Tissues

- Passive, active-assistive, or self-assisted ROM is initiated in pain-free ranges.
- Multiple-angle muscle setting and protected stabilization exercises are initiated. When exercising the shoulder, it is particularly important to stimulate the stabilizing function of the rotator cuff, biceps brachii, and scapular muscles at an intensity tolerated by the patient.

PRECAUTION: It is important to use caution with exercises during this stage to avoid the impingement positions. Often, the mid-range of abduction, with internal rotation, or an end-range position when the involved muscle is on a stretch (such as putting the hand behind the back) provokes a painful response.

Control Pain and Maintain Joint Integrity

Pendulum exercises without weights can be used to cause pain-inhibiting grade II joint distraction and oscillation motions (see Fig. 17.22 in the section on exercise).

Develop Support in Related Regions

- Postural awareness and correction techniques are used. (See related information on 'Interventions for Impaired Posture' in Chapter 14.)
- Supportive techniques, such as shoulder strapping or scapular taping, tactile cues, and mirrors, can be used for reinforcement. Repetitive reminders and practice of correct posture are necessary throughout the day.

FOCUS ON EVIDENCE

In a randomized placebo-controlled, crossover study,[112] of 120 subjects (60 with impingement and 60 without symptoms), changing posture resulted in a significant increase in ROM in flexion, abduction, and arm elevation in the scapular plane; the point in the range at which symptoms were felt was significantly higher. Thoracic and scapular taping had a positive influence in modifying posture; there was less forward head posture, smaller kyphosis, less lateral scapular displacement, less elevated and forward scapula position, and increased, pain-free arm elevation in the scapular plane compared with the measurements taken after placebo taping in both the symptomatic and asymptomatic groups.

Management: Controlled Motion Phase

After the acute symptoms are under control, the main emphasis becomes the use of the involved region with progressive, nondestructive movement and proper mechanics while the tissues heal. The components of the desired functions are analyzed and initiated in a controlled exercise program.[48,49,194,223,224,229] If there is functional laxity in the joint, the intervention is directed toward learning neuromuscular control of and developing strength in the stabilizing muscles of both the scapula and glenohumeral joint.[30,101,105,183,205] If there is restricted mobility that prevents normal mechanics or interferes with function, mobilization of the restricted tissue is performed. Exercise techniques and progressions are described later in the chapter.

Patient Education

Patient adherence to the program and avoidance of irritating the healing tissues are necessary. The home exercise program is progressed as the patient learns safe and effective execution of each exercise. Continue to reinforce proper postural habits.

Develop Strong, Mobile Tissues

- Manual therapy techniques, such as cross-fiber or friction massage, are used. The extremity is positioned so the tissue is on a stretch if it is a tendon or in the shortened position if it is in the muscle belly. The technique is applied to the tolerance of the patient.
- Following massage, the patient is instructed to perform an isometric contraction of the muscle in several positions of the range. The intensity of contraction should not cause pain.
- The patient should be taught how to self-administer the massage and isometric techniques.

Modify Joint Tracking and Mobility

Mobilization with movement (MWM) may be useful for modifying joint tracking and reinforcing full movement when there is painful restriction of shoulder elevation because of a painful arc or impingement[137] (see Chapter 5 for a description of principles).

- *Posterolateral glide with active elevation* (Fig. 17.17 A)
  - *Patient position*: Sitting with the arm by the side and head in neutral retraction.
  - *Therapist position and procedure*: Stand on the side opposite the affected arm and reach across the patient's torso to stabilize the scapula with the palm of one hand. The other hand is placed over the anteromedial aspect of the head of the humerus. Apply a graded posterolateral glide of the humeral head on the glenoid. Request that the patient perform the previously painful elevation. Maintain the posterolateral glide mobilization throughout both elevation and return to neutral. Ensure that no pain is experienced during the procedure. Adjust the grade and direction of the glide as needed to achieve pain-free function. Add resistance in the form of elastic resistance or a cuff weight to load the muscle.
- *Self-Treatment.* A mobilization belt provides the posterolateral glide while the patient actively elevates the affected limb against progressive resistance to end-range (Fig. 17.17 B).

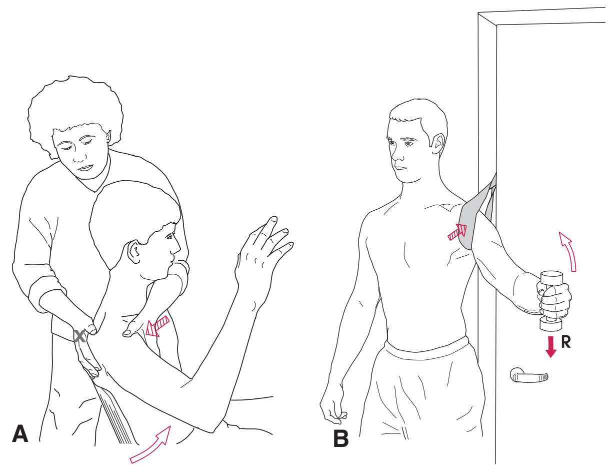

FIGURE 17.17 MWM to modify joint tracking and improve active elevation. A posterolateral glide is applied to the humeral head **(A)** manually or **(B)** with a belt for self-treatment, while the patient actively elevates the humerus. A weight is used to strengthen the muscles through the pain-free range.

Develop Balance in Length and Strength of Shoulder Girdle Muscles

It is important to design a program that specifically addresses the patient's impairments. Typical interventions in the shoulder girdle include but are not limited to:

- *Stretch shortened muscles.* Shortened muscles typically include the pectoralis major, pectoralis minor, latissimus dorsi and teres major, subscapularis, and levator scapulae.
- *Strengthen and train the scapular stabilizers.* Scapular stabilizers typically include the serratus anterior and lower trapezius for posterior tipping and upward rotation and the middle trapezius and rhomboids for scapular retraction. It is important that the patient learns to avoid scapular elevation when raising the arm. Therefore, practice scapular depression when abducting and flexing the humerus.
- *Strengthen and train the rotator cuff muscles.* Place emphasis on the shoulder external rotators.

Develop Muscular Stabilization and Endurance

- Alternating isometric resistance is applied to the scapular muscles in *open-chain positions* (side-lying, sitting, supine), including protraction/retraction, elevation/depression, and upward/downward rotation, so the patient learns to stabilize the scapula against the outside forces (see Fig. 17.37 in the exercise section).
- Scapular and glenohumeral patterns are combined using flexion, abduction, and rotation. Alternating isometric resistance is applied to the humerus while the patient holds against the changing directions of the resistance force (see Figs. 17.38, 17.39, and 17.42 in the exercise section).
- *Closed-chain stabilization* is performed with the patient's hands fixated against a wall, a table, or the floor (quadruped position) while the therapist provides a graded, alternating isometric resistance or rhythmic stabilization. Observe for abnormal scapular winging. If abnormal scapular winging

occurs, the scapular stabilizers are not strong enough for the demand, so the position should be changed to reduce the amount of body weight (see Fig. 17.43 in the exercise section).

- *Muscular endurance* is progressed by increasing the amount of time the individual holds the pattern against the alternating resistance. The limit is reached when any one of the muscles in the pattern can no longer maintain the desired hold. The goal at this phase should be stabilization for approximately 3 minutes.

Progress Shoulder Function

As the patient develops strength in the weakened muscles, it becomes important to develop a balance in strength of all shoulder and scapular muscles within the range and tolerance of each muscle. To increase coordination between scapular and arm motions, dynamically load the upper extremity within tolerance of the synergy with submaximal resistance. To improve muscular endurance, have the patient increase control from 1 minute to 3 minutes.

Management: Return to Function Phase

Specificity of training toward the desired functional outcome begins as soon as the patient has developed control of posture and the basic components of the desired activities without exacerbating the symptoms. While working with the patient, continue to teach him or her how to progress the program when discharged and how to prevent recurrences. Suggestions are summarized in Box 17.9.

Increase Muscular Endurance

To increase muscular endurance, repetitive loading of the defined patterns is increased from 3 minutes to 5 minutes.

Develop Quick Motor Responses to Imposed Stresses

- The stabilization exercises are applied with increased speed.
- Plyometric training in both open-chain and closed-chain patterns is initiated if power is a desired outcome. (Refer to Chapter 23.)

BOX 17.9 Patient Instructions to Prevent Recurrences of Shoulder Pain

- Prior to exercise or work, massage the involved tendon or muscle; follow with isometric resistance and then with full ROM and stretching of the muscle.
- Take breaks from the activity if repetitive in nature. If possible, alternate the stressful, provoking activity with other activities or patterns of motion.
- Maintain good postural alignment; adapt seating or workstation to minimize stress. If sport-related, seek coaching in proper techniques or adapt equipment for safe mechanics.
- Prior to initiating a new activity or returning to an activity for which not conditioned, begin a strengthening and training program.

Progress Functional Training

Specificity of training progresses to an emphasis on timing and sequencing of events.

- Eccentric training is progressed to maximum load.
- Desired functional activities are simulated—first under controlled conditions, then under progressively challenging conditions using acceleration/deceleration drills.
- The patient is involved in assessing performance in terms of safety, symptom provocation, postural control, and ease of execution and then practices adaptations to correct any problems.

Painful Shoulder Syndromes: Surgery and Postoperative Management

Surgical intervention is an option for painful shoulder syndromes when conservative management does not resolve symptoms and improve function. For an individual with primary impingement as a result of structural variations in the acromion (see descriptions and Fig. 17.16 in the previous section), subacromial decompression may be performed. An individual with a partial- or full-thickness rotator cuff tear may require surgical repair.

Subacromial Decompression and Postoperative Management

When pain and loss of functional mobility associated with primary impingement do not resolve sufficiently with nonoperative management, *subacromial decompression,* designed to increase the volume of the subacromial space and provide adequate gliding room for tendons, is often warranted. Subacromial decompression also is referred to as *anterior acromioplasty* or *decompression acromioplasty*. However, acromioplasty, which alters the shape of the acromion, is typically, but not always, one of the components of subacromial decompression.[128]

Indications for Surgery

The following are generally accepted indications for surgical management of impingement syndromes.[*]

- Pain during overhead activities and loss of functional mobility of the shoulder as the result of primary impingement that persists (typically for 3 to 6 months or longer) despite a trial of nonoperative interventions.
- Stage II (Neer classification; see Box 17.7) impingement with nonreversible fibrosis or boney alterations of the subacromial compartment, calcific deposits in the cuff tendons, and symptomatic subacromial crepitus.
- Intact or minor tear of the rotator cuff.

---

[*]1,59,79,84,128,142,146,170,176,215

NOTE: Patients who present with secondary impingement (GH joint hypermobility or instability associated with a partial- or full-thickness tear of the rotator cuff) are not candidates for surgical subacromial decompression alone. For these patients, subacromial decompression is combined with concomitant repair of the cuff tear; otherwise, the procedures inherent in subacromial decompression can worsen GH instability.[79,128,215]

Procedures

Surgical approach. Subacromial decompression is performed using an arthroscopic or open approach. Although an open approach has been used successfully for many years,[84,139,142,170] the preferred procedure today in most cases is an arthroscopic approach.[59,215] Unlike a traditional open approach, in which the proximal attachment of the deltoid must be detached and then repaired prior to closure,[142] with an arthroscopic approach, the deltoid remains intact, enabling the patient to regain functional use of the upper extremity more rapidly after surgery. For the most part, the traditional open approach for subacromial decompression is now reserved for some patients with a massive rotator cuff tear who also are undergoing an open repair. Another option preferred by some surgeons is a "mini-open" approach, which involves splitting the deltoid insertion vertically rather than detaching it.[128]

Component procedures. There are several surgical procedures that can be performed for subacromial decompression, depending on the pathology observed during examination of the shoulder prior to or during surgery.[1,59,75,79,128,154,176,215]

- Removal of the subacromial bursa (*bursectomy*), which is typically thickened (enlarged) by chronic inflammation
- Release of the coracoacromial ligament, which is usually hypertrophied and may also be frayed, followed by complete or partial resection or recession
- Resection of the anterior acromial protuberance and contouring the undersurface of the remaining portion of the acromion (*acromioplasty*) to enlarge the subacromial space (Fig. 17.18)

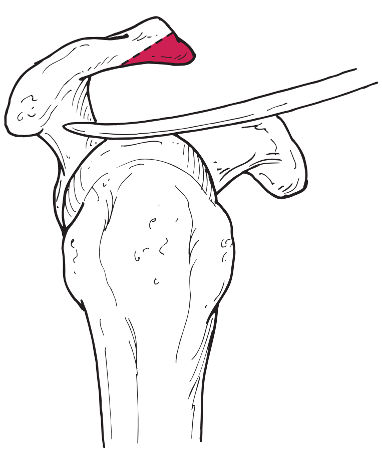

FIGURE 17.18 Arthroscopic acromioplasty showing the line of resection of the anterior acromion.

- Removal of any osteophytes at the AC joint and in some cases resection of the distal portion of the clavicle for advanced arthritis of the AC joint

Postoperative Management

The type of surgical approach used and the status of the rotator cuff significantly affect rehabilitation decisions after subacromial decompression. If the rotator cuff is intact preoperatively, rehabilitation after arthroscopic decompression progresses quite rapidly because the shoulder musculature is left intact during the procedure. In contrast, if a repair of the rotator cuff is required in addition to decompression, or a mini-open or open approach is used, rehabilitation progresses at a slower rate to allow the repaired shoulder musculature adequate time to heal.

NOTE: The guidelines outlined in this section are for postoperative rehabilitation after *arthroscopic* subacromial decompression for a patient with primary shoulder impingement who has an *intact rotator cuff*. If subacromial decompression is combined with repair of the rotator cuff, the guidelines presented in a later section of this chapter on rehabilitation after rotator cuff repair are appropriate.

Immobilization

The shoulder is immobilized and supported in a sling with the arm positioned at the patient's side or in slight abduction; the shoulder is internally rotated; and the elbow is flexed to 90°. The sling is worn for comfort for 1 to 2 weeks but is removed for exercise the day after surgery.[128,215,225]

Exercise Progression

Exercise interventions after subacromial decompression targets many of the impairments noted for rotator cuff impingement discussed previously in this chapter. This information merits review to understand why specific exercises are included in the postoperative rehabilitation program.

Because arthroscopic decompression is often performed on an outpatient basis, a patient initially may need to carry out the prescribed exercises at home with little supervision and then follow up with a series of outpatient therapy visits at a later time. Therefore, patient education is of the utmost importance for each phase of rehabilitation.

Exercise: Maximum Protection Phase

The first phase of rehabilitation after arthroscopic decompression begins on the day after surgery and extends for 3 to 4 weeks. Emphasis is placed on pain control and immediate but comfortable assisted movement of the shoulder to prevent adhesions of the cuff tendons in the subacromial space. Attaining full or nearly full passive ROM of the operated shoulder (compared to the noninvolved shoulder) is a reasonable goal by 4 to 6 weeks postoperatively.[79]

Patient education begins immediately and is directed toward helping the patient recognize and avoid postures that contribute to symptoms during exercise and ADL. Active (unassisted) shoulder ROM is permissible as soon as motions are pain-free and proper scapulothoracic and glenohumeral

control can be maintained. This may be possible as early as 2 weeks postsurgery.

Goals and interventions. The following goals and exercises are indicated for the early stage of tissue healing.[1,3,39,79,128,225]

- ***Control pain and inflammation.***
  - Use of a sling when the arm is dependent.
  - Use of cryotherapy and prescribed anti-inflammatory medication.
  - Shoulder relaxation exercises.
- ***Prevent loss of mobility of adjacent regions.***
  - Active ROM of the cervical spine, elbow, wrist, and hand.
- ***Develop postural awareness and control.***
  - Active movement of the scapula with emphasis on retraction.
  - Posture training, emphasizing cervical retraction, thoracic extension, scapula retraction and a neutral lumbo-pelvic complex.
- ***Restore pain-free shoulder mobility.***
  - Assisted shoulder ROM as tolerated by pain, initially guiding with the sound upper extremity and later a wand. Start in the supine position to provide additional stability to the scapula against the thorax and with the upper arm on a folded towel in slight abduction and flexion. Shoulder motions include elevating the arm in the plane of the scapula, forward flexion, abduction, rotation, and horizontal abduction and adduction. Progress to performing exercises in a semi-reclining position and then in a seated or standing position while maintaining thoracic extension.
  - Assisted shoulder extension in a standing position with a wand held behind the back.
  - Stretching the posterior shoulder structures in pain-free range using a cross-chest stretch into horizontal adduction. Postpone until next phase if painful.
  - Active ROM (unassisted) of the shoulder and scapula within pain-free ranges, maintaining proper scapulothoracic and glenohumeral control; begin supine and progress to sitting. Active shoulder motions may be possible by 2 weeks postoperatively.
- ***Prevent reflex inhibition and atrophy of shoulder girdle musculature.***
  - *Pain-free,* low-intensity, multiple-angle isometrics of GH musculature with the arm supported and emphasis on the rotator cuff against minimal resistance. Begin submaximal isometrics a week or so postoperatively. Lightly resist with the uninvolved upper extremity. Focus on increasing repetitions more than resistance.[118,184]
  - Submaximal alternating isometric and rhythmic stabilization exercises for scapulothoracic muscles with the involved arm supported by the therapist. Target the scapular retractors and upward rotators.

Criteria to progress. Criteria to advance to the second phase include[39,79,102,128,225]:

- Minimal discomfort when the shoulder is unsupported; arm swing is comparable to opposite arm during ambulation.
- Almost full, pain-free, *passive* ROM of the shoulder (full mobility of the scapula; at least 150° of arm elevation; full internal/external rotation).
- In the supine position, pain-free *active* elevation of the arm well above the level of the shoulder.
- Pain-free, *active* external rotation of the shoulder to about 45°.
- At least fair (3/5) and preferably good (4/5) muscle testing grade of shoulder musculature.

Exercise: Moderate Protection Phase

Exercises during the second phase of rehabilitation are directed toward attaining full, pain-free shoulder ROM and improving neuromuscular control and muscle performance (strength, muscular endurance) of the rotator cuff, scapular stabilizers, and prime movers. The patient may be ready to begin this phase of rehabilitation as early as 3 to 4 weeks postoperatively but more often by 4 to 6 weeks. This phase extends over a 4- to 6-week period or until the patient meets the criteria to progress to the next phase.

Goals and interventions. The goals, exercises, and activities during the second phase of rehabilitation are[39,79,102,225]:

- ***Restore and maintain full, pain-free passive mobility of the shoulder girdle and upper trunk.***
  - Joint mobilization emphasizing posterior and caudal glides of the humerus and scapulothoracic mobility.
  - Low-intensity self-stretching of muscles that could restrict sufficient upward rotation of the scapula and rotation of the humerus, specifically the levator scapulae, rhomboids, middle trapezius, subscapularis, latissimus dorsi, and pectoralis major and minor. Recall that tightness of these muscles may contribute to subacromial impingement during overhead movements of the arm.
  - Self-stretching of the posterior shoulder muscles and posterior capsule of the GH joint, as these structures may be tight in the presence of shoulder impingement.
  - Self-stretch of the upper trunk by lying supine on a rolled towel placed vertically between the scapulae.
  - Performance of exercises and functional movement patterns during ADL into the increased ROM.
- ***Reinforce posture awareness and control.***
  - Continue to emphasize cervical, thoracic, and lumbopelvic alignment during exercises and function.
- ***Develop dynamic stability, strength, endurance, and control of scapulothoracic and GH muscles.***
  - Stabilization exercises against increasing resistance and in weight-bearing positions. Emphasize isolated strengthening of the serratus anterior and trapezius muscles.
  - Upper extremity ergometry for muscular endurance. To avoid an impingement arc, initiate in a standing position rather than while seated.
  - Dynamic strengthening exercises of isolated shoulder muscles against low-loads (1- to 5-lb weight or light-grade elastic tubing), gradually increasing repetitions. Begin resisted elevation of the arm in the supine position

to stabilize the scapula against the thorax; progress to sitting or standing.
- Use the involved arm for functional activities that involve light resistance.

CLINICAL TIP

Target the upward rotators of the scapulothoracic joint (serratus anterior, upper and lower trapezius) and the rotator cuff muscles[187] as well as the latissimus dorsi, teres major, and biceps brachii, which act as humeral head depressors and therefore, oppose superior translation during active elevation of the arm. Initially, perform resisted motions of the humerus below the level of the shoulder; later, progress to overhead exercises if motions remain pain-free.

PRECAUTION: Be certain the patient can perform active shoulder flexion and abduction against gravity without elevating the scapula before progressing to resisted exercises above shoulder level.

Criteria to progress. The criteria to progress to the final phase of rehabilitation are[39,102,225]:

- Negative impingement tests.
- Full, pain-free, active ROM of the shoulder without evidence of substitute motions.
- At least 75% strength of the shoulder musculature compared with the sound shoulder.[225]

Exercise: Minimum Protection/Return to Function Phase

The final phase of rehabilitation usually begins 8 weeks postoperatively, at which time soft tissues are reasonably well healed and require little to no protection. Exercises continue until about 12 to 16 weeks postoperatively or until the patient has returned to full activity. Exercises are directed toward continuing to improve strength and endurance of the shoulder girdle muscles using isolated movements and those that simulate functional activities. Patients often see continued improvement in functional use of the operated upper extremity for 6 months postoperatively.[3]

The time necessary for full recovery and unrestricted activities depends largely on the level of demand of the anticipated activities. A patient wishing to return to competitive sports requires a more demanding progression of advanced exercises (e.g., plyometric training and sport-specific drills) than a sedentary individual.[39,225,228]

Goals and interventions. The goals, exercises, and activities during the final phase of rehabilitation after subacromial decompression are similar to the final phase of nonoperative management of primary impingement syndrome. Refer to the information presented in the previous section of this chapter as well as other resources.[39,49,223,225,228]

Outcomes

There appears to be no significant difference in the long-term results (pain-free ROM and return to desired functional activities) after either open or arthroscopic surgery for primary impingement syndrome with or without associated rotator cuff disease.[59,128,215] Based on the results of numerous outcome studies of open and arthroscopic procedures, 85% to 95% of patients report good to excellent results 1.0 to 2.5 years postoperatively.[1,79,128,215] In general, patients reporting the least satisfaction with their function after surgery are those who participate in high-demand athletic activities that involve overhead throwing and those with work-related injuries who are receiving workers' compensation.[128]

Follow-up studies have documented several advantages to having an arthroscopic rather than comparable open surgical management of impingement syndrome. Advantages include less postoperative pain; earlier restoration of full ROM and strength; earlier return to work (often as early as 1 week postoperatively); lower cost (shorter hospital stay or outpatient surgery); and a more favorable cosmetic result.[1,79,128,215]

Although exercises are routinely prescribed after subacromial decompression, the effectiveness of exercise has been the focus of very few studies. One prospective, randomized study carried out in Denmark looked at the effectiveness of a 6-week therapist-supervised exercise program compared to a self-managed program after arthroscopic subacromial decompression.[3] Patients in the therapist-supervised group received exercise instruction while in the hospital and then for a 1-hour therapy session once a week for 6 weeks after discharge from the hospital. Patients in the self-managed group received exercise instruction on one occasion prior to discharge from the hospital. Both groups received written instructions. At 6 weeks and at 3, 6, and 12 months, all of the patients demonstrated improvement in the parameters tested. However, there were no significant differences between the two groups with the exception of one measurement. At 3 months postoperatively, the therapist-supervised group had a higher level of pain than the self-managed group. The authors concluded that initial, therapist-directed exercise instruction followed by a home-based, self-managed exercise program achieved rehabilitation goals as effectively as a therapist-supervised program.

Rotator Cuff Repair and Postoperative Management

There are two broad categories of rotator cuff tears, defined by the depth of the tendon tear: partial-thickness and full-thickness tears. Either type may require surgical management. A *partial-thickness tear* extends inferiorly or superiorly through only a portion of the tendon from either the acromial (bursal) or humeral (articular) surface of the tendon. A *full-thickness tear* is a complete tear, which extends the entire depth of the tendon.[79,87,128]

Indications for Surgery

The primary indications for surgical management of a rotator cuff tear confirmed by imaging are pain and impaired function as the result of the following.*

- Partial-thickness or full-thickness tears of the rotator cuff tendons with irreversible, degenerative changes in soft tissues. Some patients with Neer stage II lesions and most with Neer stage III lesions who continue to be symptomatic and have functional limitations after a trial of nonoperative treatment are candidates for surgery.
- Acute, traumatic rupture of the rotator cuff tendons often combined with avulsion of the greater tuberosity, labral damage, or acute dislocation of the GH joint in individuals with no known history of prior cuff injury. Full-thickness, traumatic tears occur most often in young, active adults.

NOTE: Surgical repair is not indicated in patients who are asymptomatic despite the presence of a cuff tear confirmed by imaging.

Procedures

There are several operative options for repairing a torn rotator cuff, including arthroscopic, open, and mini-open repairs.[68,79,81,128,215] The decision about which option to choose depends on the severity and location of the tear, the number of tendons involved, the extent of associated lesions, the type of onset (repetitive microtrauma or traumatic injury), the quality and mobility of the torn tissues, bone quality, patient-related considerations (age, health, activity level), and the surgeon's preference and experience.

Type of Repair

The type of cuff repair is typically classified by the surgical approach and techniques used. There are three categories of repair.†

- ***Arthroscopic approach.*** The entire procedure is performed arthroscopically and requires only a few small incisions for port sites.
- ***Mini-open (arthroscopically assisted) approach.*** There are two variations of this type of procedure, both of which involve arthroscopic subacromial decompression and a *deltoid-splitting* approach. In one variation, only the subacromial decompression is performed arthroscopically, whereas in the other variation a portion of the cuff repair itself is also performed arthroscopically.[236] In both cases, an anterolateral incision is made at the acromion and is extended distally (either 1.5 or 3.5 cm but no more than 4 cm to avoid the axillary nerve) along the fibers of the deltoid insertion. The deltoid is split longitudinally between its anterior and middle portions to allow visualization of the cuff tear without detaching the deltoid from its proximal insertion.[62,68,128,160,204]
- ***Traditional open approach.*** An anterolateral incision is made that extends obliquely from the middle one-third of the inferior aspect of the clavicle, across the coracoid process, and to the anterior aspect of the proximal humerus. The proximal insertion of the deltoid must be detached and reflected for exposure of the operative field during an open subacromial decompression and cuff repair. After the cuff repair is complete, the deltoid is reattached to the acromion.* As arthroscopic and arthroscopically assisted repairs of the rototor cuff have advanced, the use of the traditional open approach has decreased.

Components of a Rotator Cuff Repair

Regardless of the approach, subacromial decompression is performed (particularly for cuff tears associated with chronic impingement) before repair of the cuff is undertaken. After the tear is visualized, the margins of the torn tendon are débrided and released from any adherent soft tissues. Then the cuff tendon is mobilized for advancement and apposition to bone that has been prepared for sutures and is attached by *tendon-to-bone* fixation. Depending on whether an arthroscopic or mini-open approach is used, fixation is accomplished by sutures and suture anchors, tacks, or staples.[62,66,79,128,203,215]

In addition to subacromial decompression, other concomitant procedures may be required. For example, capsular tightening or labral reconstruction may be performed if unidirectional or multidirectional instability of the GH joint is present. Because degenerative changes in the tendon of the long head of the biceps brachii are often associated with chronic rotator cuff disease, a repair of this tendon also may be necessary.

Selection of Surgical Procedures

The surgeon weighs many factors when determining which type of cuff repair is most appropriate for each patient. One such consideration is the severity of the tear, including thickness (partial or full), size, and number of tendons torn. Although there is some variability in the literature, there are four generally accepted categories that describe the longitudinal size of rotator cuff tears: *small* (1 cm or less), *medium* (1 to 3 cm), *large* (3 to 5 cm), and *massive* (more than 5 cm or a full-thickness tear of more than one tendon).[8,62,79,217]

A small, *partial-thickness* cuff tear is usually managed surgically with a fully arthroscopic approach to débride the frayed margins of the torn tendon and includes a subacromial decompression. The torn portion of the tendon may or may not be repaired.[8,79,128,195,203,215]

Two decades ago, primarily small and medium *full-thickness* cuff tears were managed with a fully arthroscopic approach.[67,79,128] With the evolution of arthroscopic techniques, an increasing number of large, full-thickness tears and some massive tears are managed with a fully arthroscopic approach.[215,236] However, variations of the mini-open (deltoid

*8,12,79,87,128,160,162,188,202,215,236
†8,66,67,68,79,128,195,215,236

*12,68,87,110,128,162,202

splitting) approach are frequently the surgeon's choice for repair of medium and large tears.[62,128,204] Even some massive tears are managed with a deltoid-splitting approach.[128,217] The traditional open approach, requiring detachment and repair of the deltoid, is now primarily reserved for repairs of multiple tendon tears associated with extensive injury to the shoulder.[62,128]

The location of the cuff tear, amount of retraction and mobility of a full-thickness tear, and the quality of the remaining tendon and underlying bone also influence the surgeon's selection of the type of cuff repair expected to be most effective.[79,128,203,215] Whereas small, medium, and large tears of the supraspinatus or infraspinatus are routinely managed with arthroscopic or mini-open approaches, tears of the subscapularis are often managed with a traditional open approach.[62] If there is significant retraction and poor mobility of the torn tendon or poor tissue quality, many surgeons believe that a stronger repair can be achieved with an open procedure than an arthroscopic repair.[79]

Postoperative Management

After surgical repair of a torn rotator cuff tendon, there are many factors that influence decisions about the position and duration of immobilization, the selection and application of exercises, and the rate of progression of each patient's postoperative rehabilitation program. These factors and their potential impact are summarized in Table 17.4. These factors also will affect postoperative prognosis and outcomes.

There is little consensus in the literature or in clinical practice as to how and to what extent each of these factors, singularly or collectively, has an impact on the decisions made by the surgeon and the therapist about a patient's postoperative rehabilitation program. Hence, predetermined guidelines and protocols for postoperative management after rotator cuff repair are diverse and sometimes contradictory.* For example, some authors have pointed out that if deltoid

*8,25,39,56,58,62,68,79,128,212

TABLE 17.4 Factors That Influence Progression of Rehabilitation After Repair of the Rotator Cuff

Factors	Potential Impact on Rehabilitation
■ Onset of injury	■ Chronic impingement and atraumatic cuff deficiency → slower progression than after acute traumatic injury.
■ Size and location of the tear	■ Larger tears with more tendons involved → slower progression.
■ Associated pathologies such as GH instability or fracture	■ More involved surgeries and potential for longer period of immobilization → slower progression of exercises or the need for additional precautions.
■ Preoperative strength and mobility of the shoulder	■ Preexisting weakness and atrophy of the dynamic stabilizers or limited passive and active mobility of the shoulder → slower postoperative progression.
■ Patient's general health	■ Patient in poor health; history of smoking; history of inflammatory disease → slower progression.
■ History of steroid injections or previous, failed cuff surgery	■ Compromised bone and tendon tissue quality, which affects the security of the repair (fixation) → slower progression.
■ Pre-injury level of activity or postoperative goals	■ Higher level activities increase risk of re-injury → a more extended and advanced postoperative training program.
■ Age of patient	■ Older patient → slower progression more likely.
■ Type of surgical approach	■ Traditional open approach (with deltoid detachment and repair) → slightly slower progression than after an arthroscopic or arthroscopically assisted (mini-open/deltoid splitting) repair.
■ Type of repair	■ Tendon to tendon → slower progression than tendon to bone.
■ Mobility (no excessive tension on the repaired tendon when arm at side) and integrity of the repair	■ If mobility is inadequate → longer duration of exercise within a protected ROM during early rehabilitation.
■ Patient's compliance with the program	■ Lack of compliance (doing too much or too little) can affect outcome.
■ Philosophy, skill, and training of the surgeon	■ All may have an impact that could → either slower or more accelerated progression

detachment and repair are components of the surgery, as is necessary for a traditional open repair, deltoid strengthening exercises should be postponed for approximately 6 to 8 weeks postoperatively until the repaired deltoid has healed.[39,58,128] Yet another author suggested that rehabilitation should proceed similarly regardless of whether deltoid detachment was required so long as secure fixation of the deltoid was achieved.[77]

Given the diverse characteristics of patients undergoing rotator cuff repair and the variety of surgical options available, it is not surprising that no single postoperative program can be used for all patients or has been shown to yield better outcomes than another. Therefore, to meet each patient's needs and goals, a therapist can use published protocols or those developed at individual clinical facilities as general guidelines for postoperative management. Modifications to protocols and guidelines should be made based on ongoing examination of the patient's response to interventions and through close communication with the surgeon.

Despite variations among postoperative programs, they share three common elements: (1) immediate or early postoperative motion of the GH joint; (2) control of the rotator cuff for dynamic stability; and (3) gradual restoration of strength and muscular endurance. This section will present *general* exercise guidelines that incorporate these elements into the phases of rehabilitation after arthroscopic or mini-open repair of a *full-thickness* cuff tear. Potential modifications and precautions due to a traditional open procedure or on factors such as size, location of the tear, and the quality of the repair will be noted.

NOTE: The goals, exercise interventions, and progression of rehabilitation after débridement rather than repair of a *partial-thickness* tear are comparable to postoperative management after subacromial decompression for cuff impingement presented in the previous section of this chapter.

Immobilization

The position and duration of immobilization of the operated shoulder after rotator cuff repair depends on many factors, including the size, severity, and location of the tear and the type and quality of the repair. The size of the cuff tear partially determines whether the patient's operated arm is supported in a sling (shoulder adducted, internally rotated, and elbow flexed to 90°) or in an abduction orthosis or pillow (shoulder elevated in the plane of the scapula approximately 45°, shoulder internally rotated, and elbow flexed). Patients supported in an abduction splint may require assistance from a family member to support the operated arm in the 45° shoulder position when the splint is removed for exercise, dressing, or bathing.

Table 17.5 summarizes the immobilization recommendations for fully arthroscopic and mini-open/deltoid-splitting approaches. Immobilization after a traditional open procedure that involves deltoid detachment and repair is not included in Table 17.5 because of the variations in guidelines reported in the literature.[39,79,128,217]

The rationale for initially immobilizing the shoulder in abduction is based on two principles. (1) In the abducted position, the repaired shoulder is held in a more relaxed, neutral position, reducing the possibility of reflexive muscle contractions that could disrupt the repairs. (2) Supporting the arm in abduction, rather than adduction, reduces tension on the tendons and, therefore, may improve blood flow to the repaired tendon(s).

Exercise Progression

Regardless of whether a patient undergoes a rotator cuff repair on an inpatient or outpatient basis, contact with a therapist for exercise instruction after surgery is usually limited to a few visits unless the patient does not progress satisfactorily. Therefore, the emphasis of a therapist's interaction with a patient must be placed on patient education for an effective and safe home-based exercise program.

FOCUS ON EVIDENCE

In a randomized, controlled study by Roddey and colleagues,[171] two approaches to exercise instruction following arthroscopic repair of a full-thickness rotator cuff tear were compared, specifically in-person instruction by a therapist and video-based instruction. On the first postoperative day, both groups of patients (total 108) received one visit from the therapist for initial instruction in the postoperative program (sling use and passive shoulder exercises). Patients in both groups received written handouts about the home exercise program. In addition, patients in the video-instruction group received a

TABLE 17.5 Relationships of Type and Duration of Immobilization after Arthroscopic and Mini-Open Repair* to the Size of the Rotator Cuff Tear

Size of Tear	Type and Duration of Immobilization
Small (≤ 1 cm)	Sling for 1–2 weeks; removal for exercise the day of surgery or 1 day postop
Medium to large (1 cm to 5 cm)	Sling or abduction orthosis/pillow for 3–6 weeks; removal for exercise 1–2 days postop
Massive (> 5 cm)†	Sling or abduction orthosis/pillow for 4–8 weeks; removal for exercise 1–3 days postop

*Fully arthroscopic and mini-open (arthroscopically assisted/deltoid splitting) approaches.
†A fully arthroscopic approach is not often used to repair massive cuff tears.

video demonstrating exercises for all phases of the rehabilitation program.

After discharge, patients in the video group saw the therapist four times (at 2, 6, 12, and 24 weeks) for evaluation and approval to advance to the next phase of rehabilitation, but they received all exercise instruction by watching the video at home. Patients in the other group also saw the therapist four times at identical intervals after discharge for follow-up evaluations and one-to-one instructions from the therapist on how to perform the exercises during the next phase of the home program. Between visits both groups had telephone access to their therapist for questions, and at 52 weeks, all patients were evaluated a final time.

Results of this study indicated that there were no significant differences between the two groups in compliance with the exercise program and functional outomes measured with a self-report instrument. The authors concluded that video-based exercise instruction was equally effective as therapist-directed exercise instruction. It is important to note that 30% of the patients dropped out of the study. The authors did not report whether these patients were progresssing well or if any of them left the study to seek individualized or more frequent therapy.

Goals and interventions for each phase of rehabilitation after arthroscopic or mini-open cuff repair follow. General guidelines for exercise and precautions after rotator cuff repair are summarized in Box 17.10. Precautions specific to a particular type of cuff tear or surgical procedure are also noted. The suggested timelines for each phase are general and must be adjusted based on factors already noted (see Table 17.4).

BOX 17.10 General Exercise Guidelines and Precautions Following Repair of a Full-Thickness Rotator Cuff Tear

Early Shoulder Motion

- Perform passive or assisted shoulder ROM within *safe and pain-free ranges* based on the surgeon's intraoperative observation of the mobility and strength of the repair and the patient's comfort level during exercise.
- Only passive, nonassisted ROM for 6 to 8 weeks after repair of a massive cuff tear or after a traditional open approach to prevent avulsion of the repaired deltoid.
- Initially perform passive and assisted shoulder ROM in the supine position to maintain stability of the scapula on the thorax.
- Minimize anterior and superior translations of the humeral head and the potential for impingement. Position the humerus slightly anterior to the frontal plane of the body and in slight abduction
  - While at rest in the supine position, support the distal humerus on a folded towel.
  - When initiating passive or assisted shoulder rotation while lying supine, position the shoulder in slight flexion and approximately 45° of abduction.
  - When initiating assisted shoulder extension, perform the exercise in prone (arm over the edge of the bed) from 90° to just short of neutral. Later progress to exercises behind the back.
- When performing assisted or active exercises in the upright position (sitting or standing), be certain that the patient maintains an erect trunk posture to minimize the possibility of impingement.
- To ensure adequate humeral depression and avoid superior translation of the head of the humerus when beginning *active* elevation of the arm, restore strength in the rotator cuff, especially the supraspinatus and infraspinatus muscles, before dynamically strengthening the shoulder flexors and abductors.
- Do not allow *active* shoulder flexion or abduction until the patient can lift the arm without hiking the shoulder.

Strengthening Exercises

- When beginning isometric resistance to scapulothoracic musculature, be sure to support the operated arm to avoid excessive tension in repaired GH musculature.
- Use low exercise loads; resisted motions should not cause pain.
- No weight-bearing (closed-chain) exercises or activities for 6 weeks.
- Delay dynamic strengthening (progressive resistive exercise, or PRE) for a *minimum* of 8 weeks postoperatively for small, strong repair and for at least 3 months for larger tears.
  - If the supraspinatus or infraspinatus was repaired, proceed cautiously when resisting external rotation.
  - If the subscapularis was repaired, proceed cautiously with resisted internal rotation.
- After an open repair, postpone isometric resistance exercises to the repaired deltoid and cuff musculature for *at least* 6 to 8 weeks unless advised otherwise.

Stretching Exercises

- Avoid vigorous stretching, the use of contract-relax procedures, or grade III joint mobilizations for at least 6 weeks and often for 12 weeks postoperatively to give time for the repaired tendon(s) to heal and become strong.
  - If the supraspinatus or infraspinatus was repaired, initially avoid end-range stretching into internal rotation.
  - If the subscapularis was repaired, initially avoid end-range stretching into external rotation.
  - If the deltoid was detached and repaired, initially avoid end-range shoulder extension, adduction, and horizontal adduction.

Activities of Daily Living

- Wait until about 6 weeks after a mini-open or arthroscopic repair and 12 weeks after a traditional open repair before using the operated arm for light functional activities.
- After repair of a large or massive cuff tear, avoid use of operated arm for functional activities that involve heavy resistance (pushing, pulling, lifting, carrying heavy loads) for 6 to 12 *months* postoperatively.

Exercise: Maximum Protection Phase

The priorities during the initial phase of rehabilitation are to protect the repaired tendon, which is at its weakest approximately 3 weeks after repair,[203] and to prevent the potential adverse effects of immobilization. For almost all patients, the immobilization (sling or splint) is removed for brief sessions of passive or assisted ROM within limited (protected) and comfortable ranges during the first few days after surgery (see Table 17.5).

The maximum protection phase extends for as little as 3 to 4 weeks after a fully arthroscopic or mini-open repair of small or medium tears or as long as 6 to 8 weeks after repair of large or massive tears. After a fully arthroscopic repair of a small or medium cuff tear, every effort is made to attain nearly full passive shoulder ROM, particularly elevation and external rotation, by 6 to 8 weeks postoperatively.[62,128,215]

Goals and interventions. The following goals and selected interventions combined with the appropriate use of pain medication are initiated during the maximum protection phase.*

- ***Control pain and inflammation.***
  - Periodic use of ice.
  - Arm support for comfort.
  - Shoulder relaxation exercises.
  - Grade I oscillations of the GH joint.
- ***Prevent loss of mobility of adjacent regions.***
  - Assisted ROM of the elbow.
  - Active ROM of the cervical spine, wrist, and hand.
- ***Prevent shoulder stiffness/restore shoulder mobility.***
  - Pendulum exercises typically the first postoperative day or when the immobilizer may be removed for exercise.
  - Passive ROM of the shoulder within safe and pain-free ranges. Initially perform exercises in the supine position; begin both arm elevation and external rotation in the plane of the scapula.
  - Self-assisted ROM using the opposite hand or a wand for control by 1 to 2 weeks for patients with repairs of small to medium tears and about 2 weeks later for patients with repairs of large tears.
  - Active control of the shoulder with assistance as needed from the therapist or family members. With the patient lying supine, place the arm in 90° of shoulder flexion if pain-free. In this position, the effect of gravity on the shoulder musculature is minimal. This position has been called the "balance point position" of the shoulder.[56] Help the patient control the shoulder while moving to and from the balance point position, making small arcs and circles with the arm.
  - Active shoulder ROM by the latter part of this phase for small tears and as symptoms permit, initially supine with the elbow flexed, progressing to a semi-reclining position with the elbow less flexed.

PRECAUTION: Use only passive, nonassisted ROM for 6 to 8 weeks for a repair of a massive cuff tear or after a traditional open repair with deltoid detachment.[39,217]

- ***Prevent or correct postural deviations.***
  - Posture training and exercises to facilitate proper spinal alignment and shoulder retraction. (See Chapters 14 and 16.)
- ***Develop control of scapulothoracic stabilizers.***
  - Active movements of the scapula.
  - Submaximal isometrics to isolated scapular muscles.[118] To avoid excessive tension in repaired GH musculature, see that the operated arm is supported but not bearing weight.
  - Side-lying scapular protraction/retraction to emphasize control of the serratus anterior.
- ***Prevent inhibition and atrophy of GH musculature.***
  - Low-intensity, muscle-setting exercises (against minimal resistance). Setting exercises should not provoke pain in a healing cuff tendon. Begin as early as 1 to 3 weeks postoperatively depending on the size of the tear and quality of the repair.[39,56,58]

PRECAUTION: Recommendations for the safest position of the shoulder in which to begin isometric training of the GH musculature after cuff repair are inconsistent. Perhaps the safest suggestion is to start in a position that creates minimal tension on the repaired cuff tendons (shoulder internally rotated and flexed and abducted to about 45° and elbow flexed).[58] As the strength of the cuff muscles improves during the later phases of rehabilitation, exercises and activities can be performed with the arm positioned in more challenging and functional positions.

Criteria to progress. Criteria to advance to the second phase include:

- A well healed incision.
- Minimal pain with assisted shoulder motions.
- Progressive improvement in ROM.

Exercise: Moderate Protection Phase

The focus of the second phase of rehabilitation is to begin to develop neuromuscular control, strength, and endurance of the shoulder while continuing to attain full or nearly full, pain-free shoulder motion. Emphasis is placed on developing control of the scapular stabilizers and rotator cuff muscles.

For a patient with a repair of a small or medium tear, this phase begins around 4 to 6 weeks postoperatively and extends an additional 6 weeks. For most patients, strengthening exercises typically begin around 8 weeks postoperatively. This phase may begin as late as 12 weeks for a patient with a repair of a large or massive tear.

FOCUS ON EVIDENCE

In a descriptive study by Ellenbecker and colleagues,[56] patients ($n = 37$) who had undergone a mini-open repair for

*8,25,39,56,58,68,79,128,215,217

full-thickness cuff tears (small, medium, and large) but no concomitant lesions received physical therapy that emphasized early mobilization of the operated shoulder a mean of 10 visits by 6 weeks after surgery. Investigators measured passive shoulder ROM at 6 weeks and compared these measurements to those of the noninvolved limb.

At 6 weeks, mean values for passive flexion, abduction, and external and internal rotation (in 90° of abduction) of the operated shoulder approached those of the noninvolved shoulder: 154°, 138°, 74°, and 39°, respectively, in the operated shoulder compared to 156°, 164°, 91°, and 48°, respectively, in the noninvolved shoulder. Preoperative ROM was not reported in this study, nor were subjects divided into subgroups based on the size of the tear. However, the authors suggested that knowledge of short-term, objective measures of ROM and strength can assist a therapist in the clinical decision-making process, such as when to place more or less emphasis on restoring ROM or strength during a rehabilitation program. The ROM results of this study also demonstrate the value of early postoperative mobilization and to what extent return of shoulder mobility is possible just 6 weeks after mini-open rotator cuff repair.

Goals and interventions. The following goals and interventions are appropriate during this phase of rehabilitation.[8,25,39,56,58,62,128]

- ***Restore nearly complete or full, pain-free, passive mobility of the shoulder.***
  - Self-assisted ROM with an end-range hold by means of wand or pulley exercises, in single planes and combined (diagonal) patterns. Add shoulder internal rotation, extension beyond neutral, and horizontal adduction.
  - Mobilization of the incision site if well healed to prevent adherence of the scar.

PRECAUTION: The use of passive stretching and grade III joint mobilizations, if initiated during this phase of rehabilitation, must be done *very cautiously*. Vigorous stretching is not considered safe for 3 to 4 months, the time needed for the repaired tendons to have healed and become reasonably strong.[128]

- ***Increase strength and endurance and re-establish dynamic stability of the shoulder musculature.***
  - Active ROM of the shoulder through gradually increasing the pain-free ranges. Continue to have the patient perform active elevation of the arm in the supine position until the motion can be initiated without first elevating the scapula. When transitioning to upright positions (sitting or standing), reinforce the importance of maintaining an erect trunk during exercises.
  - Isometric and dynamic strengthening to scapulothoracic stabilizers. First, use alternating isometrics in nonweight-bearing positions; then progress to rhythmic stabilization during light upper extremity weight-bearing activities.
  - Submaximal multiple-angle isometrics of the rotator cuff and other GH musculature against gradually increasing resistance.
  - Dynamic strengthening and endurance training of the GH musculature within pain-free ranges against light resistance, such as light-grade elastic tubing or a 1- to 2-lb weight. Perform exercises below the level of the shoulder if pain is provoked with active movements above the shoulder.
  - Upper extremity ergometry at or just below shoulder level against light resistance to increase muscular endurance.
  - Use of the involved upper extremity for *light* (no-load or low-load) functional activities.

CLINICAL TIP

Because weakness and atrophy of the rotator cuff often are present prior to injury, strengthen and increase endurance of the cuff muscles before dynamically strengthening the shoulder abductors and flexors.

Criteria to progress. Criteria to transition to the final phase of rehabilitation and gradually return to unrestricted activities include:

- Full, pain-free passive ROM.
- Progressive improvement of shoulder strength and muscular endurance.
- A stable GH joint.

Exercise: Minimum Protection/Return to Function Phase

This final phase usually begins no earlier than 12 to 16 weeks postoperatively for patients with strong repairs or at 16 weeks or later for a tenuous repair. This phase may continue 6 months or more depending on the patient's expected functions during activities.

Goals and interventions. The goals and interventions during this final phase of rehabilitation are consistent with those previously discussed for late-stage nonoperative management of cuff disorders and for the final phase of rehabilitation after subacromial decompression. However, the progression of activities after a cuff repair is more gradual, and the time frame for adhering to precautions is more extended.

If full ROM still has not been restored by the beginning of this phase, include passive stretching of the GH musculature and joint mobilization. Incorporate activities that move the arm into the increased ranges of motion, such as gently swinging a golf club or tennis racket if the motions are pain-free. Advanced, task-specific strengthening activities dominate this phase of rehabilitation.

Patients generally are not allowed to return to high-demand activities for 6 months to 1 year postoperatively, depending

on the patient's level of comfort, strength, and flexibility as well as the demands of the desired activities.

Outcomes

A considerable number of outcome studies of operative management of rotator cuff tears have been reported in the literature with follow-up ranging from less than 6 months to 5 years or more. Outcomes commonly measured include pain relief, shoulder ROM and strength, overall function, and patient satisfaction.

Long-term outcomes after fully arthroscopic, mini-open, and traditional open repairs are comparable.[79] For example, after fully arthroscopic repair of full-thickness tears (mostly small or medium but some large or massive tears), overall outcomes of several studies were reported as good to excellent in 84%[66,67] and 92%[195] of patients followed for 2 to 3 years. These results are comparable to results reported for open repairs.[79,128] However, it has been shown that regardless of the type of operative repair performed, the size of the cuff tear influences postoperative outcomes. For example, comparably favorable long-term functional outcomes and pain relief have been reported after mini-open and traditional open repairs of small to medium-sized, full-thickness tears,[9,79,128] while outcomes are less favorable after repairs of large or massive tears.[128,217]

Other factors, such as the acuity or chronicity of the tear and the patient's age, also affect outcomes. Repairs of acute tears in young patients are more successful than repairs of similar-size tears associated with chronic cuff impingement and insufficiency in elderly patients (>65 years).[75] The presence of fewer associated pathologies, such as a biceps tendon tear or cuff tear arthropathy, also are associated with better postoperative outcomes.[128]

Pain relief. Although the results of individual studies vary, a systematic review of the literature indicated that an average of 85% of patients who have operative repair of the rotator cuff report satisfactory relief of pain. Pain relief after arthroscopic and mini-open repairs ranges between 80% and 92%.[178] This is comparable to results of previous studies of traditional open repairs, in which satisfactory pain relief was reported by 85% to 95% of patients.[78,87] The preoperative size of the tear has an impact on pain relief; specifically, patients with small and medium tears report a higher percentage of satisfaction with pain relief than patients with large or massive lesions.[78,128,178]

Shoulder ROM. In a prospective descriptive study of patients undergoing rotator cuff repair, the preoperative factor that most closely correlated with long-term limitation of shoulder ROM after surgery was the inability to place the hand behind the back.[207] Postoperative shoulder ROM is also associated with the size of the tear, with one study demonstrating that patients who had repairs of small to medium tears had more active flexion and abduction than patients with large tears.[87]

Strength. The rate of recovery of shoulder muscle strength also appears to be associated with the size of the tear, with faster recovery occurring with repair of small and medium tears than with repair of large or massive tears. Near-complete restoration of shoulder muscle strength occurs gradually and may take a year after repair of small and medium tears, while recovery of strength after repair of large or massive tears is inconsistent.[128,178]Although recovery of shoulder muscle strength occurs gradually throughout the first postoperative year, the most substantial gains are seen during the first 6 months.[128] In most cases, patients achieve 80% strength in the operated shoulder (compared to the noninvolved shoulder) by 6 months and 90% by 1 year.[173]

Functional abilities. It has been suggested that long-term functional outcomes correlate with the size of the tear, type of repair, tissue quality, and the integrity of the repair.[128] For example, patients who have undergone a mini-open repair return to functional activities about a month earlier than those who have had an open repair.[9] However, this outcome may be skewed by the fact that mini-open repairs are performed more often in younger patients with less severe tears.

Lastly, in a study of patients who presented with recurrence of a rotator cuff tear after repair, 80% of the patients had been reported to have good to excellent short-term functional outcomes, measured by objective criteria. This suggests that the evidence regarding whether there is a direct relationship between the integrity of the repair and the functional outcome is inconsistent.[78]

Shoulder Instabilities: Nonoperative Management

Related Pathologies and Mechanisms of Injury

Glenohumeral joint hypermobility can be atraumatic or traumatic. *Atraumatic hypermobility*, often referred to as instability, can be due to generalized connective tissue laxity or from microtrauma related to repetitive activities. *Traumatic instability* is caused by a single or sequence of high force events that compromise the integrity of the stabilizing structures, often dislocating the GH joint. With traumatic dislocation, there is complete separation of the articular surfaces of the GH joint from direct or indirect forces applied to the shoulder.[156]Atraumatic instability may be a predisposing factor to traumatic dislocation, especially with repetitive stressful overhead activities.[89] GH joint hypermobility, regardless of whether atraumatic or traumatic, is often categorized as unidirectional or multidirectional. A secondary effect of hypermobility is an impingement syndrome (described in an earlier section).

Atraumatic Hypermobility

Unidirectional instability. Unidirectional instability can be anterior, posterior, or inferior and is named for the direction that the joint is compromised. It may be the result of physiological laxity of the connective tissues or repetitive

nonuniform loading of the joint. With the compromise of stabilizing structures, the humeral head may continue to dislocate or sublux in the direction of the instability. This can lead to progressive degeneration of tissues and eventually tears in the supporting structures.

- *Anterior instability* usually occurs with forces against the arm when it is in an abducted and externally rotated position, resulting in anterior humeral head translations. If these forces occur with enough frequency and force to compromise anterior GH joint structures, instability results. Often these forces are self-generated, as in throwing athletes who repetitively position the arm such that the anterior capsule is overloaded. Positive signs include apprehension, load and shift, and anterior drawer tests.[123,226]
- *Posterior instability* is much less common but can occur from repetitive forces against a forward-flexed humerus, translating the humeral head posteriorly. There is a positive posterior drawer sign.[123,226]
- *Inferior instability* is typically the result of rotator cuff weakness/paralysis and is frequently seen in patients with hemiplegia.[72] It is also prevalent in patients who repetitively reach overhead (workers or swimmers, for example) and those with multidirectional instability. This is detected with a positive sulcus sign.[123,226]

Multidirectional instability. The GH joint is considered to have multidirectional instability when stability is compromised in more than one direction. Some individuals have physiologically increased extensibility of connective tissue, causing excessive joint mobility. In the GH joint, this increased extensibility allows larger than normal humeral head translations in all directions.[156,181] Many individuals, particularly those involved in overhead activities, develop laxity of the capsule from continually subjecting the joint to stretch forces.[65,98] Multidirectional instability is confirmed by a combination of the positive tests noted previously for unidirectional instability.

Common Structural and Functional Impairments

With atraumatic instability, symptoms are often chronic, intermittent, and activity dependent. Acute symptoms are infrequent but may occur if there is a significantly increased demand placed on the joint. Decreased endurance of the rotator cuff muscles may be a precipitating factor of repetitive trauma of the joint.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Possibility of recurrence when replicating the dislocating position or with forces applied to the arm in the dislocating position
- With anterior instability, restricted ability in sports activities, such as pitching, swimming, serving (tennis, volleyball), spiking (volleyball)
- With posterior dislocation, restricted ability in sports activities, such as follow-through in pitching and golf; restricted ability in pushing activities, such as pushing open a heavy door or pushing one's self up out of a chair or out of a swimming pool
- Discomfort or pain when sleeping on the involved side
- Inability to maintain arm positions or complete tasks requiring prolonged effort, especially overhead tasks

Traumatic Hypermobility

Traumatic anterior shoulder dislocation. Anterior dislocation most frequently occurs when there is a posteriorly directed force to the arm while the humerus is in a position of elevation, external rotation, and horizontal abduction. In that position, stability is provided by the subscapularis, GH ligaments (particularly the anterior band of the inferior ligament), and long head of the biceps.[109,172,208] A significant force to the arm may damage these structures, along with the attachment of the anterior capsule and glenoid labrum (Bankart lesion depicted in Fig. 17.19).

Traumatic anterior dislocation is usually associated with complete rupture of the rotator cuff. There may also be a compression fracture at the posterolateral margin of the humeral head (Hill-Sachs lesion also depicted in Fig. 17.19). Neurological or vascular injuries may also occur during dislocations.[76] The axillary nerve is most commonly injured, but the brachial plexus or one of the peripheral nerves could be stretched or compressed.

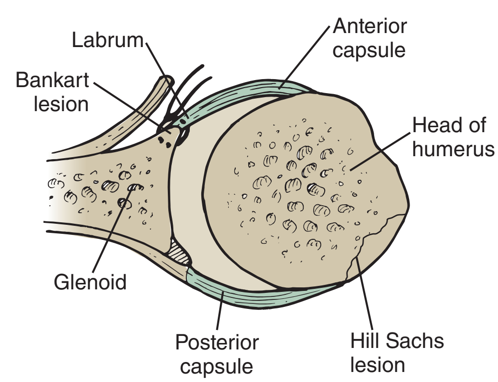

FIGURE 17.19 Lesions associated with traumatic anterior dislocation of the GH joint. A Bankart lesion is a fracture of the anterior rim of the glenoid with the attached labrum. The labrum is pulled away from the anterior glenoid along with a small piece of glenoid. A Hill-Sachs lesion, a compression fracture of the posterolateral humeral head, also may occur. *(Adapted from Tovin, BJ, Greenfield, BH: Evaluation and Treatment of the Shoulder—An Integration of the Guide to Physical Therapist Practice.* Philadelphia, FA Davis, 2001, p 295, with permission.*)*

Traumatic posterior shoulder dislocation. Traumatic posterior shoulder dislocation is less common. The mechanism of injury is usually a force applied to the arm when the humerus is positioned in flexion, adduction, and internal rotation, such as falling on an outstretched arm.[164] The person complains of symptoms when doing activities such

as push-ups, a bench press, or follow-through on a golf swing.[76]

Recurrent Dislocations

With significant ligamentous and capsular laxity, unidirectional or multidirectional recurrent subluxations or dislocations may occur with any movement that reproduces the humerus positions and forces that caused the original instability, causing significant pain and functional limitation. Some individuals can voluntarily dislocate the shoulder anteriorly or posteriorly without apprehension and with minimal discomfort.[156,185] The rate of recurrence after the first traumatic dislocation is highest in the younger population (< 30 years). Because they are more active and place greater demands on the shoulder, longer immobilization (> 3 weeks) is advocated after dislocation than in the less than 30-year-old patient. Shorter immobilization (1 to 2 weeks) is advocated for older patients.[127,130]

Common Structural and Functional Impairments

- After an acute traumatic injury, symptoms resulting from tissue damage include pain and muscle guarding due to bleeding and inflammation.
- When a dislocation is associated with a complete rotator cuff tear, there is an inability to abduct the humerus against gravity, except the range provided by the scapulothoracic muscles.
- Asymmetrical joint restriction/hypermobility. With anterior instability, the posterior capsule may become tight; with posterior instability, the anterior capsule may become tight. After healing from a traumatic event, there may be capsular adhesions.
- With recurrent dislocations, the individual can dislocate the shoulder at will, or the shoulder may dislocate during specific activities.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- With rotator cuff rupture, inability to reach or lift objects to the level of horizontal, thus interfering with all activities using humeral elevation
- Possibility of recurrence when replicating the dislocating position or with forces applied to the arm in the dislocating position
- With anterior dislocation, restricted ability in sports activities, such as pitching, swimming, serving (tennis, volleyball), spiking (volleyball)
- Restricted ability, particularly when overhead or horizontal abduction movements are required while dressing, such as putting on a shirt or jacket, and with self-grooming, such as combing the back of the hair
- Discomfort or pain when sleeping on the involved side in some cases
- With posterior dislocation, restricted ability in sports activities, such as follow-through in pitching and golf; restricted ability in pushing activities, such as pushing open a heavy door or pushing one's self up from a chair or out of a swimming pool

Closed Reduction of Anterior Dislocation

NOTE: Reduction manipulations should be undertaken only by someone specially trained in the maneuver because of the vulnerability of the brachial plexus and axillary blood vessels.

Management: Protection Phase

Protect the Healing Tissue

- Activity restriction is recommended for 6 to 8 weeks in a young patient. If a sling is used, the arm is removed from the sling only for controlled exercise. During the first week, the patient's arm may be continuously immobilized because of pain and muscle guarding.
- An older, less active patient (> 40 years of age) may require immobilization for only 2 weeks.
- The position of dislocation must be avoided when exercising, dressing, or doing other daily activities.

FOCUS ON EVIDENCE

Traditionally, after acute anterior shoulder dislocation, immobilization (for various lengths of time) has been instituted. A clinical commentary that looked at outcomes from various studies found that the literature does not support the use of a traditional sling for immobilizing the shoulder following primary anterior shoulder dislocation.[89] Still, it was noted that reports showed significantly better results (relative to redislocation) with activity restriction for 6 to 8 weeks in those < 30 years of age compared to activity restriction of less than 6 weeks.

The commentary also summarized two studies that looked at joint positioning during immobilization (magnetic resonance imaging with 18 patients and a cadavaric study). The study supported positioning the humerus in adduction and external rotation (rather than internal rotation) for better approximation between the detached glenoid labrum (Bankart lesion) and the glenoid neck.

Promote Tissue Health

Protected ROM, intermittent muscle setting of the rotator cuff, deltoid, and biceps brachii muscles, and grade II joint mobilization techniques (with the humerus at the side or in the resting position) are initiated as soon as the patient tolerates them.

PRECAUTIONS: In order not to disrupt healing of the capsule and other damaged tissues after anterior dislocation, ROM into external rotation is performed with the elbow at the patient's side, with the shoulder flexed in the sagittal plane, and with the shoulder in the resting position (in the plane of the scapula, abducted 55° and 30° to 45° anterior to the frontal plane) but not in the 90° abducted position. The forearm is moved from in front of the trunk (maximal internal rotation) to 0° or possibly 10° to 15° external rotation.

CONTRAINDICATION: Extension beyond 0° is contraindicated.

Management: Controlled Motion Phase

Provide Protection

The patient continues to protect the joint and delay full return to unrestricted activity. If a sling is being used, the patient increases the time the sling is off. The sling is used when the shoulder is tired or if protection is needed.

Increase Shoulder Mobility

- Mobilization techniques are initiated using all appropriate glides except the anterior glide. The anterior glide is *contraindicated* even though external rotation is necessary for functional elevation of the humerus. For a safe stretch to increase external rotation, place the shoulder in the resting position (abducted 55° and horizontally adducted 30°); then externally rotate the humerus to the limit of its range, and apply a grade III distraction force perpendicular to the treatment plane in the glenoid fossa (Fig. 17.20).
- The posterior joint structures are passively stretched with horizontal adduction self-stretching techniques.

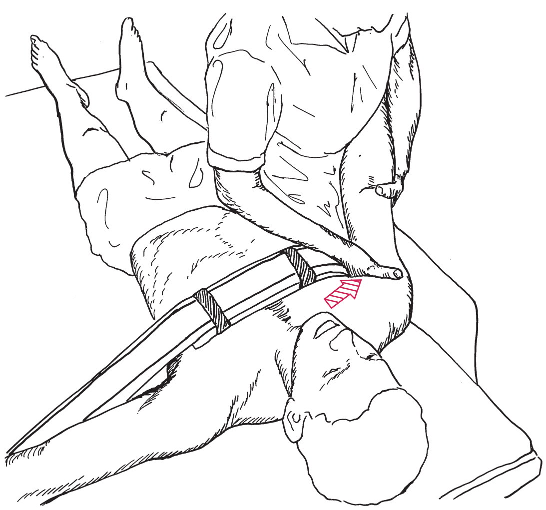

FIGURE 17.20 Mobilizing to increase external rotation when an anterior glide is contraindicated. Place the shoulder in resting position, externally rotate it, then apply a grade III distraction force.

Increase Stability and Strength of Rotator Cuff and Scapular Muscles

Both the internal and external rotators need to be strengthened as healing occurs.[26] The internal rotators and adductors must be strong to support the anterior capsule. The external rotators must be strong to stabilize the humeral head against anterior translating forces and to participate in the deltoid-rotator cuff force couple when abducting and laterally rotating the humerus. Scapular stability is important for normal shoulder function and to maintain the scapula in normal alignment. The following exercises are initiated.

- *Isometric resistance* exercises with the joint positioned at the side and progressed to various pain-free positions within the available ranges.
- Partial weight-bearing and stabilization exercises.
- *Dynamic resistance,* limiting external rotation to 50° and avoiding the position of dislocation.
- At 3 weeks, supervised *isokinetic resistance* for internal rotation and adduction at speeds of 180° per second or higher may be used.[7] Position the patient standing with the arm at the side or in slight flexion and elbow flexed 90°. The patient performs internal rotation beginning at the zero position with the hand pointing anteriorly and moving across the front of the body.
- Progress to positioning the shoulder at 90° flexion. Have the patient perform the exercise from zero to full internal rotation. Do not position in 90° abduction.
- By 5 weeks, all shoulder motions are incorporated into exercises on isokinetic or other mechanical equipment except in the position of 90° abduction with external rotation.

Management: Return to Function Phase

Restore Functional Control

The following are emphasized.

- A balance in strength of all shoulder and scapular muscles
- Coordinated scapulothoracic and arm motions
- Endurance for each previously described shoulder instability exercise

As stability improves, progress to:

- Eccentric training to maximum load.
- Increasing speed and control of combined motions.
- Simulating desired functional patterns for activity.

Return to Full Activity

- The patient can return to normal activities when there is no muscle strength imbalance, good coordination is present during skilled movements, and the apprehension test is negative. Full rehabilitation takes 2.5 to 4 months.[7]
- It is important that the patient learns to recognize signs of fatigue and impingement and is educated about how to reduce the exercise load when these signs are noticed.

Closed Reduction of Posterior Dislocation

The management approach is the same as for anterior dislocation with the exception of avoiding the position of humeral flexion with adduction and internal rotation during the acute and healing phases.

CLINICAL TIP

Use of a sling following a posterior dislocation may be uncomfortable because of the adducted and internally rotated position of the humerus, particularly if the sling elevates the humerus so the head translates in a superior and posterior direction. The patient may be more comfortable with the arm hanging freely in a dependent position while kept immobile.

When mobilization is allowed, begin joint mobilization techniques using all appropriate glides except the posterior glide. Posterior glide is *contraindicated.* If adhesions develop that limit internal rotation, mobility can be regained safely by placing the shoulder in the resting position (abducted 55° and horizontally adducted 30°), internally rotating it to the limit of its range, and applying a grade III distraction force perpendicular to the treatment plane in the glenoid fossa (same as in Fig. 17.20 but with the arm internally rotated).

Shoulder Instabilities: Surgery and Postoperative Management

Surgical stabilization procedures are often necessary to repair chronic, recurrent instabilities and acute traumatic lesions in the glenohumeral, acromioclavicular, and sternoclavicular joints to restore function. Background information on GH joint instabilities and injuries that frequently occur with dislocations to this joint was described in the previous sections on nonoperative management.

Glenohumeral Joint Stabilization Procedures and Postoperative Management

If a reasonable trial of nonoperative management has not been successful in preventing recurrence of GH joint instability, surgical stabilization may be considered. Recurrent instability after a traumatic event responds more favorably to surgical management than atraumatic instabilities.[14,127] Young, active patients who have sustained an acute, traumatic, anterior dislocation for the first time may elect to undergo surgery without a prior course of rehabilitation, because there is a particularly high rate of recurrence of dislocation in this group after nonoperative management.[127,130]

FOCUS ON EVIDENCE

In a small, prospective, randomized study[21] of young athletes who had sustained a first-time, acute, traumatic, anterior shoulder dislocation, one group of patients ($n = 14$) participated in a nonoperative rehabilitation program of immobilization and exercise and another group ($n = 10$) underwent arthroscopic stabilization (repair of a Bankart lesion) and postoperative rehabilitation (the same program the nonoperative group followed). Over an average of 36 months, of the 12 nonoperatively managed patients who were available for follow-up, 9 (75%) experienced recurrent instability, whereas of the 9 operatively managed patients available for follow-up, only 1 (11.1%) experienced recurrent instability. Six of the nine nonoperatively treated patients who experienced recurrent instability subsequently had an open Bankart repair.

In another randomized study[107] of young patients (mean age 22 years) who sustained traumatic anterior dislocations, patients either participated in a trial of nonoperative management or underwent immediate arthroscopic stabilization. Over a 2-year period, 47% of the patients in the nonoperative group—but only 15% of the surgical group—experienced recurrence of the dislocation. The results of these studies demonstrate that in young patients, early surgical stabilization followed by postoperative rehabilitation significantly reduces the incidence of recurrent instability compared to nonoperative management.

Indications for Surgery

The following are common indications for surgical stabilization of the GH joint.[127,130,199,215,219]

- Recurrent episodes of GH joint dislocation or subluxation that impair functional activities
- Unidirectional or multidirectional instability during active shoulder movements that causes apprehension about placing the arm in positions of potential dislocation, leading to compromised use of the arm for functional activities
- Instability-related impingement (secondary impingement syndrome) of the shoulder
- Significant inherent joint laxity resulting in recurrent involuntary dislocation
- High probability of subsequent episodes of recurrence of dislocation after an acute traumatic dislocation in young patients involved in high-risk (overhead), work-related, or sport activities
- Dislocations associated with significant cuff tears or displaced tuberosity or glenoid rim fractures
- Irreducible (chronic, fixed) dislocation
- Failure to resolve the instability and restore function with nonoperative management.

Procedures

Procedures designed to improve stability and prevent recurrent instability of the GH joint must balance stabilization of the joint with retention of near-normal, functional mobility. Stabilization procedures, which may involve the anterior, posterior, or inferior portions of the capsule, are performed today using either an arthroscopic or open approach depending on the type of lesion(s) present and type of procedure selected by the surgeon.[127,130,164,194,215] Open stabilization procedures are highly successful (low recurrence of dislocation) and have been considered the standard for years. However, with advances in arthroscopic techniques and methods of tissue fixation, the use and success of arthroscopic stabilization procedures has steadily increased.[215]

Recurrent anterior (unidirectional) dislocation is by far the most common form of GH instability managed with surgical stabilization.[130] In contrast, posterior or posteroinferior instabilities are less fequently managed with surgical stabilization.[164] The surgical procedures can be organized into several categories.

Bankart repair. A Bankart repair involves an open or arthroscopic repair of a Bankart lesion (detachment of the

capsulolabral complex from the anterior rim of the glenoid) (see Fig. 17.19), which commonly accompanies a traumatic anterior dislocation. During the repair an anterior capsulolabral reconstruction is performed to reattach the labrum to the surface of the glenoid lip.*

With an open repair, the humeral insertion of the subscapularis is detached (a takedown) or split longitudinally for access to the lesion and capsule.[71,127,175,179] Occasionally, access is achieved through the rotator cuff interval, which allows the subscapularis to remain intact.[127] If the subscapularis is detached, it is repaired after the labrum has been reattached. With an arthroscopic approach, multiple portal sites are used, and the subscapularis is not disturbed.[5,215] Repair of a Bankart lesion is combined with an anterior capsular shift if capsular redundancy is present.

With an open procedure, the labrum is reattached with direct transglenoid sutures or suture anchors, whereas with an arthroscopic approach transglenoid sutures, suture anchors, or tacks are used.[89,215] Generally, more secure fixation is achieved with an open repair than with an arthroscopic repair, although in recent years advances in arthroscopic tissue fixation have improved.[215]

Capsulorrhaphy (capsular shift). Capsulorrhaphy, which can be performed using either an open or arthroscopic approach, involves tightening the capsule to reduce capsular redundancy and overall capsule volume by incising, overlapping in a pants-and-vest manner (imbrication), and then securing the lax or overstretched portion of the capsule (plication) with direct sutures, suture anchors, tacks, or staples.†

A capsular shift procedure is tailored to the direction(s) of instability: anterior, inferior, posterior, or multidirectional (anteroinferior or posteroinferior). For example, if a patient has recurrent anteroinferior (multidirectional) instability, an anterior or inferior capsular shift is performed in which the anterior or inferior portion of the capsule is incised, tightened by imbrication (plication), and resutured. Most capsular shift procedures are performed because of anterior instability.[13,127,130,233]

Electrothermally assisted capsulorrhaphy. Electrothermally assisted capsulorrhaphy (ETAC) involves an arthroscopic approach that uses thermal energy (radiofrequency thermal delivery or nonablative laser) to shrink and tighten loose capsuloligamentous structures. The procedure—also referred to as a *thermal-assisted capsular shift* (TACS) or *thermocapsular shrinkage*—can be used alone but more often is used in conjunction with other arthroscopic procedures, such as repair of a glenoid tear, a capsular shift, débridement of a partial rotator cuff tear, or subacromial decompression.‡

It has been shown in animal and human cadaveric studies that thermal energy initially makes collagen fibrils more extensible; but as the collagen tissue of the capsuloligamentous structures heals, it shortens or "shrinks," causing a decrease in capsular laxity.[88,186] If one or more of the glenohumeral ligaments is detached or if rotator cuff lesions that could be contributing to the instability are detected, they are repaired arthroscopically prior to ETAC.

Posterior capsulorrhaphy (posterior or posteroinferior capsular shift). Recurrent, involuntary posterior or posteroinferior instability (far less common than anterior instability), if treated surgically, can be managed with either an open or arthroscopic capsular shift to remove posterior and inferior redundancy of the capsule.* Additional soft tissue procedures, such as repair of a posterior labral tear (reverse Bankart lesion) or in rare instances plication and advancement of the infraspinatus to reinforce the posterior capsule, may be necessary. Shoulders without an effective posterior glenoid can be surgically managed with capsulolabral augmentation[215] or occasionally with a glenoid osteotomy.[127,164]

Employing arthroscopic posterior stabilization, a capsular shift and repair of the posterior labrum can be accomplished with the shoulder musculature remaining intact.[163] For an open stabilization, a posterolateral incision is made; the deltoid is split; and the infraspinatus, teres minor, and posterior capsule are incised.[164,200] In some instances of traumatic multidirectional instability, anterior capsulorrhaphy is used to tighten the posterior capsule indirectly.[127,164,215]

Repair of a SLAP lesion. A tear of the superior labrum is classified as a SLAP lesion (*s*uperior *l*abrum extending *a*nterior to *p*osterior).[50,199,215,231] Some SLAP lesions are associated with a tear of the proximal attachment of the long head of the biceps tendon and recurrent anterior instability of the GH joint. An arthroscopic repair involves débridement of the torn portion of the superior labrum, abrasion of the boney surface of the superior glenoid, and reattachment of the labrum and biceps tendon with tacks or suture anchors. Concomitant anterior stabilization is also performed if instability is present.

Postoperative Management

General Considerations

As with rehabilitation after repair of rotator cuff tears, guidelines for postoperative management after surgical stabilization of the GH joint are based on many factors. These factors, all of which can influence the composition and progression of a postoperative program, are summarized in Table 17.6. Additional factors, such as the philosophy and training of the surgeon and a number of patient-related variables (general health, medications, preinjury functional status and postoperative goals, education, compliance) that affect rehabilitation after GH stabilization and rotator cuff repair already have been addressed (see Table 17.4).

The content in this section identifies *general* principles of management across three broad phases of postoperative rehabilitation after a variety of surgical stabilization and

*14,85,90,127,163,164,199,200,215

TABLE 17.6 Factors that Influence the Rehabilitation Program After Surgery for Recurrent Instability of the GH Joint

Factors	Potential Impact on Rehabilitation
▪ Atraumatic onset of instability	▪ More conservative postoperative rehabilitation due to greater risk of recurrent dislocation.[127]
▪ Severity of associated lesions	▪ Increased severity or number of associated lesions will slow the progression of rehabilitation.
▪ Previous failure of a surgical Stabilization	▪ Slower progression.
▪ Direction of instability	▪ Stabilization of anterior instability allows more rapid advancement than stabilization of posterior or multidirectional instabilities.[164]
▪ Type of surgical approach	▪ Less postoperative pain with arthroscopic procedure but rate of progression essentially the same after open and arthroscopic stabilization procedures, because rate of healing of repaired tissues is the same in both procedures.
▪ Type of procedure	▪ Electrothermally assisted capsulorrhaphy requires slower progression than arthroscopic or open capsular tightening without thermal application.[57,167,209] ▪ Boney reconstruction requires slower progression than after soft tissue reconstruction.
▪ Patient variables ▪ Tissue integrity ▪ Preoperative status of dynamic stabilizers ▪ Generalized joint laxity	▪ The progression of postoperative rehabilitation is more conservative for the inactive patient with multidirectional atraumatic instability who has generalized joint laxity and poor preoperative strength of the dynamic (muscular) stabilizers.

reconstruction procedures for recurrent unidirectional or multidirectional instabilities of the GH joint. These general guidelines cannot begin to address the many variations of rehabilitation programs recommended for specific stabilization procedures. However, many detailed protocols or case-based descriptions of rehabilitation programs for use after specific procedures and for specific types of shoulder instabilities and associated labral or rotator cuff lesions in various patient populations are available in the literature.*

Regardless of the type of instability, associated pathology, or type of surgical stabilization procedure, a postoperative rehabilitation program must be based on the findings of a comprehensive examination and individualized to meet the unique needs of each patient. The focus of postoperative rehabilitation is to restore pain-free shoulder mobility and muscular strength and endurance, particularly the dynamic joint stabilizers, to meet the patient's functional needs *while preventing recurrence of shoulder instability.*

Immobilization

Position. The position in which the patient's shoulder is immobilized after surgery is determined by the *direction(s) of instability* prior to surgery. After surgical reconstruction for recurrent *anterior* or *anteroinferior* instability, the shoulder is immobilized in a sling or splint in adduction (arm at the side) or varying degrees of abduction and in internal rotation (forearm across the abdomen) with the arm slightly anterior to the frontal plane of the body.[96,127] After surgery for *posterior* or *posteroinferior* instability, the upper extremity is supported in an orthosis, and the shoulder is immobilized in the "handshake" position (neutral rotation to 10° to 20° of external rotation, 20° to 30° of abduction, elbow flexed, and arm at the side or sometimes with the shoulder in slight extension).[60,127,164]

Duration. The duration of immobilization—that is, the period of time before use of the immobilizer is *completely* discontinued—is determined by many factors, including the type of instability, the procedure(s) performed, and the surgeon's intraoperative assessment. This period can range from 1 to 3 weeks to as long as 6 to 8 weeks. However, the period of *continuous* immobilization of the operated shoulder (before shoulder motion can be initiated) is kept as short as possible but varies with the type of procedure. For example, after an anterior stabilization procedure, the immobilizer may need to be worn continuously for only a day to a few days but in some cases up to 1 to 2 weeks.[130] In contrast, repairs of posterior or multidirectional instabilities, which are associated with a higher recurrence of dislocation, usually require a longer period of immobilization.[127,164,200] After a posterior stabilization procedure, the shoulder may be continuously immobilized and ROM delayed for up to 6 weeks postoperatively.[102,164]

*25,39,57,89,102,151,166,209,231,237

Time frames for immobilization also vary based on the factors that influence all aspects of postoperative rehabilitation (see Table 17.5). For example, the duration of immobilization is usually shorter for an elderly patient than for a young patient, because the elderly patient is more likely to develop postoperative shoulder stiffness than the young patient. In contrast, a patient with generalized hyperelasticity or a younger patient involved in high-demand activities, who is likely to place excessive stresses on healing tissues, requires a longer period of immobilization to reduce the risk of redislocation.[127]

Exercise Progression

As with the position and duration of immobilization, the decisions of when the arm may be temporarily removed from the immobilizer to begin shoulder exercises and to what extent specific shoulder motions are either permissible or must be limited are also based on many of the factors previously summarized (see Table 17.6).

CLINICAL TIP

During the early weeks of rehabilitation after a surgical stabilization procedure, determining what ranges fall within "safe" limits of motion is based on the extent of intraoperative ROM that was possible without placing excessive tension on the repaired, tightened, or reconstructed tissues. This information may be available in the operative report or should be communicated by the surgeon to the therapist prior to initiating postoperative exercises.

Rehabilitation after anterior stabilization (anterior capsular shift or Bankart repair) is similar after open and arthroscopic procedures. In both instances, there are precautions that must be heeded, particularly during the first 6 weeks after surgery while soft tissues are healing. During this time period after an open procedure, the anterior capsule and the detached and repaired subscapularis must be protected from excessive stresses. With an arthroscopic anterior stabilization, although the subscapularis remains intact, it is also necessary to protect the anterior capsule fixation during the initial phase of rehabilitation, because soft tissue fixation may not be as secure as the fixation used in an open procedure.

FOCUS ON EVIDENCE

In a 4-year follow-up study by Sachs and colleagues[179] of 30 patients who had sustained a traumatic anterior dislocation and had undergone an open Bankart repair (that included takedown and repair of the subscapularis tendon), only postoperative subscapularis function was significantly correlated with the patients' perception of a successful outcome after surgery. Although only two patients (6.7%) reported recurrence of instability over the 4-year period, postoperative testing indicated that seven patients (23%) had incompetence of the subscapularis muscle. Specifically, the mean strength of the subscapularis in these patients was only 27%, whereas in the remaining patients, said to have a competently functioning subscapularis, the mean strength was 80% of the noninvolved shoulder. There was no significant loss of strength in other shoulder muscles in either group of patients.

Of the patients with a reasonably strong subscapularis at the 4-year follow-up, 91% reported good to excellent results, and 100% indicated that they would have the surgery again. However, among the patients with a substantially weak subscapularis, 57% reported good to excellent results, but only 57% would undergo the surgery again. The investigators suggested that the handling of the subscapularis tendon during the repair and protection of the subscapularis the first few weeks following surgery was critical to shoulder function and the patients' perceptions of successful outcomes.

Precautions after arthroscopic or open anterior stabilization or reconstruction procedures are summarized in Box 17.11.[39,71,89,102,127,130,151,215] Precautions for thermally assisted capsular tightening,[57,61,167,209,230] posterior stabilization procedures,[60,102,163,164] and repair of a SLAP lesion[39,50,231] are noted in Box 17.12.

Exercise: Maximum Protection Phase

The initial phase of rehabilitation extends for about 6 weeks after surgery during which time protection of the tightened capsule or repaired or reconstructed structures, such as the labrum or the subscapularis, is necessary while minimizing the negative consequences of immobilization. Exercises may be initiated the day after surgery for select patients who have had an anterior stabilization procedure,[39] but more often are begun 1 to 2 weeks postoperatively.[102,151] ROM is delayed for a longer period of time after a thermally assisted stabilization,[57,61,167,209,230] a posterior stabilization procedure,[60,102,163,164] or repair of a SLAP lesion and torn biceps tendon[39,50,231] (see Box 17.12).

Goals and interventions. The goals and exercises for the maximum protection phase are summarized in this section.[39,57,60,89,151,228,237]

- ***Control pain and inflammation.***
  - A sling for comfort when the arm is dependent or for protection when in public areas. While seated, remove the sling (if permissible) and rest the forearm on a table or wide armrest with the shoulder positioned in abduction and neutral rotation to provide support but prevent potential contracture of the subscapularis and other internal rotators of the shoulder.
  - Cryotherapy and prescribed anti-inflammatory medication
  - Shoulder relaxation exercises
- ***Prevent or correct posture impairments.***
  - Emphasis on spinal extension and scapular retraction; avoid excessive thoracic kyphosis

BOX 17.11 Precautions After Anterior Glenohumeral Stabilization and/or Bankart Repair*

- Limit *ER, horizontal abduction,* and *extension* (shoulder positions that place stress on the anterior capsule) during first 6 weeks postoperatively.
  - After an arthroscopic stabilization, although the subscapularis is intact, to avoid pull-out of fixation, limit ER to 5° to 10° with the arm in slight abduction or at the side for the first 2 weeks.[39] Then, gradually progress to 45° over the next 2 to 4 weeks with the shoulder in greater abduction. With a tenuous stabilization, may need to limit ER to only neutral for the first 4 to 6 postoperative weeks.[215]
  - After an open procedure involving subscapularis takedown and repair, limit ER to 0° (no ER past neutral), to no more than 30° to 45° or to the "safe" limits identified during the intraoperative assessment for 4 to 6 weeks.[39]
  - Postpone ER combined with full shoulder abduction for at least 6 weeks.[89]
- After an arthroscopic stabilization, progress forward flexion of the shoulder more cautiously than after an open stabilization.
- After boney procedures, delay passive or assisted ROM for 6 to 8 weeks to allow time for bone healing.[127,130]
- No vigorous passive stretching to increase end-range ER for 8 to 12 weeks after either arthroscopic or open procedure except for patients with hypoelastic tissue quality.[215]
- When stretching is permissible, avoid positioning the shoulder in abduction and external rotation during grade III joint mobilization procedures.
- After procedures with subscapularis detachment and repair, no *active* or *resisted* IR for 4 to 6 weeks; avoid lifting objects, especially if pushing the hands together is required.[39,71,89,151]
- Avoid activities involving positions that place stress on the anterior aspect of the capsule for about 4 to 6 weeks.
  - Avoid functional activities that require ER, especially if combined with horizontal abduction during early rehabilitation as when reaching to put on a coat or shirt.
  - Avoid upper extremity weight bearing particularly if the shoulder is extended, as when pushing up from the armrests of a chair.
- When dynamically strengthening the rotator cuff, maintain the shoulder in about 45°, rather than 90°, of abduction.

*Precautions apply primarily to early rehabilitation during the first 6 weeks after surgery except as noted. The allowable ROM during the initial phase of rehabilitation depends on the type of pathology, surgical procedure, the patient's tissue quality (degree of hyper- or hypo-elasticity), and the intraoperative evaluation of shoulder stability.

BOX 17.12 Precautions After Selected Glenohumeral Stabilization Procedures

Thermally Assisted Capsular Tightening

- Be extremely cautious with ROM exercises for the first 4 to 6 weeks postoperatively because collagen in the thermally treated capsuloligamentous structures is initially more extensible (more vulnerable to stretch) until it heals. Some patients may begin ROM within protected ranges the day after surgery, whereas others may be required to postpone ROM exercises entirely for 2 weeks or more.
- While sleeping, complete immobilization (sling and swathe) for 2 weeks or more.
- Precautions for ROM depend on the direction of instability, patient's tissue quality (hyper- or hypoelastic), and the extent of concomitant surgical procedures necessary. For example, progress patients with congenital hyperelasticity more cautiously than those with hypoelasticity.

Posterior Stabilization Procedure and/or Reverse Bankart Repair

- Postpone all shoulder exercises or limit elevation of the arm to 90° and IR to neutral or no more than 15° to 20° and horizontal adduction to neutral (up to 6 weeks postoperatively).
- Restrict upper extremity weight bearing, particularly when the shoulder is flexed, to avoid stress to the posterior aspect of the capsule, for example during closed-chain scapulothoracic and GH stabilization exercises and functional activities, for at least 6 weeks postoperatively.
- Avoid resistance exercises that direct loads and place stress on the posterior capsule, such as bench press exercises and prone push-ups until late in the rehabilitation program, if at all.

Repair of a SLAP Lesion

- For SLAP lesions where the biceps tendon is detached, progress rehabilitation more cautiously than when the biceps remain intact.
  - Limit passive or assisted elevation of arm to 60° for the first 2 weeks and to 90° at 3 to 4 weeks postoperatively.
  - Perform only passive assisted humeral rotation with the shoulder in the plane of the scapula for the first 2 weeks (ER to only neutral or up to 15° and IR to 45°); during weeks 3 to 4, progress ER to 30° and IR to 60°.
- Avoid positions that create tension in the biceps, such as elbow extension with shoulder extension (as when reaching behind the back), during the first 4 to 6 weeks postoperatively.
- Postpone active contractions of the biceps (elbow flexion with supination of the forearm) for 6 weeks and resisted biceps exercises or lifting and carrying weighted objects until 8 to 12 weeks postoperatively depending on the extent and type of biceps repair; then progress cautiously.
- If the mechanism of injury was a fall onto the outstretched hand and arm causing joint compression, progress weight-bearing exercises gradually.
- If anterior instability is also present, follow precautions in Box 17.11.
- Avoid positions of abduction combined with maximum external rotation, as this places torsion forces on the base of the biceps attachment on the glenoid.

- ***Maintain mobility and control of adjacent regions.***
  - Active ROM of the cervical region, elbow, forearm, wrist, and fingers the day after surgery
  - Active scapulothoracic movements

PRECAUTION: Initially, strengthen the scapular stabilizing muscles in open-chain positions to avoid the need for weight bearing on the operated upper extremity. When weight-bearing activities are initiated, be cautious about the position of the operated shoulder to avoid undue stress to the vulnerable portion of the capsule for about 6 weeks postoperatively.

- ***Restore shoulder mobility while protecting tightened or repaired tissues.***
  - Pendulum exercises for the first 2 weeks postoperatively.
  - Self-assisted ROM and wand exercises for the GH joint *within protected ranges* as early as 2 weeks or as late as 6 weeks postoperatively. Begin shoulder elevation in the supine position; begin humeral rotation with the arm supported and the shoulder in a slightly abducted and flexed position.
  - With an anterior stabilization, gradually progress to near-complete ROM by 6 to 8 weeks except for external rotation, extension, and horizontal abduction beyond neutral.
  - With a posterior stabilization, progress cautiously into flexion, horizontal adduction, and internal rotation.
  - Progress to active shoulder ROM when motion can be performed without pain, apprehension, or use of substitute motions, such as elevating the scapula to initiate arm elevation.
  - Use the operated arm for *nonweight-bearing, waist-level* functional activities with no external resistance by 2 to 4 weeks postoperatively.
- ***Prevent reflex inhibition and atrophy of GH musculature.***
  - Multiple-angle, low-intensity isometric exercises of GH musculature as early as the first week or by 3 to 4 weeks postoperatively. Use caution with resisted internal rotation after subscapularis repairs.
  - *Possible* initiation of dynamic exercises against *light* resistance in protected ranges of motion at 4 to 6 weeks emphasizing the GH stabilizers.
  - Be particularly cautious when applying any type of resistance to musculature that has been torn or surgically detached, incised, or advanced and then repaired. Note that following a SLAP repair, resisted elbow flexion and resisted shoulder elevation will result in increased tensile loading of the long head of the biceps tendon.

NOTE: In some cases, dynamic exercises against light resistance are delayed until the intermediate phase of rehabilitation (about 6 to 8 weeks postoperatively), when only moderate protection is necessary.

Criteria to progress. Criteria to advance to the second phases of rehabilitation are:[39,57,89,102]

- A well healed incision.
- Reasonable improvement in ROM.
- Minimal pain.
- No sense of apprehension about instability with active motions.

Exercise: Moderate Protection Phase

The moderate protection phase of rehabilitation begins around 6 weeks postoperatively and continues until approximately 12 to 16 weeks. The focus is on maintaining joint stability while achieving nearly full active (unassisted) ROM of the shoulder; developing neuromuscular control, strength, and endurance of scapulothoracic and GH musculature; and using the upper extremity through greater ranges for functional activities.

Goals and interventions. The goals and interventions for the intermediate phase of rehabilitation are as follows.[39,57,89,102,228,237]

- ***Regain nearly full, pain-free, active ROM of the shoulder.***
  - Continue active ROM with the goal of achieving nearly full ROM by 12 weeks.
  - Incorporate ROM gains into functional activities.
  - Stretching and grade III mobilization in positions that do not provoke instability. After an anterior stabilization procedure, pay particular attention to increasing horizontal adduction, as the posterior structures are often tight preoperatively and continue to be tight postoperatively.
- ***Continue to increase strength and endurance of shoulder musculature.***
  - Alternating isometrics against increasing resistance with emphasis on the scapula and rotator cuff musculature.
  - Dynamic resistance exercises initiated or progressed using weights and elastic resistance with emphasis on scapulothoracic and glenohumeral stabilizers. Begin in mid-range positions, progressing to end-range positions. Emphasize both the concentric and eccentric phases of muscle activation.
  - Dynamic strengthening in diagonal and simulated functional movement patterns.
  - Upper extremity ergometry with a portable reciprocal exerciser on a table for muscular endurance. Include forward and backward motions.
  - Progressive upper extremity weight bearing during strengthening and stabilization exercises.

PRECAUTIONS: *After anterior stabilization*, do not initiate dynamic strengthening of the internal rotators from full external rotation, particularly in the 90° abducted position. When strengthening the shoulder extensors, do not extend posterior to the frontal plane. Similarly, when strengthening the horizontal abductors, do not horizontally abduct posterior to the coronal plane. In addition, maintain the shoulder in neutral rotation during horizontal abduction and adduction. *After posterior stabilization,* do not initially begin dynamic strengthening of the external rotators from a position of full internal rotation

Criteria to progress. Criteria to progress to the final phase of rehabilitation and the focus of exercises are similar to the

criteria already identified for the final phase of rehabilitation after rotator cuff repair.

Exercise: Minimum Protection/Return to Function Phase

This phase usually begins around 12 weeks postoperatively or as late as 16 weeks, depending on individual characteristics of the patient and the surgical stabilization procedure. Stretching should continue until ROM consistent with functional needs has been attained. Gains in ROM are possible for up to 12 months as collagen tissue continues to remodel. Resistance exercises to improve strength and endurance are progressed to replicate movements involved in functional activities, including positions of provocation of instability. Plyometric training (discussed in Chapter 23) is introduced and gradually progressed, particularly in patients intending to return to high-demand sports or work-related activities. Participation in desired work-related and sports activities often takes up to 6 months postoperatively.

PRECAUTIONS: Some patients may have permanent restrictions placed on functional activities that involve high-risk movements and that could potentially cause recurrence of the instability. After some anterior stabilization procedures, full external rotation (ER) in 90° of abduction may not be advisable or possible.[102]

Outcomes

A successful postoperative outcome involves regaining the ability to participate in desired functional activities without a recurrence of instability of the GH joint. There is a wealth of follow-up studies describing various outcomes after stabilization procedures. However, most of the studies comparing the success of one surgical intervention with that of another are not randomized—understandably so because the surgeon's examination is the basis for determining which procedure is most appropriate and will most likely lead to successful results for each patient.

Although postoperative exercise is consistently described as essential for optimal outcomes after stabilization surgery, no current, randomized studies were identified that compared the effectiveness of postoperative exercise programs after stabilization of the GH joint (method of instruction, content, rate of progression) for this review. As with surgical decisions, most postoperative rehabilitation programs are customized to meet each patient's needs, making comparison of outcomes difficult.

Results of surgery and postoperative rehabilitation are typically reported for specific pathologies, patient populations, and surgical stabilization procedures and are determined by means of a variety of outcome measures. Despite this, some generalizations can be made.

Recurrence of instability. Recurrent instability of traumatic origin responds more favorably to surgical management than atraumatic instability.[14,127] In addition, the rate of recurrence of instability is substantially higher in young patients (<30 to 40 years of age) and patients who return to high-demand, work-related activities or competitive overhead sports than less active, older patients (>30 to 40 years of age).[127,215]

The recurrence of dislocation rates after open and arthroscopic procedures also have been compared. Historically, recurrence rates after arthroscopic stabilization have been higher than after open stabilization.[40,127] In a review of studies on anterior stabilization procedures, the mean redislocation rate after open stabilization (Bankart lesion repair) was 11% (range 4% to 23%), but recurrence rates after arthroscopic stabilization were 18% (range 2% to 32%) with transglenoid suture fixation and 17% (range 0% to 30%) with tack fixation.[89] In another review of recent studies, the recurrence rates of anterior instability after an arthroscopic Bankart repair ranged from 8% to 17%.[215] Decreasing redislocation rates after arthroscopic procedures are attributed to improved arthroscopic techniques. Today, arthroscopic stabilization has been shown in many instances to be equal to open stabilization for patients with unidirectional, anterior instability.[40,215,220] However, for multidirectional instabilities, outcomes after arthroscopic stabilization are not yet equal to outcomes after open stabilization.[215]

Outcomes after stabilization procedures for anterior and posterior instabilities also have been compared. Surgical stabilization of a recurrent, unidirectional *anterior* instability has yielded more predictable results and lower recurrence rates than stabilization of *posterior* or *multidirectional* instabilities.[14,127,164,215,233] The average recurrence rate of posterior instability after arthroscopic stabilization has been reported to be particularly high. One source reported a 30% to 40% rate of redislocation,[200] and another reported rates as high as 50%.[215] In contrast, after anterior stabilization procedures, mean recurrence rates have been reported at 11% and 17% to 18%, respectively, for open and arthroscopic procedures.[89]

As the preoperative diagnosis has improved and the selection of appropriate candidates for surgery has become better, the recurrence of instability after posterior stabilization has decreased. In a study[163] with a mean follow-up of 39.1 months, the recurrence rate of instability after arthroscopic posterior stabilization was only 12.1%. The patients in this study had a mean age of 25 years with a history of involuntary or voluntary dislocation of the GH joint associated with acute traumatic and chronic repetitive microtrauma.

Regarding ETAC as the primary stabilization procedure, Hawkins and colleagues[86] reported failure in 37 of 85 patients. Failures were those procedures that resulted in the need for a revision stabilization, recurrent instabilities, or recalcitrant pain and stiffness. The authors noted that, for their practice, ETAC is now reserved primarily for augmentation of plication or other procedures in special circumstances

Shoulder ROM. After anterior stabilization procedures, full ER or horizontal abduction is sometimes not advisable or possible.[102] Likewise, some posterior stabilization procedures permanently limit full internal rotation (IR) and, to some extent, overhead elevation of the arm.[127]

After open anterior stabilization and Bankart repair, which usually requires detachment and repair of the subscapularis,

a mean loss of 12° of ER has been reported.[69] It has been suggested that there is less loss of shoulder ER after arthroscopic procedures than after open procedures.[89] However, in a nonrandomized study that compared open and arthroscopic anterior stabilization procedures, both groups had some loss of ER (mean loss of 9° and 11°, respectively, in the arthroscopic and open groups), but these differences between groups were not significant.[40]

After open GH stabilization for instability due to repetitive microtrauma, postoperative loss of shoulder ER is the most common reason athletes involved in overhead sports are unable to successfully return to competition. Loss of shoulder rotation is reported to be less after arthroscopic stabilization procedures, thus enabling a greater percentage of these athletes to return to competition.[167] Early follow-up of patients who have undergone thermally assisted capsular stabilization is encouraging,[61] but long-term outcomes are just becoming available. To date, the largest study of overhead athletes who underwent thermally assisted stabilization followed 130 patients for a mean of 29.3 months. Of these athletes, 113 (87%) returned to competition in a mean of 8.4 months. Although postoperative ROM was not reported, the implication was that the return of ROM after thermally assisted arthroscopic stabilization was sufficient for a high percentage of athletes being able to return to competition.

Acromioclavicular and Sternoclavicular Joint Stabilization Procedures and Postoperative Management

Acromioclavicular Joint Stabilization

A grade III separation, in which the acromioclavicular (AC) and coracoclavicular ligaments are completely ruptured may be surgically reduced and stabilized with a variety of techniques.[147,169] Techniques for management of acute dislocations include primary stabilization of the AC joint with Kirschner wires, Steinman pins, screws, or most recently bioabsorbable tacks, sutures, or fiber wires. Other procedures include a muscle-tendon transfer that moves the tip of the coracoid process with the attached tendons of the coracobrachialis and short head of the biceps to the undersurface of the clavicle[154] or the Weaver-Dunn procedure, which resects the distal clavicle and transfers the CA ligament from the acromion to the shaft of the distal clavicle.[147] Based on a small body of evidence in the literature, it appears the best results are achieved with primary AC and coracoclavicular stabilization procedures. Chronic AC dislocations, which are usually associated with degenerative changes of the AC joint, are most often managed with distal clavicle resection coupled with coracoclavicular stabilization.[154,169]

Sternoclavicular Joint Stabilization

Although most sternoclavicular (SC) dislocations are managed nonoperatively, an acute posterior dislocation of the SC joint that cannot be successfully reduced with a closed maneuver or an SC joint that dislocates recurrently are managed surgically. Surgical reduction of a traumatic anterior dislocation is not recommended.[168,234] Surgical options for posterior SC dislocations include open reduction with repair of the stabilizing ligaments or resection of a portion of the medial clavicle and fixation of the remaining clavicle to the first rib or sternum with a soft tissue graft.[168,234]

Postoperative Management

After surgical stabilization of either the AC or SC joint, the shoulder is immobilized for up to 6 weeks.[44] Exercise interventions are directed toward functional recovery as healing allows. No muscles provide dynamic stabilization of the AC and SC joints, so scapular and glenohumeral strength must be developed to provide indirect stability.

During the first few weeks of immobilization, the patient is encouraged to perform active ROM of the wrist and hand. If the elbow is supported on a table, the patient is permitted to perform active ROM of the elbow and forearm. The operated extremity, if supported, may be used for light functional activities, such as holding a utensil or typing, but weight bearing and shoulder ROM are completely prohibited during the first 6 weeks.[44]

When the immobilization can be removed, restoration of shoulder and elbow mobility and neuromuscular control of the shoulder girdle are the focus of the exercise program. Shoulder ROM (passive, progressing to assisted ROM), active scapular motions, and light isometrics of the shoulder musculature are initiated. Stabilization exercises, dynamic strengthening of the shoulder and scapula musculature, and stretching to restore full ROM are gradually introduced and progressed, as graduated functional activities are integrated into the rehabilitation program.

Exercise Interventions for the Shoulder Girdle

Exercise Techniques During Acute and Early Subacute Stages of Tissue Healing

During the *protection* and *early controlled motion* phases of management, when inflammation is present or just beginning to resolve and the healing tissues should not be stressed, early motion may be utilized to inhibit pain, minimize muscle guarding, and help prevent deleterious effects of complete immobilization. During the acute and early subacute stages of tissue healing, when motion in the shoulder itself is limited to allow tissues to begin to heal, it is also valuable to treat associated regions, such as the cervical and thoracic spine, the scapulae, and the remainder of the upper extremity, to relieve stresses to the shoulder girdle and prevent fluid stasis in the extremity.

General guidelines for management during the acute stage are described in Chapter 10, and specific precautions for various pathologies and surgical interventions in the shoulder are identified throughout the second major section of this chapter.

Early Motion of the Glenohumeral Joint

Early motion usually is passive ROM (PROM) and applied within pain-free ranges. When tolerated, active-assistive range of motion (A-AROM) is initiated. Manual PROM and A-AROM techniques are described in detail in Chapter 3. This section expands on self-assisted exercises.

Wand Exercises

- *Patient position and procedure:* Initiate A-AROM using a cane, wand, or T-bar in the supine position to provide stabilization and control of the scapula. Motions typically performed are flexion, abduction, elevation in the plane of the scapula, and internal/external rotation (Fig. 17.21 A).
- If it is necessary to relieve stress on the anterior capsule, following surgical repair of the capsule or labrum, place a folded towel under the distal humerus to position the humerus anterior to the midline of the body when the patient performs internal or external rotation (Fig. 17.21 B).

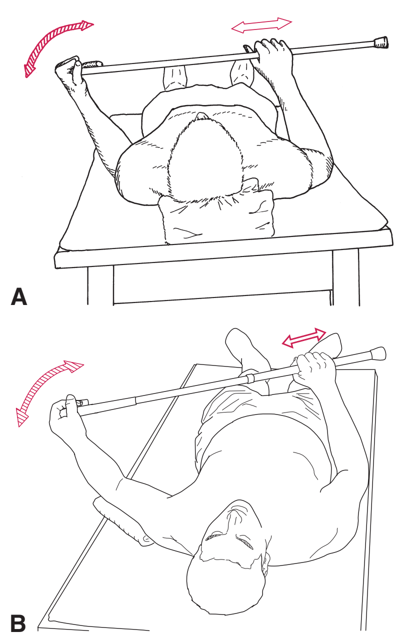

FIGURE 17.21 Self-assisted shoulder rotation using a cane **(A)** with the arm at the side and **(B)** in scaption. To relieve stress on the anterior capsule, elevate the distal humerus with a folded towel.

- When treating a shoulder impingement (primary or secondary), have the patient grasp the wand with the forearm supinated when performing shoulder flexion and abduction to encourage humeral external rotation.

Ball Rolling or Table Top Dusting

Patient position and procedure: Sitting with the arm resting on a table and hand placed on a 6- to 8-inch ball or towel and the humerus in the plane of the scapula. Have the patient initiate gentle circular motions of the shoulder by moving the trunk forward, backward, and to the side, allowing the hand to roll the ball or "dust the table." As pain subsides, have the patient use the shoulder muscles to actively move the ball or cloth through greater ROMs.

Wall (Window) Washing

Patient position and procedure: Standing with the hand placed against a wall supporting a towel or a ball. Instruct the patient to perform clockwise and counterclockwise circular motions with the hand moving the towel or rolling the ball. Progress this activity by having the patient reach upward and outward as far as tolerated without causing symptoms.

Pendulum (Codman's) Exercises

Patient position and procedure: Standing, with the trunk flexed at the hips about 90°. The arm hangs loosely downward in a position between 60° and 90° elevation (Fig. 17.22).

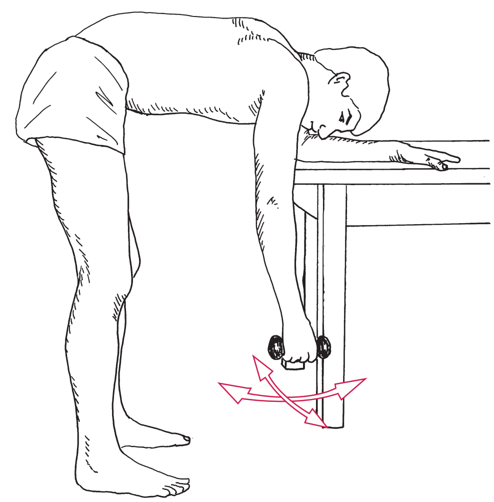

FIGURE 17.22 Pendulum exercises. For gentle distraction, no weight is used. Use of a weight causes a grade III (stretching) distraction force.

- A pendulum or swinging motion of the arm is initiated by having the patient move the trunk slightly back and forth. Motions of flexion, extension, and horizontal abduction, adduction, and circumduction can be done.[36] Increase the arc of motion as tolerated. This technique should not cause pain.
- If the patient cannot maintain balance while leaning over, have him or her hold on to a solid structure or lie prone on a table.
- If the patient experiences back pain from bending over, use the prone position.
- Adding a weight to the hand or using wrist cuffs causes a greater distraction force on the GH joint. Weights should

be used only when joint stretching maneuvers are indicated late in the subacute and chronic stages—and then only if the scapula is stabilized by the therapist or a belt is placed around the thorax and scapula, so the stretch force is directed to the joint, not the soft tissue of the scapulothoracic region.

PRECAUTIONS: If a patient gets dizzy when standing upright after being bent over, have the patient sit and rest. With increased pain or decreased ROM, the technique may be an inappropriate choice. Pendulum exercises are also inappropriate for a patient with peripheral edema.

FOCUS ON EVIDENCE

A recent electromyographic (EMG) analysis[116] demonstrated peak percent maximum voluntary isometric contraction (MVIC) greater than 15% in the supraspinatus and infraspinatus muscles when asymptomatic subjects performed large diameter pendulum exercises, regardless of whether they were performed correctly (using trunk motion to create GH movement) or incorrectly (using shoulder muscles to create GH movement). These muscle activation levels may be too high for recently repaired tissues. Smaller diameter exercises kept percent activation levels below 15% for infraspinatus and below 10% for supraspinatus.

"Gear Shift" Exercises

Patient position and procedure: Sitting with the involved arm at the side, holding a cane or wand with the tip resting on the floor to support the weight of the arm. Instruct the patient to move the pole forward and back, diagonally, or laterally and medially in a motion similar to shifting gears in a car with a floor shift (Fig. 17.23).

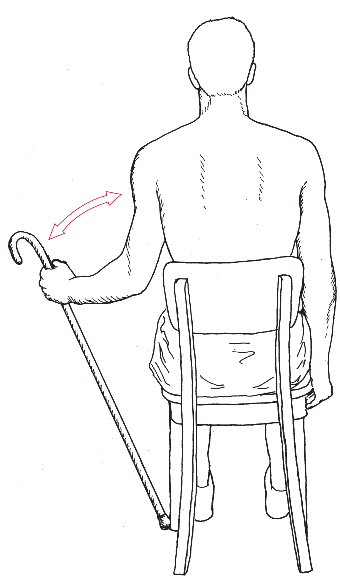

FIGURE 17.23 Gear shift exercise. Self-assisted shoulder rotation using a cane. Flexion/extension and diagonal patterns also can be done.

Early Motion of the Scapula

PROM and A-AROM of the scapula are described in Chapter 3. During the acute phase, the side-lying position is usually more comfortable than prone-lying. If the patient can perform active scapular elevation/depression and protraction/retraction, use the sitting position.

Early Neuromuscular Control

Frequently, the muscles of the rotator cuff are inhibited after trauma or surgery.[223] Initiate the following to stimulate activation and develop control in key muscles as soon as the patient tolerates it.

Multiple-Angle Muscle Setting

Begin gentle multiple-angle muscle-setting exercises of the internal and external rotators in pain-free positions of humeral flexion or scapular plane elevation. Activate the scapular and remaining GH muscles with gentle muscle-setting techniques in positions that do not exacerbate symptoms.

Protected Weight Bearing

In sitting, have the patient lean onto his or her hands or elbows and gently move from side-to-side. This helps to seat the humeral head in the glenoid fossa and stimulate muscle action.

Exercise Techniques to Increase Flexibility and Range of Motion

To regain neuromuscular control and function in the shoulder girdle, it may be necessary to increase flexibility in restricted muscles and fascia, so proper shoulder girdle alignment and functional ranges are possible. The principles of muscle inhibition and passive stretching are presented in Chapter 4. Techniques to stretch tight joints in the shoulder girdle were discussed earlier in this chapter with reference to Chapter 5 (joint mobilization procedures). Specific manual and self-stretching techniques are described in this section.

FOCUS ON EVIDENCE

In a randomized study of 20 subjects with restricted GH joint mobility, the experimental group underwent an intervention of soft tissue mobilization of the subscapularis, followed by contract-relax against manual resistance to the internal rotators, and then actively moved their extremity through the D_2 PNF pattern (flexion, abduction, and external rotation). The control group received no treatment; they rested for 10 minutes. Those who underwent the interventions had an

immediate post-treatment increase in external rotation of 16.4° ± 5.5° compared with 0.9° ± 1.5° in the control group ($p < 0.0005$) and an increase in overhead reach of 9.6 ± 6.2 cm compared with 2.4 ± 4.5 cm in the control group ($p<0.009$).[70]

It is worth noting the immediate positive results in this study; however, because long-term results were not determined, it is important to reinforce the need for follow-up self-stretching and ROM exercises in the patient's home exercise program.

Self-Stretching Techniques to Increase Shoulder ROM

Teach the patient a low-intensity, prolonged stretch. Emphasize the importance of not bouncing at the end of the range.

To Increase Flexion and Horizontal Adduction: Cross-Chest Stretch

Patient position and procedure: Sitting or standing. Teach the patient to adduct the tight shoulder horizontally by placing the arm across the chest and then applying sustained overpressure to the adducted arm by pulling the arm toward the chest, being careful not to rotate the trunk (Fig. 17.24).

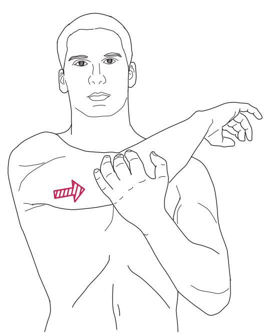

FIGURE 17.24 Self-stretching to increase horizontal adduction.

NOTE: The cross-chest stretch is used to increase mobility in the structures of the posterior GH joint, typically seen in shoulder impingement syndromes.[131]

To Increase Flexion and Elevation of the Arm

Patient position and procedure: Sitting with the involved side next to the table, forearm resting along the table edge, and elbow slightly flexed (Fig. 17.25 A). Have the patient slide the forearm forward along the table while bending from the waist. Eventually, the head should be level with the shoulder (Fig. 17.25 B).

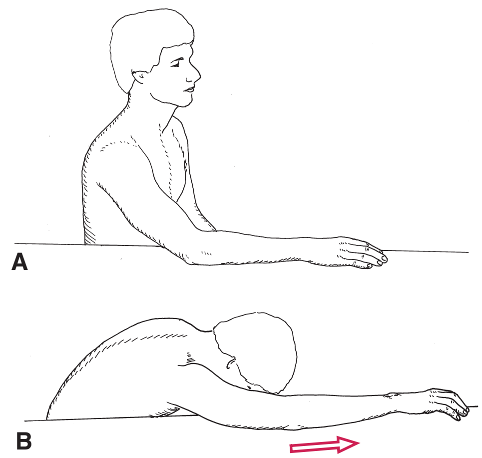

FIGURE 17.25 **(A)** Beginning and **(B)** end positions for self-stretching to increase shoulder flexion with elevation.

To Increase External (Lateral) Rotation

- *Patient position and procedure:* Standing and facing a doorframe with the palm of the hand against the edge of the frame and elbow flexed 90°. While keeping the arm against the side or in slight abduction (held in abduction with a folded towel or small pillow under the axilla), have the patient turn away from the fixed hand (Fig. 17.26 A).
- *Patient position and procedure:* Sitting at the side of a table with the forearm resting on the table and elbow flexed to 90°. Have the patient bend from the waist, bringing the head and shoulder level with the table (Fig. 17.26 B).

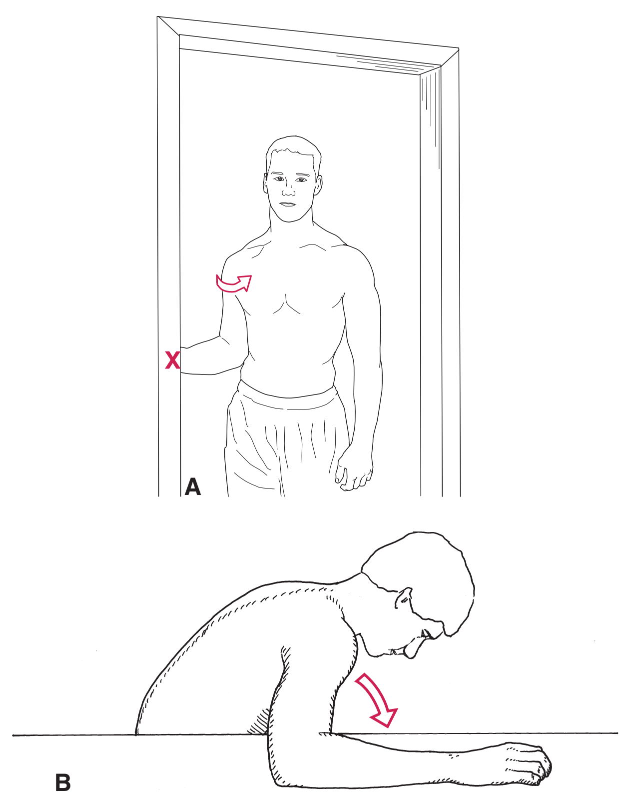

FIGURE 17.26 Self-stretching to increase external rotation of the shoulder **(A)** with the arm at the side using a doorframe and **(B)** with the arm in the plane of the scapular using a table to stabilize the forearm.

PRECAUTION: Avoid the stretch position (illustrated in Figure 17.26 B) if there is anterior GH instability.

To Increase Internal Rotation

- *Patient position and procedure:* Standing facing a doorframe with the elbow flexed to 90° and the back of the hand against the frame. Have the patient turn his or her trunk toward the fixed hand.
- *Patient position and procedure:* Side-lying on the affected side, with the shoulder and elbow each flexed to 90° and arm internally rotated to end position ("sleeper" position). Have the patient then push the forearm toward the table with the opposite hand (Fig. 17.27).

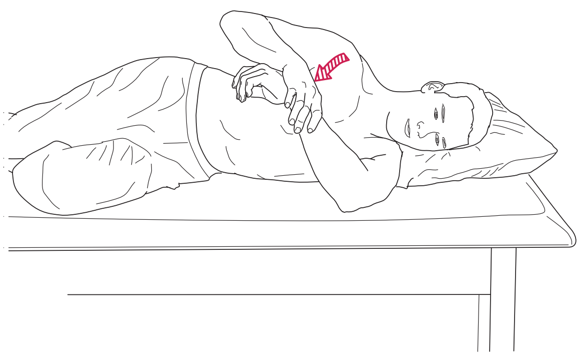

FIGURE 17.27 Self-stretching in the "sleeper position" to increase internal rotation of the shoulder using a table to stabilize the humerus.

FOCUS ON EVIDENCE

The horizontal cross-chest stretch described earlier in this section (see Fig 17.24) can also increase GH internal rotation ROM. In subjects with loss of GH internal rotation of at least 10° compared to their contralateral shoulder, performing this stretch five times daily for 30 seconds over a 4-week duration significantly increased GH internal rotation and total GH rotation compared to the opposite shoulder and to a control group.[131] Another stretch that targets the posterior GH joint structures, the side-lying "sleeper" stretch (see Fig. 17.27), also has been shown to effectively increase GH internal rotation, total GH rotation, and reaching up the back compared to the opposite shoulder.[131]

To Increase Abduction and Elevation of the Arm

Patient position and procedure: Sitting with the side next to a table, the forearm resting with palm up (supinated) on the table and pointing toward the opposite side of the table (Fig. 17.28 A). Have the patient slide his or her arm across the table as the head is brought down toward the arm and the thorax moves away from the table (Fig. 17.28 B).

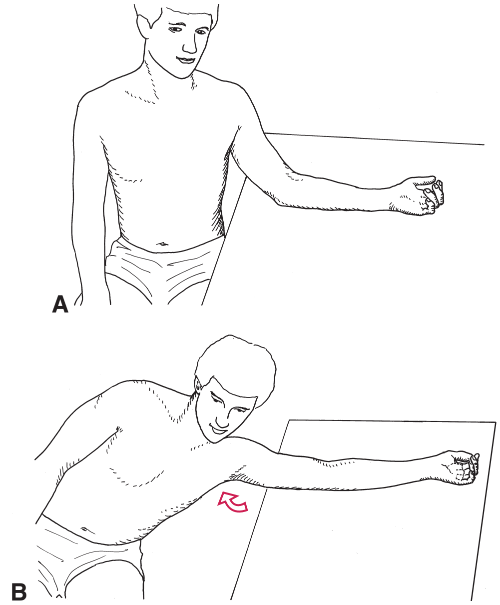

FIGURE 17.28 (A) Beginning and **(B)** end positions for self-stretching to increase shoulder abduction with elevation.

To Increase Extension of the Arm

Patient position and procedure: Standing with the back to the table, both hands grasping the edge with the fingers facing forward (Fig. 17.29 A). Have the patient begin to squat while letting the elbows flex (Fig. 17.29 B).

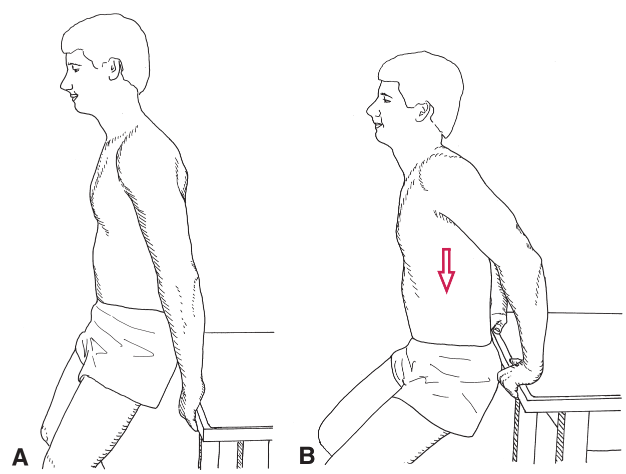

FIGURE 17.29 (A) Beginning and **(B)** end positions for self-stretching to increase shoulder extension.

PRECAUTION: If a patient is prone to anterior subluxation or dislocation, this stretching technique should not be done.

To Increase Internal Rotation, Extension, and Scapular Tilting

- ***Towel or Wand Stretch***

Patient position and procedure: Sitting or standing. Have the patient hold each end of a towel (or wand) with one arm

overhead and the arm to be stretched behind the lower back, and then pull up on the towel with the overhead hand (see Fig. 17.13). This stretch is used to increase the ability to reach behind the back. It is a generalized stretch that does not isolate specific tight tissues. Before using it, each component of the motion should be stretched, so no one component becomes overstretched relative to the other components.

PRECAUTION: If a patient has anterior or multidirectional GH joint instability or has had recent anterior stabilization surgery to correct a dislocated shoulder, this exercise should not be done until late in the rehabilitation program when the capsule is well healed, because it forces the head of the humerus against the anterior capsule.

Manual and Self-Stretching Exercises for Specific Muscles

Manual stretching of specific multijoint muscles that affect alignment of the shoulder girdle are presented in this section along with self-stretching techniques for these muscles.

To Stretch the Latissimus Dorsi Muscle

Manual Stretch

Patient position and procedure: Supine, with hips and knees flexed so the pelvis is stabilized in a posterior pelvic tilt. If necessary, provide additional stabilization to the pelvis with one hand. With the other hand, grasp the distal humerus and flex, laterally rotate, and partially abduct the shoulder to the end of the available range. Have the patient contract into extension, adduction, and medial rotation while providing resistance for a hold–relax maneuver. During the relaxation phase, elongate the muscle (see Fig. 4.16 B).

Self-Stretch

- *Patient position and procedure:* Hook-lying with the pelvis stabilized in a posterior pelvic tilt and the arms flexed, laterally rotated, and slightly abducted overhead as far as possible (thumbs pointing toward floor). Allow gravity to provide the stretch force. Instruct the patient not to allow the back to arch.
- *Patient position and procedure:* Standing with back to a wall and feet forward enough to allow the hips and knees to partially flex and flatten the low back against the wall, with the arms in a "hold-up" position (abducted 90° and laterally rotated 90° if possible). Tell the patient to slide the back of the hands up the wall as far as possible without allowing the back to arch.

NOTE: This exercise is also used to activate the lower trapezius and serratus anterior, as they upwardly rotate and depress the scapulae during humeral abduction.

To Stretch the Pectoralis Major Muscles

Manual Stretch

Patient position and procedure: Sitting on a treatment table or mat, with the hands behind the head. Kneel behind the patient and grasp the patient's elbows (Fig. 17.30). Have the patient breathe in as he or she brings the elbows out to the side (horizontal abduction and scapular adduction). Hold the elbows at this end-point as the patient breathes out. No forceful stretch is needed against the elbows, because the rib cage is elongating the proximal attachment of the pectoralis major muscles bilaterally. As the patient repeats the inhalation, again move the elbows up and out to the end of the available range and hold as the patient breathes out. Repeat only three times in succession to avoid hyperventilation.

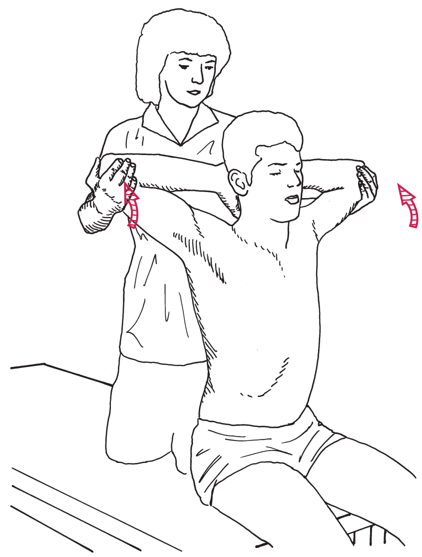

FIGURE 17.30 Active stretching of the pectoralis major muscle. The therapist gently pulls the elbows posteriorly while the patient breathes in and then holds the elbows at the end-point as the patient breathes out.

PRECAUTION: Hyperventilation should not occur, because the breathing is slow and comfortable. If the patient does become dizzy, allow time to rest; then reinstruct for proper technique. Be sure the patient maintains the head and neck in the neutral position, not forward.

Self-Stretch

- *Patient position and procedure:* Standing, facing a corner or open door, with the arms in a reverse T or a V against the wall (Fig. 17.31). Have the patient lean the entire body forward from the ankles (knees slightly flexed). The degree of stretch can be adjusted by the amount of forward movement.
- *Patient position and procedure:* Sitting or standing and grasping the wand with the forearms pronated and elbows flexed 90°. Have the patient then elevate the shoulders and bring the wand behind the head and shoulders (Fig. 17.32). The scapulae are adducted, and the elbows are brought out to the side. Combine with breathing by having the patient inhale as he or she brings the wand into position behind the shoulders; then exhale while holding this stretched position.

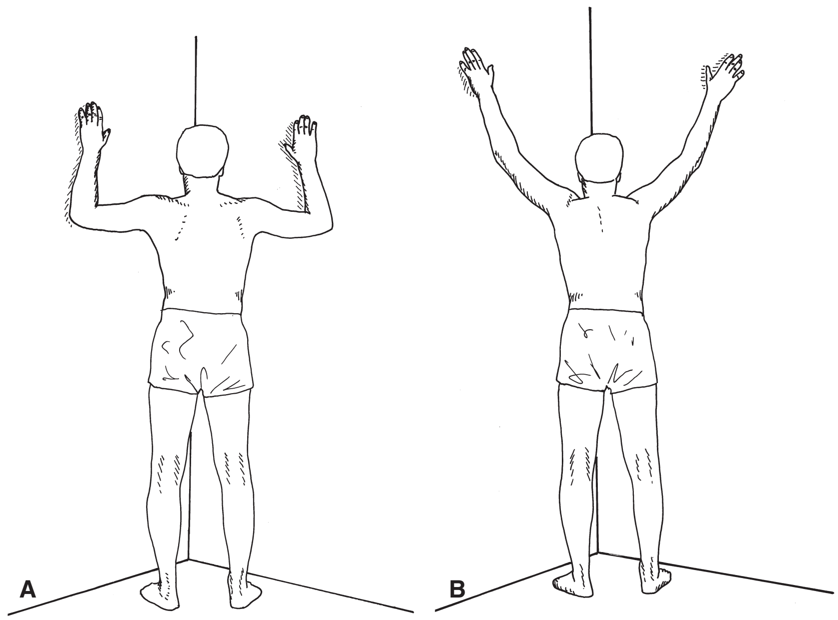

FIGURE 17.31 Self-stretching the pectoralis major muscle with the arms in a reverse-T position to stretch **(A)** the clavicular portion and in a V-position to stretch **(B)** the sternal portion.

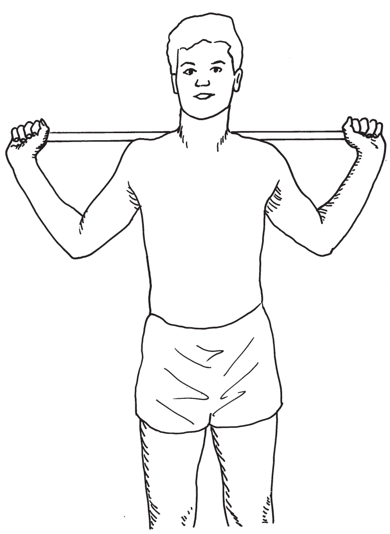

FIGURE 17.32 Wand exercises to stretch the pectoralis major muscle.

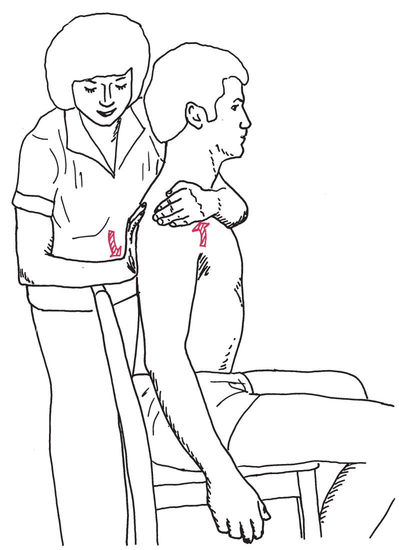

FIGURE 17.33 Active stretching of the pectoralis minor muscle. The therapist holds the scapular and coracoid process at the end-point as the patient breathes out.

To Stretch the Pectoralis Minor Muscle

Manual Stretch **VIDEO 17.1.**

Patient position and procedure: Sitting, place one hand posterior on the scapula and the other hand anterior on the shoulder just above the coracoid process (Fig. 17.33). As the patient breathes in, tip the scapula posteriorly by pressing up and back against the coracoid process while pressing downward against the inferior angle of the scapula; then hold it at the end-position while the patient breathes out. Repeat, readjusting the end-position with each inhalation and stabilizing as the patient exhales.

Self-Stretch

Patient position and procedure: Standing with the involved humerus at 90° abduction and elbow at 90° flexion and the forearm stabilized against a doorway. Instruct the patient to rotate the trunk away from the involved shoulder until a stretch is felt.[20] Note that this stretch may not be appropriate for patients with anterior instability, as this is their position of apprehension and it may overly strain the anterior restraints.

To Stretch the Levator Scapulae Muscle

NOTE: The levator scapulae muscle attaches to the superior angle of the scapula and causes it to rotate downward and elevate; it also attaches to the transverse processes of the upper cervical vertebrae and causes them to backward bend and rotate to the ipsilateral side. To minimize stress to the cervical spine, it is recommended that the cervical spine and head be placed at end-range and stabilized and that the stretch force be applied against the scapula.

Manual Stretch VIDEO 17.1.

Patient position and procedure: Sitting with the head rotated opposite to side of tightness (looking away from the tight side) and forward bent until a slight pull is felt in the posterolateral aspect of the neck. The arm on the side of tightness is abducted, and the hand is placed behind the head to help stabilize it in the rotated position. Stand behind the patient and stabilize with one arm; place the other hand (same side as the tight muscle) over the superior angle of the scapula (Fig. 17.34). With the muscle now in its stretched position, have the patient breathe in, then out. Hold the shoulder and scapula down to maintain the stretch as the patient breathes in again (he or she contracts the muscle against the resistance of the fixating hand). To increase the stretch, press down against the superior angle of the scapula. This is not a forceful stretch but a gentle hold-relax maneuver. Do not stretch the muscle by forcing rotation on the head and neck.

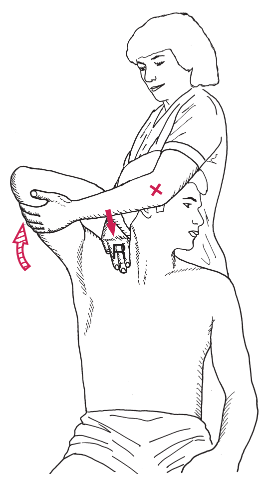

FIGURE 17.34 Stretching of the levator scapulae muscle. The therapist stabilizes the head and scapula as the patient breathes in, contracting the muscle against the resistance. As the patient relaxes, the rib cage and scapula depress, which stretches the muscle.

Self-Stretch

- *Patient position and procedure:* Standing with the head side bent and rotated away from the tight side, place the ipsilateral hand behind the head and the bent elbow against a wall. The other hand can be placed across the forehead to stabilize the rotated head. Instruct the patient to slide the elbow up the wall as he or she takes in a breath, then hold the position while exhaling (Fig. 17.35 A).
- *Patient position and procedure:* Sitting with head side bent and rotated away from the tight side. To stabilize the scapula, have the patient reach down and back with the hand on the side of the tightness and hold onto the seat of the chair. The other hand is placed on the head to gently pull it forward and to the side in an oblique direction opposite the line of pull of the tight muscle (Fig. 17.35 B).

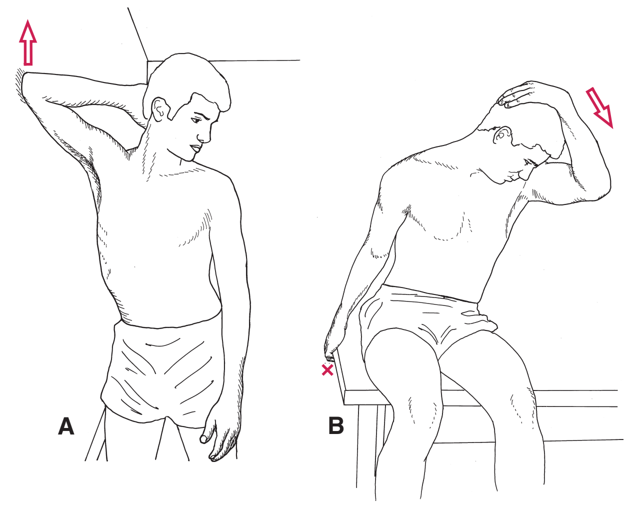

FIGURE 17.35 Self-stretching of the levator scapulae muscle **(A)** using upward rotation of the scapula and **(B)** using depression of the scapula.

To Stretch the Upper Trapezius Muscle

Manual Stretch

- *Patient position and procedure:* Sitting with the ipsilateral hand behind the back to stabilize the scapula and the head rotated to the tight side. Stand behind the patient and apply the stretch by adding a combination of cervical flexion, further rotation to the tight side, and side bending away from the tight side. A more aggressive manual stretch can be performed by using the other hand to depress the distal clavicle and the scapula.

PRECAUTION: Appling a stretch force against the head should not be done if the patient has cervical symptoms.

Self-Stretch

Patient position and procedure: Sitting or standing with the ipsilateral hand behind the back to stabilize the scapula. Instruct the patient to rotate his neck toward the tight side, then side bend away from the tight side and then add neck flexion. The patient may use the contralateral arm to grasp his or her own head to apply the stretch (Fig. 17.36).

FIGURE 17.36 Self-stretching of the upper trapezius muscle.

Exercises to Develop and Improve Muscle Performance and Functional Control

Developing control of the scapula and GH musculature is fundamental to correcting pathomechanics of the shoulder girdle and for improving strength, muscle endurance, power, and performance of functional activities. During observation of scapular alignment and movement, if excessive scapular tilting, winging, or poorly coordinated scapulohumeral rhythm during humeral elevation is identified, it is important to correct these faulty mechanics with properly chosen exercises. Likewise, insufficient stabilization and control of GH rotation and translation during humeral elevation necessitate the selection of exercises that emphasize training the rotator cuff musculature.

- The exercises described in the following sections begin at the simplest or least stressful level and progress to more complex and difficult levels.
- Exercises also progress from uniplanar or isolated muscle activation to use of combined, functional patterns.
- Initially, choose exercises that help the patient focus on activating correct muscles with appropriate timing and sequencing to counteract the identified impairments.
- Then increase the challenge by emphasizing patterns of exercises that prepare the musculature to respond to functional demands.

Regardless of the level of exercise, it is important to challenge patients at intensities they can meet so they can safely progress to more intense levels. Before teaching the resistance exercises and functional training activities presented in this section, it is important that the reader understands and applies the principles of resistance exercise, open- and closed-chain training, specificity of training, aerobic conditioning, and balance training described in Chapters 6 through 8. It is also important to apply the principles of tissue healing described in Chapter 10 and integrate the precautions for exercise associated with various shoulder pathologies and surgical interventions presented in this chapter. Because posture has a direct effect on the function of the shoulder girdle, refer to Chapters 14 and 16 for principles and exercises to correct postural impairments that might underlie faulty shoulder girdle mechanics. In addition to the exercises described in this section, high-demand exercises, such as plyometric training[222] and advanced activities for balance and stability, that may be appropriate in a shoulder rehabilitation program for selected individuals are presented in Chapter 23.

Box 17.13 summarizes a sequence for progressing exercises to improve muscle performance and shoulder girdle function and move an individual toward functional recovery.

Isometric Exercises

Isometric exercises are applied along a continuum of very gentle to maximum contraction, and they are applied at varying muscle lengths by changing joint angles. Choice of the intensity, muscle length, or joint angle and the number of repetitions is based on current strength, stage of recovery after injury or surgery, and/or the pathomechanics of the region.

BOX 17.13 Summary of Exercise Progressions for Shoulder Function

- Develop awareness and control of weak or disused muscles. Place emphasis on activating scapulothoracic and trunk musculature prior to glenohumeral musculature.
- For weak or surgically repaired musculature, begin with setting exercises and multiple-angle isometrics against minimal resistance and active-assistive ROM in open- and closed-chain positions within pain-free or protected ranges.
    - Provide just enough resistance and repetitions to challenge the muscles without provoking symptoms.
    - Include concentric and eccentric exercises.
- Develop control in postural muscles for stability of scapular and glenohumeral joints with stabilization exercises in both open- and closed-chain positions.
- As stabilizing control develops in the scapula and GH muscles, progress to dynamic resistance exercises, emphasizing scapular and rotator cuff muscle control during open- and closed-chain motions.
- First isolate and strengthen weak motions and muscles so substitute motions and inappropriate timing of muscle actions do not dominate.
- Develop muscle endurance simultaneously with muscle strength.
- Progress to combined movement patterns that simulate functional activities and train muscle groups to function in a coordinated sequence of control and motion.
- Integrate simple functional tasks into the exercise program and progress to more complex and challenging activities, always incorporating proper body mechanics.
- Implement total body exercises to improve cardiopulmonary endurance and balance.
- As necessary, based on functional goals, incorporate high-intensity eccentric exercises and plyometric training (stretch-shortening drills)[222] and agility drills at increasing speeds of movement into the shoulder rehabilitation program.

Scapular Muscles

Patient position and procedure: Side-lying, prone-lying, or sitting, with the arm supported if necessary. Resist elevation, depression, protraction, or retraction with pressure directly on the scapula in the direction opposite the motion.

Depression (lower trapezius). Activation of the lower trapezius is indicated when there is anterior tilting and delayed upward rotation of the scapula often seen with impingement syndromes. Apply resistance against the inferior angle of the scapula (Fig. 17.37 A).

Protraction (serratus anterior). Activation of the serratus anterior is emphasized when there is scapular winging, delayed or incomplete upward rotation of the scapula with GH elevation, or with accelerated downward rotation ("dumping") of the scapula during arm lowering. Apply resistance against the axillary border of the scapula or coracoid process or indirectly against the humerus positioned in the plane of the scapula (Fig. 17.37 B).

Retraction (rhomboids and trapezius). Activation of the rhomboids and trapezius muscle groups is emphasized when the scapular posture is protracted (abducted), as typically seen with a forward head and increased kyphotic posture. Apply resistance against the medial border of the scapula.

Multiple-Angle Isometrics: GH Muscles

Patient position and procedure: Supine, sitting, or standing. If pain from joint compression occurs, a slight distractive force to the GH joint as resistance is applied may decrease patient discomfort.

External and internal rotation. Position the humerus at the patient's side in slight flexion, slight abduction, or slight scapular plane elevation and the elbow flexed 90°. Apply resistance against the dorsal surface of the forearm to resist external rotation (Fig. 17.38 A) and to the volar surface to resist internal rotation (Fig. 17.38 B).

Abduction. Maintain the humerus neutral to rotation and resist abduction at 0°, 30°, 45°, and 60°. If there are no contraindications to motion above 90°, preposition the humerus

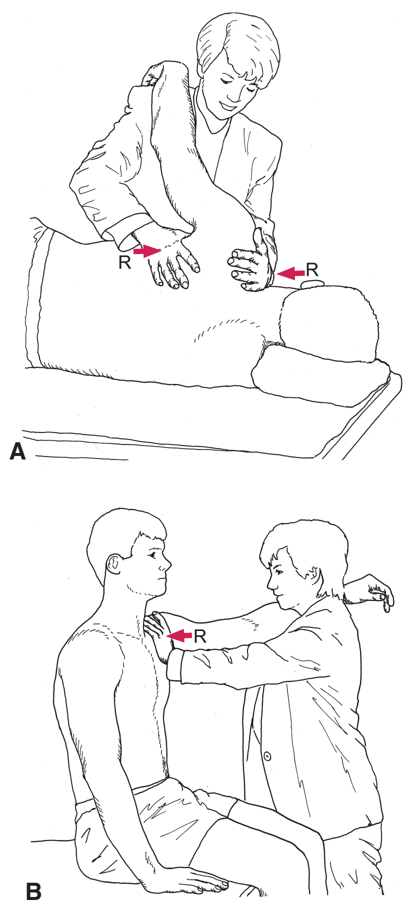

FIGURE 17.37 Isometric or dynamic manual resistance to scapular muscles. **(A)** Resistance to elevation/depression. **(B)** Resistance to protraction/retraction. Direct the patient to reach across the therapist's shoulder to protract the scapula while the therapist resists against the coracoid and acromion process. The therapist's other hand is placed behind the scapula to resist retraction.

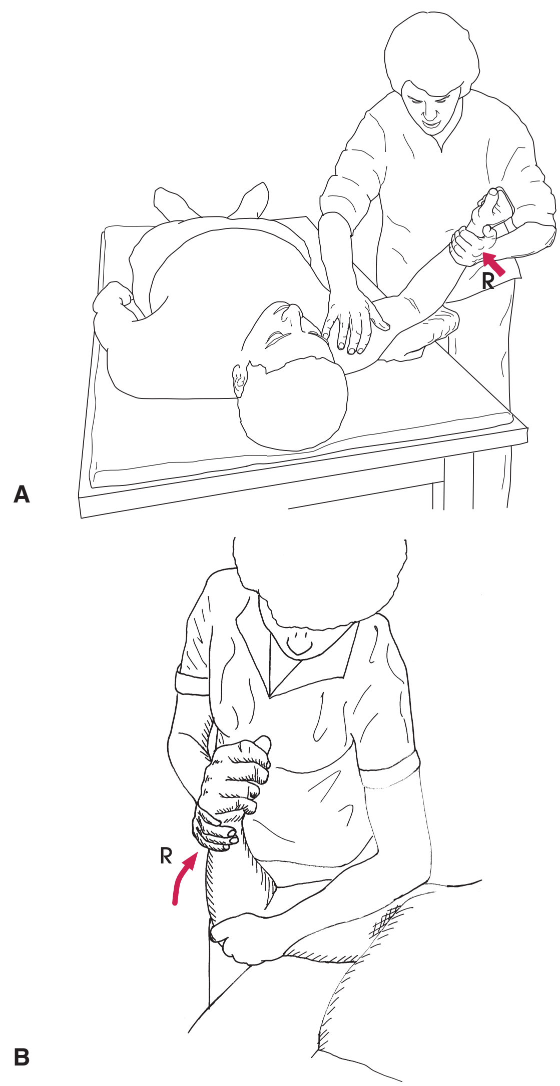

FIGURE 17.38 Isometric or dynamic resistance to shoulder rotation. **(A)** External rotation with the shoulder in the plane of the scapula. **(B)** Internal rotation with the shoulder at 90° abduction.

in external rotation before elevating the humerus and resisting above 90° abduction.

Scapular plane elevation. Position midway between flexion and abduction and resist at various positions in the range, such as 30° and 60° in the plane of the scapula (Fig. 17.39).

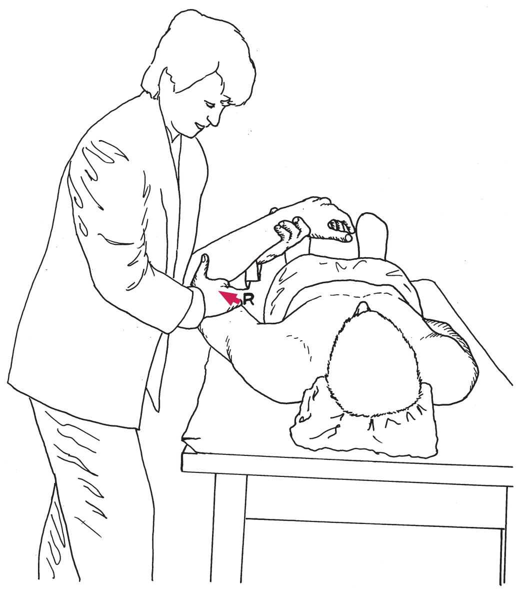

FIGURE 17.39 Isometric resistance in scapular plane elevation. The shoulder is positioned between 30° and 60° degrees of elevation, and controlled manual resistance is applied against the humerus.

Extension. Position the humerus at the side or in various positions of flexion and apply resistance against the humerus.

Adduction. Position the humerus between 15° and 30° abduction and apply resistance against the humerus.

Elbow flexion with forearm supination. Position the humerus at the side and neutral to rotation. Apply resistance to forearm flexion, causing tension in the long head of the biceps. Change the position of the shoulder into more flexion or extension and repeat the isometric resistance to elbow flexion.

Self-Applied Multiple-Angle Isometrics

Teach the patient how to independently apply isometric resistance using positions and intensities consistent with therapeutic goals. The patient can use the opposite hand (Fig. 17.40) or a stationary object, such as a wall or door frame (Fig. 17.41).

Stabilization Exercises

The application of alternating isometrics and rhythmic stabilization techniques (described in Chapter 6) is designed to develop strength and stability of proximal muscle groups in response to shifting loads. The shoulder girdle functions in both open- and closed-chain activities, and therefore, the muscles should be trained to respond to both situations.

- Begin training the scapular muscles so that when the muscles of the GH joint contract, they have a stable base on which to produce force (scapular stability).
- Initially, apply the alternating resistance slowly and instruct the patient to "hold" against the resistance.
- At the beginning of training, it also may be necessary to tell the patient which way you are going to push to help the patient focus on the contracting muscles and alternating forces.
- As the patient learns to respond by contracting the proper muscles and stabilizing the joints, increase the rapidity of the shifting resistance and decrease the verbal cues to enhance automatic responses.

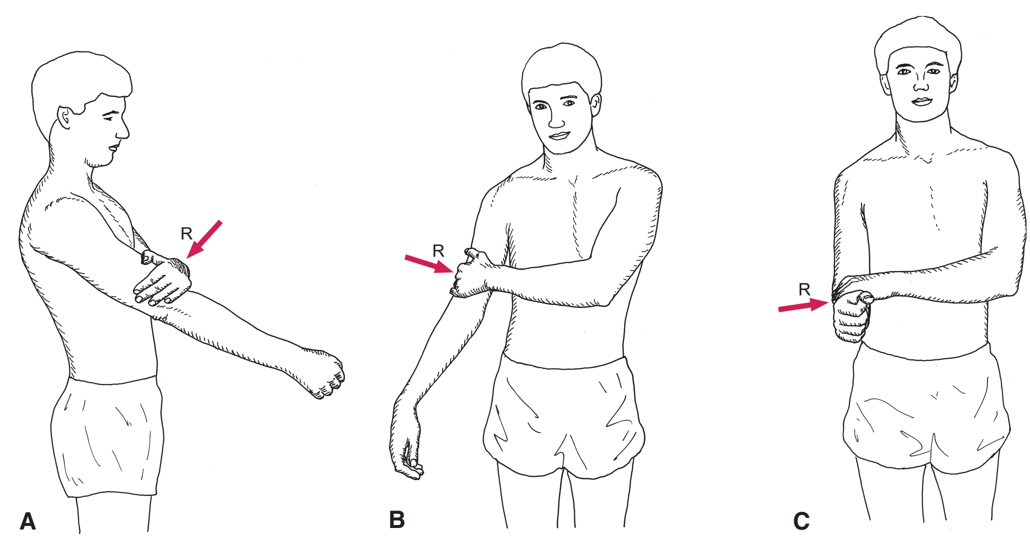

FIGURE 17.40 Self-resistance for isometric shoulder **(A)** flexion, **(B)** abduction, and **(C)** rotation.

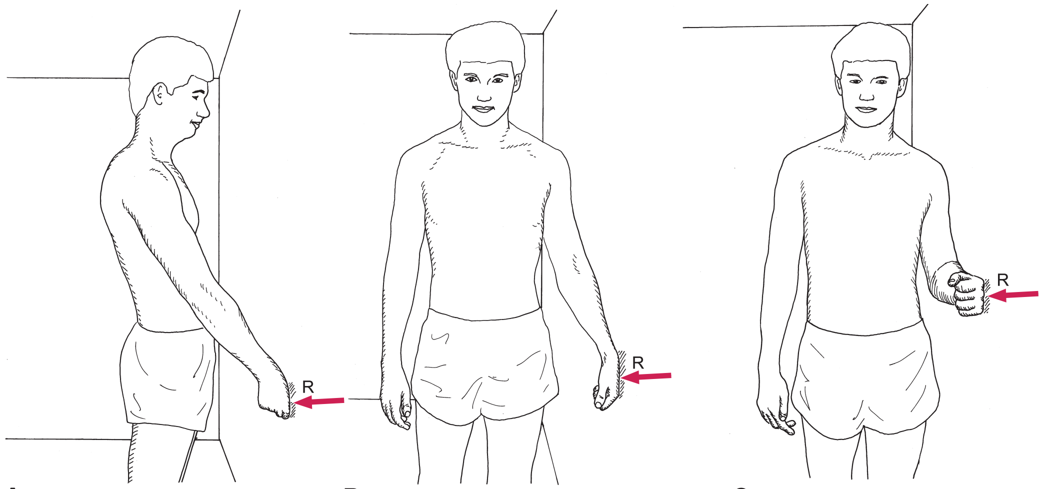

FIGURE 17.41 Using a wall to provide resistance for isometric shoulder **(A)** flexion, **(B)** abduction, and **(C)** rotation.

Open-Chain Stabilization Exercises for the Scapular Muscles VIDEO 17.2.

Begin with the patient side-lying, with the affected extremity up. Drape the forearm of the involved extremity over your shoulder. The degree of shoulder flexion, scaption, or abduction can be controlled by your stance and the relative position of the patient. Progress to sitting with the patient's arm draped over your shoulder; apply resistance to all scapular motions in the same manner as described previously.

Scapular elevation/depression. Place your top hand superiorly and the other hand inferiorly around the scapula to provide manual resistance (see Fig. 17.37 A).

Scapular protraction/depression. Place your top hand along the medial border and the other around the coracoid process to provide resistance (see Fig. 17.37 B).

Scapular upward and downward rotation. Place one hand around the inferior angle and the other hand around the acromion and coracoid process to provide resistance.

Open-Chain Stabilization Exercises for the Shoulder Girdle

Patient position and procedure: Supine holding a rod or ball with elbows extended and shoulders flexed to 90°. Stand at the patient's head and grasp the rod; instruct the patient to hold against or match the resistance you provide. Push, pull, and rotate the rod in various directions (Fig. 17.42). Resistance can also be applied directly against the arm or forearm.

- If too much assistance is being provided by the normal extremity, apply the stabilization technique to just the involved extremity.
- As the patient gains control, progress to sitting and then standing and have the patient hold the arm in various positions as alternating resistance is applied. Observe the scapula to be sure there is good stabilization. If not, return to the exercises described above or decrease the intensity of resistance. Progress these exercises to functional patterns as strength and control improve.

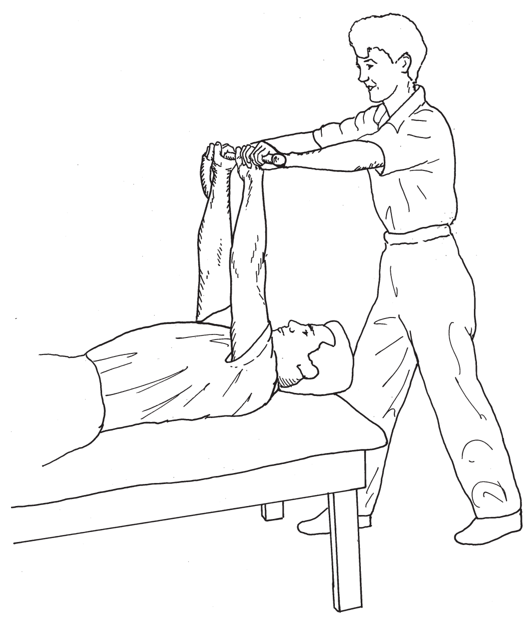

FIGURE 17.42 Stabilization exercises. The patient stabilizes with the shoulder girdle musculature (isometrically) against the resistance imposed by the therapist. Resistance to flexion/extension, abduction/adduction, and rotation is applied in a rhythmic sequence.

CLINICAL TIP

Studies have documented that when healthy individuals[113] or patients with shoulder instability[31] use the BodyBlade® during dynamic glenohumeral exercises (see Fig. 6.50), such as shoulder flexion and abduction, the scapulothoracic stabilizing muscles are activated to a greater extent than when the exercises are performed using weights or elastic resistance.

Static Closed-Chain (Weight-Bearing) Stabilization Exercises

Weight bearing activates the stabilizing muscles in proximal joints and may be a stimulus for improving fluid dynamics of articular cartilage as described in Chapter 5. Early during the controlled motion phase of management, it may be beneficial to initiate stabilization exercises in protected weight-bearing positions if tolerated by the healing tissues. The amount and intensity of weight bearing and resistance are progressively increased as tissues heal.

NOTE: If scapular winging occurs when the patient is weight bearing, do not progress these exercises until there is enough strength to stabilize the scapula against the rib cage.

FOCUS ON EVIDENCE

To help determine when upper extremity weight-bearing exercises could be included in an exercise program, Uhl and colleagues[210] analyzed the pectoralis major, anterior and posterior deltoid, supraspinatus, and infraspinatus with surface electromyography (EMG) in a progression of static exercises in 18 healthy subjects. Positions for isometric exercises included the prayer position (to simulate weight bearing against a wall), quadruped, tripod, pointer, push-up position (shoulders flexed to 90°), push-up position with feet elevated 18 inches (45 cm), and one-arm push-up position. There was a significant correlation between the increasing weight-bearing postures and increased muscular activity ($r = 0.97$, $p < 0.01$) in all the muscles. Also, the infraspinatus was the most active of the muscles tested in all positions except the prayer position (in which the pectoralis major was most active).

The authors suggested that the prayer and quadruped positions were appropriate for early rehabilitation owing to the low-activity level in all the muscles; that the tripod and pointer positions placed an intermediate demand on the infraspinatus and deltoid musculature; and that the push-up positions placed a high demand on the infraspinatus. They also concluded that the two-handed positions required less demand on the posterior deltoid but more load on the anterior deltoid and pectoralis muscles and that the one-arm push-up placed a high demand on all muscles except the supraspinatus.

- ***Scapular stabilization.***

Patient position and procedure: Side-lying on the uninvolved side. Both the elbow and shoulder of the involved arm are flexed to 90°, with the hand placed on the table and bearing some weight. Resist the scapular motions of elevation/depression and retraction directly against the scapula; resist protraction by pushing against the elbow.

- ***Alternating isometrics in protected weight bearing.*** **VIDEO 17.3.**

Patient position and procedure: Sitting with forearms placed on thighs or a table; or standing with hands placed on a table. Lean forward slightly to place light body weight through the extremities. Apply gentle resistance against the shoulders and ask the patient to match the resistance and "hold." Alternately apply resistance in various directions.

- ***Progression of closed-chain stabilization exercises.***

Patient position and procedure: Standing with shoulder at 90° and one or both hands leaning against a wall or on a ball (Fig. 17.43).

  - Additional, more advanced activities include having the patient assume the quadruped (all-fours) position with

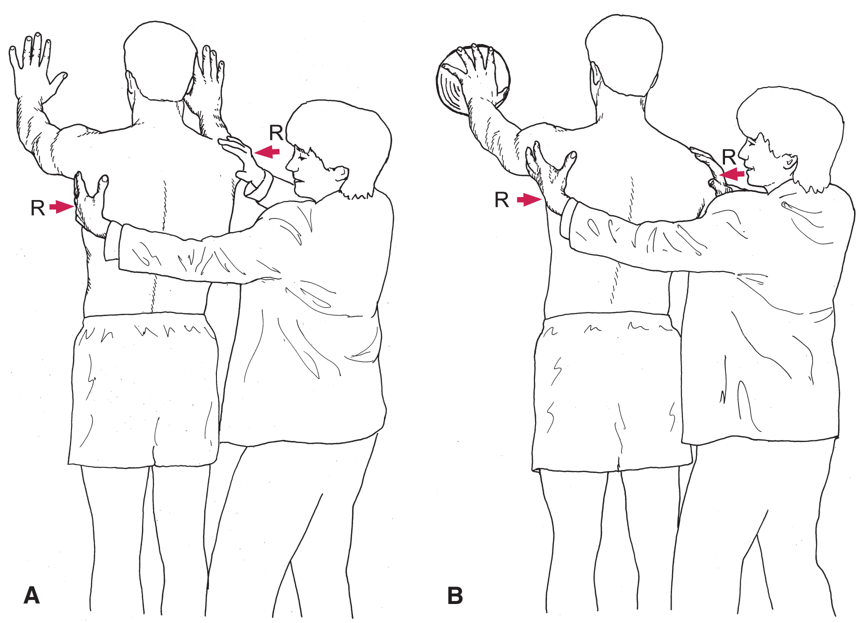

FIGURE 17.43 Closed-chain scapular and glenohumeral stabilization exercises. **(A)** Bilateral support in a minimal weight-bearing position with both hands against a wall. **(B)** Unilateral support on a less stable surface (ball). The therapist applies alternating resistance while the patient stabilizes against the resistance, or the therapist applies resistance as the patient moves from side-to-side.

hands on the floor. Apply alternating resistance against the shoulders or trunk and ask the patient to "hold" against the force. Pressing forward against the trunk increases the effect of body weight through the upper extremities and requires the serratus anterior to stabilize more strongly against the additional force. As already noted, if scapular winging occurs, reduce the resistance or the degree of weight bearing.
- Progress further by placing hands on unstable surfaces, such as a rocker or wobble board or on a ball, to require greater neuromuscular control and balance reactions. Each of these activities also can be done with weight only on the involved upper extremity.

Dynamic Closed-Chain Stabilization Exercises

Dynamic stabilization in weight-bearing positions requires the stabilizing muscles to maintain control of the scapula and GH joint while moving the body weight over the fixed extremity or extremities.

- *Patient position and procedure:* Standing with shoulders flexed 90° and hands supported against a wall or leaning into hands on a table. Have the patient shift his or her body weight from one extremity to the other (rock back and forth). Apply resistance against the shoulders (see Fig. 17.43).
- *Progression:* Have the patient alternately lift one upper extremity and then the other, so that one extremity bears the body weight and stabilizes against the shifting load.
  - Apply manual resistance to the shoulders or strap a weight around each wrist.
  - Apply manual resistance to the shoulders or trunk that becomes more variable in direction, timing, and amount of force.
- *Patient position and procedure:* Quadruped (all-fours) position with both hands on a stable surface; have the patient raise the ipsilateral and then contralateral leg to increase serratus activity and lower trapezius activity respectively.[122]
  - *Progression:* Perform with both hands on a rocker board, wobble board, or BOSU™ or perform alternating leg raises while only one hand bears weight on a stable or unstable support surface (see Chapter 23).

Dynamic Strengthening Exercises: Scapular Muscles

It is imperative that the proximal stabilizing muscles of the thorax, neck, and scapula function properly before initiating dynamic strengthening of the muscles that move the GH joint through the ROM to avoid faulty mechanics. Strengthening exercises can be performed in both open- and closed-chain positions. Progress exercises with repetitions and resistance within the mechanical limits of the involved tissues.

Initially apply light resistance with multiple repetitions for dynamic control and muscular endurance. As control develops, progress to combined patterns of motion and training for muscle groups to function in a coordinated sequence. Begin with simple functional activities and progress to more complex and challenging activities. Both muscular endurance and strength are necessary for postural and dynamic control of activities.

FOCUS ON EVIDENCE

A number of studies have been carried out to identify muscle activation during a variety of exercises for the shoulder girdle. Two EMG studies[54,91] analyzed exercises often used to strengthen the scapular muscles using either free weights or elastic tubing against maximum resistance. The findings of these two studies and a subsequent review of the literature[165] indicated the degree of activation of the trapezius and serratus anterior muscles during the following exercises.

- *Shoulder shrug, standing:* strongly activates the upper trapezius.
- *Full elevation of the arm above the head in the prone-lying position:* activates all three portions of the trapezius and serratus anterior when the shoulder is in line with the fibers of the lower trapezius.
- *External rotation in the prone-lying position with the shoulder positioned at 90° abduction and the elbow flexed 90°:* strongly activates the lower trapezius. This position is the "best exercise" to cause maximum depression of the scapula and isolation of the lower trapezius from the middle and upper portions.[54]
- *Horizontal abduction in the prone-lying position with the shoulder in external rotation:* activates the middle and lower trapezius.
- *Rowing action, seated or prone-lying:* emphasizes the middle trapezius over the upper and lower trapezius.[165]
- *Push-up with a plus:*strong activation of serratus anterior.[165]
- *Diagonal exercises* (flexion, abduction, external rotation), and *shoulder abduction in the plane of the scapula above 120°*: higher activity in the serratus anterior than in the trapezius.
- *Isolated protraction exercises:* do not activate the serratus anterior to as great a degree as upward rotation exercises.[54]

In another study, based on evidence suggesting that upper trapezius activation should be minimized compared to activation of other scapulothoracic muscles during movement, Cools and associates[41] examined several exercises for the activation ratios among the muscles. Favorable exercises (those with decreased upper trapezius activation and increased lower or middle trapezius activation) included side-lying flexion, side-lying external rotation, prone horizontal abduction with humeral external rotation, and prone extension. Favorable exercises for decreased upper trapezius and increased serratus anterior activation included high rowing and arm elevation with humeral external rotation in both the sagittal and scapular planes.

Scapular Retraction (Rhomboids and Middle Trapezius)

The following exercises are designed to isolate scapular retraction. Once the patient is able to retract the scapula against resistance, combine patterns with the GH joint to progress strength and functional patterns as described in the next sections.

- *Patient position and procedure:* Prone, sitting, and standing. Instruct the patient to clasp the hands together behind the low back. This activity should cause scapular adduction. Draw attention to the adducted scapulae and have the patient hold the adducted position of the scapulae while the arms are lowered to the sides. Have the patient repeat the activity without arm motion.
- *Patient position and procedure:* Prone with the arm over the edge of the table in a dependent position and a weight in the hand. Instruct the patient to pinch the scapulae together (Fig. 17.44). Progress this exercise to prone rowing and horizontal abduction against gravity (described below).

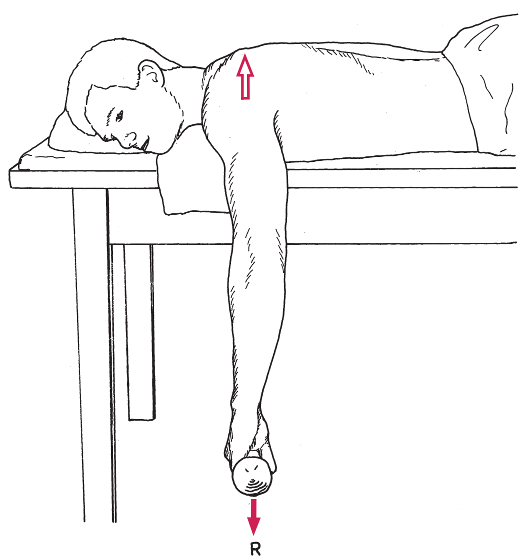

FIGURE 17.44 Scapular retraction against handheld resistance in the prone position.

- *Patient position and procedure:* Sitting or standing with the shoulder flexed to 90° and elbows extended. Have the patient grasp each end of an elastic band or tubing that has been secured at shoulder level or a two-handled pulley that is at shoulder level, and pinch the scapulae together by pulling against the resistance.

Scapular Retraction Combined with Shoulder Horizontal Abduction/Extension (Rhomboids, Middle Trapezius, Posterior Deltoid)

- *Patient position and procedure:* Prone with shoulders abducted 90°, elbows flexed, and forearms perpendicular to the floor. Instruct the patient to perform horizontal abduction with scapular retraction. This exercise can also be done with the elbows extended for greater resistance (Fig. 17.45). Progress this exercise by adding weights and then by having the patient perform the rowing motion standing or sitting in front of a length of elastic resistance that has been secured at shoulder level.

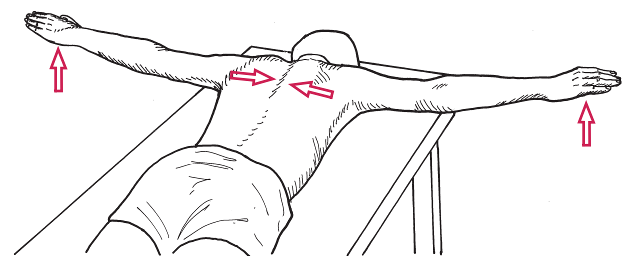

FIGURE 17.45 Horizontal abduction and scapular retraction exercises, with the arms positioned for maximal resistance from gravity. External rotation of the shoulders (thumbs pointing upward) emphasizes the middle and lower trapezius. To progress the exercise further, weights can be placed in the patient's hands.

- ***Corner press-out.***

Patient position and procedure: Standing with the back toward a corner, shoulders abducted 90°, and elbows flexed. Instruct the patient to press the elbows into the walls and push the body weight away from the corner (Fig. 17.46).

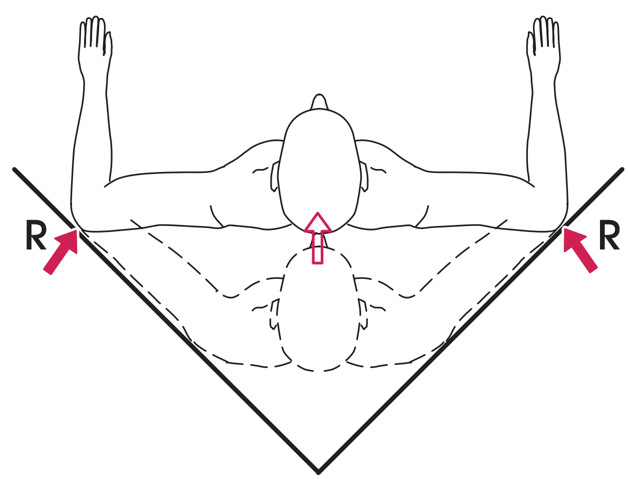

FIGURE 17.46 Corner press-out to strengthen scapular retraction and shoulder horizontal abduction (view from above).

Scapular Retraction and Shoulder Horizontal Abduction Combined with External Rotation (Rhomboids, Trapezius, Posterior Deltoid, Infraspinatus, Teres Minor)

- *Patient position and procedure:* Prone with shoulders abducted 90° and externally rotated 90° (90/90 position). The elbows can be flexed 90° (easier position) or extended (more difficult position). Instruct the patient to lift the arm a few degrees off the table. To do this correctly, the scapulae

must adduct simultaneously. Greater ROM can be used if these exercises are done on a narrow bench so the arm can begin in a horizontally adducted position.

- *Patient position and procedure:* Sitting or standing with shoulders in the 90/90 position. Secure the middle of a piece of elastic resistance in front of the patient slightly above the shoulders and have the patient grasp each end of the resistance. Then have the patient pull the hands and elbows back (moving into horizontal abduction and external rotation of the shoulder) while simultaneously adducting the scapulae (Fig. 17.47). **VIDEO 17.4.**

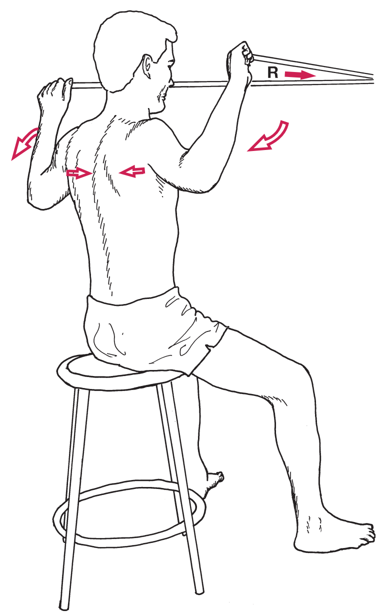

FIGURE 17.47 Combined scapular retraction with shoulder horizontal abduction and external rotation against resistance.

Scapular Protraction (Serratus Anterior)

- *Patient position and procedure:* Sitting or standing with shoulder flexed approximately 90° and elbow extended. Secure a piece of elastic resistance behind the patient at shoulder level or use a pulley system. Have the patient "push" outward against the resistance without rotating the body (Fig. 17.48).
- *Patient position and procedure:* Supine with the arm flexed 90° and slightly abducted and the elbow extended. Place a light weight in the hand if resistance is tolerated and have the patient "push" the weight upward without rotating the body.

CLINICAL TIP

According to a study by Ekstrom and colleagues,[54] isolated protraction exercises do not activate the serratus anterior as effectively as exercises that involve dynamic upward rotation of the scapula as occurs during arm elevation.

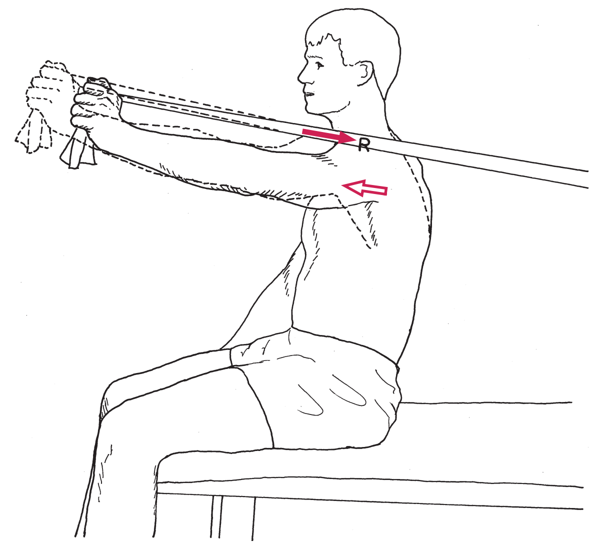

FIGURE 17.48 Scapular protraction; pushing against elastic resistance.

- ***Push-ups with a "plus."*** **VIDEO 17.5.**

Patient position and procedure: Standing and leaning on forearms or hands against a wall. Have the patient place his or her forearms or hands directly in front or slightly to the side of the shoulders and push the trunk away from the wall. Then have the patient "give an extra push" to protract the scapulae. Progress wall push-ups to table push-ups, then to prone push-ups on the knees, and finally prone-lying push-ups on the toes with knees extended (Fig. 17.49). Add weight around the trunk if the patient is able to tolerate greater resistance.

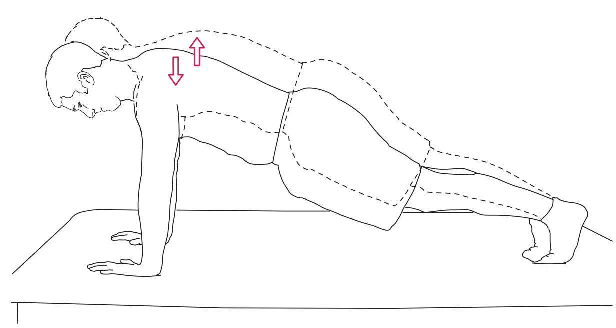

FIGURE 17.49 Push-ups with a "plus" to strengthen scapular protraction.

- ***Push-ups with a "plus" with leg lifts.***

Patient position and procedure: Quadruped (all-fours) position. Perform a push-up with a "plus" on a stable surface. Then alternately lift the lower extremities. Progress to an unstable surface (see Chapter 23 for examples).

CLINICAL TIP

A study examining scapulothoracic muscle activation compared activation during variations of the push-up with a "plus" exercise performed while in the quadruped position.

The findings of this study demonstrated that raising the ipsilateral leg during the push up with a “plus” increased serratus anterior activity, whereas raising the contralateral leg increased lower trapezius activity.[122]

Scapular Depression (Lower Trapezius, Lower Serratus Anterior)

- *Patient position and procedure:* Sitting with elbow flexed. Provide manual resistance in an upward direction under the elbow, and ask the patient to push down into your hands. Caudal gliding of the humeral head may also occur (Fig. 17.50 A).
- ***Upright press-up.*** **VIDEO 17.5.**

Patient position and procedure: Sitting or standing with both hands on blocks, the armrests of a chair, or parallel bars. Have the patient push down on the hands and lift the body. After the elbows are fully extended, emphasize scapular depression. (Fig. 17.50 B).

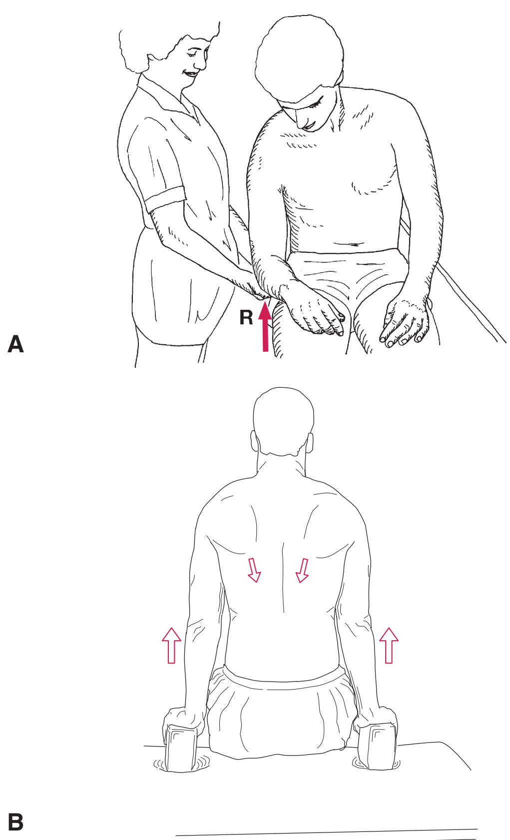

FIGURE 17.50 Exercises that emphasize the lower trapezius. **(A)** Shoulder girdle depression against manual resistance. **(B)** Closed-chain shoulder girdle depression using body weight for resistance.

Scapular Upward Rotation with Depression (Lower Trapezius, Serratus Anterior)

Scapular upward rotation with depression cannot be isolated from movement of the humerus. The upward rotation action of the trapezius and serratus anterior require coordination with humeral elevation. As noted elsewhere in this chapter, a patient may substitute with scapular elevation, primarily using the upper trapezius, so this exercise draws attention to maintaining the scapula in depression while upwardly rotating.

- ***Arm slide against a wall.***

Patient position and procedure: Standing with the back to the wall, heels away from the wall enough to comfortably do a posterior pelvic tilt and maintain the back flat against the wall. Begin with arms slightly abducted and externally rotated and the elbows flexed 90°. The backs of the arms should be against the wall. Have the patient slide the hands and arms up the wall (abduction) as far as possible while maintaining the back flat against the wall.

- ***“Superman” motion prone.***

Patient position and procedure: Prone, with humerus elevated overhead. Ask the patient to barely lift the arm off the table. This end-range motion may not be possible for patients with restricted glenohumeral mobility or impingement syndrome.

- ***“Superman” motion prone.***

Patient position and procedure: Sitting or standing with arms in a comfortable overhead position. (This position can be used if the patient has a tight shoulder and cannot assume the “superman motion” while lying prone.) Secure elastic resistance overhead in front of the patient. Instruct the patient to move the shoulder into greater flexion with scapular depression. The scapular depression is most important; it may be necessary to use tactile cues on the lower trapezius to help the patient focus on scapular depression, not scapular elevation (Fig. 17.51).

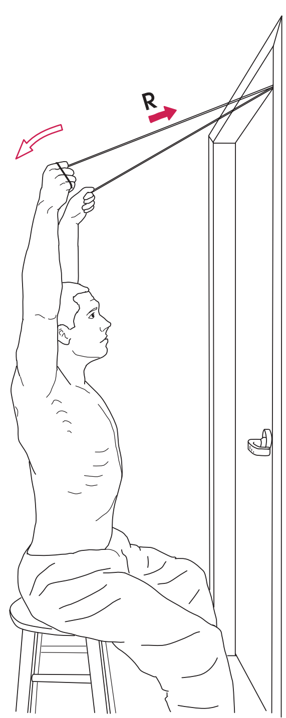

FIGURE 17.51 Scapular depression with upward rotation of the scapula against elastic resistance (also activates the upper and middle trapezius and serratus anterior).

Dynamic Strengthening Exercises: Glenohumeral Muscles

Dynamic strength of GH musculature coupled with strength of the scapular stabilizers is necessary for active, pain-free movement of the shoulder girdle during functional activities. Open- and closed-chain strengthening exercises should be incorporated into a shoulder rehabilitation and injury prevention program. Many of the exercises used to strengthen scapular muscles in nonweight-bearing and weight-bearing positions, described in the previous section, also dynamically strengthen some GH muscles. Additional exercises to improve dynamic strength of the shoulder girdle in anatomical and diagonal movement patterns are described in this section.

FOCUS ON EVIDENCE

Several EMG studies have investigated exercises commonly used to activate and strengthen shoulder muscles using either free weights or elastic resistance.[10,17,91,165,166] The findings of these studies indicate the extent of activation of the rotator cuff, deltoid, pectoralis major, and latissimus dorsi muscles under maximum load conditions during the following exercises.

- *Shoulder shrug:* causes highest activation in the subscapularis, trapezius, and latissimus dorsi; also activates the supraspinatus, infraspinatus, and serratus anterior.[91]
- *Middle-grip and narrow-grip seated rowing:* activates subscapularis.[91]
- *Wide grip seated rowing:* activates the infraspinatus and trapezius and to a lesser extent the supraspinatus.[91]
- *External rotation in prone and side-lying positions and in the plane of the scapula:* activates the infraspinatus and teres minor.[10,17,165,166]
- *Internal rotation:* movement of the forearm across the body with arm at side and elbow flexed 90° activates the subscapularis and pectoralis major.[91,165]
- *Forward punch:* causes highest activation in the supraspinatus and anterior deltoid; resistance also activates the pectoralis major and infraspinatus.[91]
- *Horizontal abduction at 100° with full external rotation:* activates the supraspinatus, middle and posterior deltoid.[166]

Shoulder External Rotation (Infraspinatus, Teres Minor) VIDEO 17.6.

Position the arm at the patient's side or in various positions of abduction, scapular plane elevation, or flexion. Flex the elbow to 90° and apply the resistive force at right angles to the forearm. Be sure the patient rotates the humerus and does not extend the elbow. When the arm is positioned at the patient's side, a folded towel placed between the elbow and side of the rib cage reminds the patient to keep the elbow at the side and ensures proper technique.[165] However, it does not significantly alter recruitment of the external rotators.[166] As indicated in the supporting evidence just presented, external rotation applied in the side-lying position (arm at side), prone-lying in the 90/90 position, and standing with the humerus in scapular plane (45° abduction, 30° horizontal adduction) produces the strongest contractions of these muscles compared with other external rotation exercises.[165,166]

- *Patient position and procedure:* Sitting or standing, using elastic resistance or a wall pulley in front of the body at elbow level. Have the patient grasp the elastic material or the pulley handle and rotate his or her arm outward (Fig. 17.52 A).
- *Patient position and procedure:* Side-lying on the uninvolved side with the involved shoulder up, the arm resting on the side of the thorax, and a rolled towel under the elbow. Have the patient use a handheld weight, cuff weight, or elastic resistance and rotate the arm through the desired ROM.
- *Patient position and procedure:* Prone on a table, upper arm resting on the table with the shoulder at 90° if possible, elbow flexed with forearm over the edge of the table. Lift the weight as far as possible by rotating the shoulder, not extending the elbow (Fig. 17.52 B).
- *Patient position and procedure:* Sitting with elbow flexed 90° and supported on a table so the shoulder is in the resting position (plane of the scapula). The patient lifts the weight from the table by rotating the shoulder (Fig. 17.52 C).

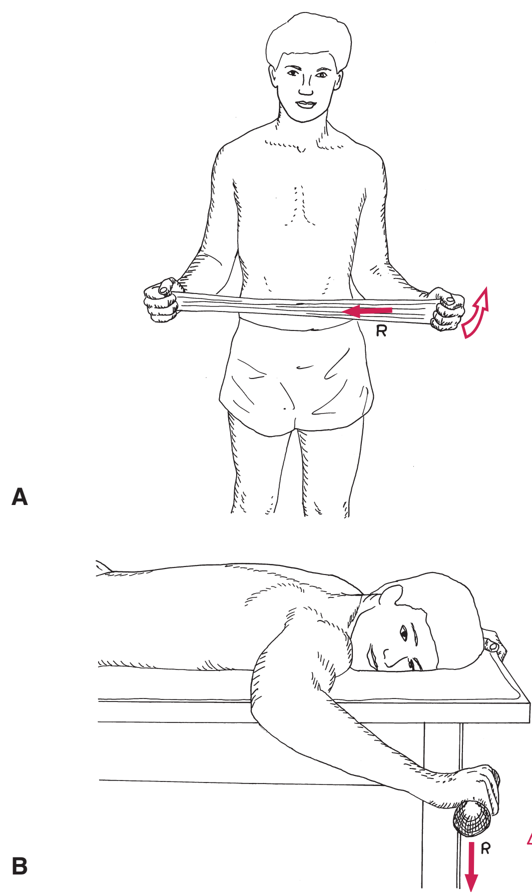

FIGURE 17.52 Resisted external rotation with **(A)** the arm at the side using elastic resistance **(B)** the arm at 90° using a free weight and the patient lying prone, and

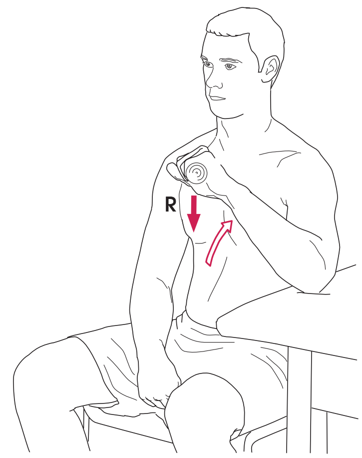

FIGURE 17.52—cont'd (C) with the shoulder in scapular plane elevation using a free weight and the patient sitting.

Shoulder Internal Rotation (Subscapularis)

Position the arm at the patient's side or in various positions of flexion, abduction, or scapular plane elevation. The elbow is flexed to 90°, and the resistive force is held in the hand.

- *Patient position and procedure:* Side-lying on the involved side with the arm forward in partial flexion. Have the patient lift the weight upward off the table into internal rotation (Fig. 17.53).
- *Patient position and procedure:* Sitting or standing using elastic resistance or a pulley system with the line of force out to the side and at the level of the elbow. Have the patient pull across the front of the trunk into internal rotation.

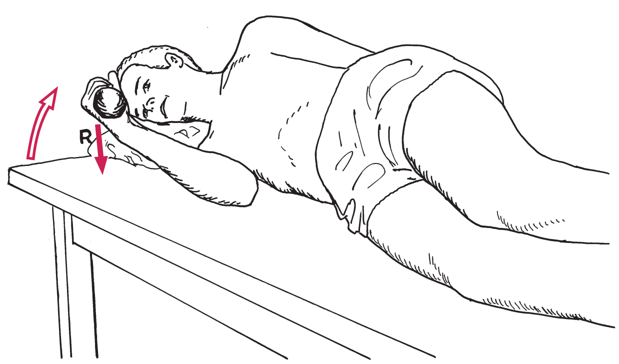

FIGURE 17.53 Resisted internal rotation of the shoulder using a handheld weight. To resist external rotation, place the weight in the patient's upper hand.

Shoulder Abduction and Elevation of the Arm in Scapular Plane (Deltoid and Supraspinatus)

Abduction exercises are classically done with the humerus moving in the frontal plane. It is commonly accepted that most functional activities occur with the humerus 30° to 45° forward to the frontal plane in which the arc of motion is more in line with the glenoid fossa of the scapula. Many abduction exercises can be adapted to be performed in the plane of the scapula.

PRECAUTION: Teach the patient that whenever the shoulder elevates beyond 90°, it must externally rotate to avoid impingement of the greater tubercle against the acromion. If the patient has impingement syndrome, limit the range to avoid the painful arc.

- *Patient position and procedure:* Sitting or standing with a weight in hand. Have the patient abduct the arm to 90° and then externally rotate and elevate the arm through the rest of the range. This same motion can be performed with elastic resistance secured under the patient's foot, but be cautious in that the greater the elastic stretch, the greater the resistance. The patient may not be able to complete the ROM because of increased resistance at the end of the range.
- *Patient position and procedure:* Side-lying with the involved arm uppermost and elbow extended. Have the patient lift a weight up to 90°. The greatest effect of the resistance is at the beginning of the range. At 90°, all of the force is through the long axis of the bone.
- ***"Full can" arm elevation.***

Patient position and procedure: Standing with the humerus externally rotated (full can position). Have the patient raise the arm away from the side in the plane of the scapula, halfway between abduction and flexion (Fig. 17.54). Apply resistance with a handheld weight or elastic resistance secured under the patient's foot. "Full can" elevation of the arm may

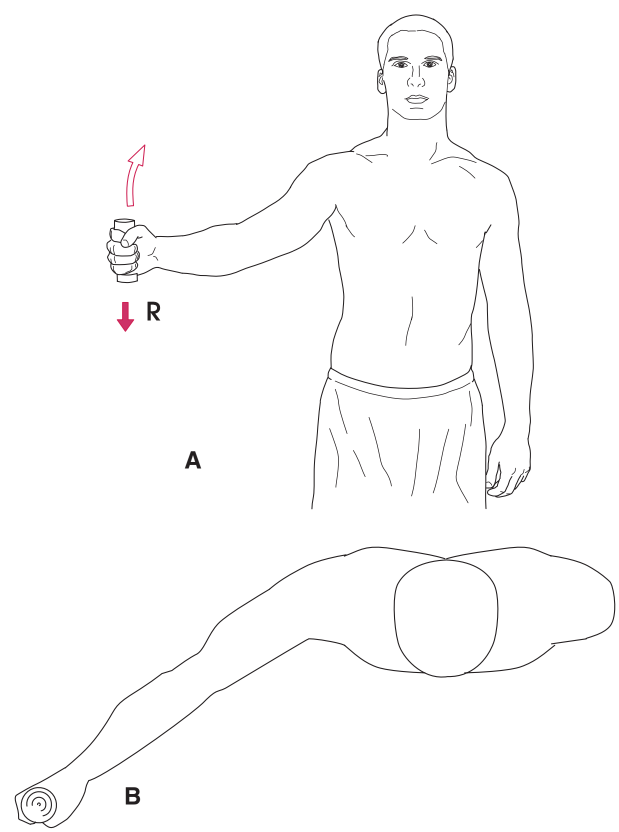

FIGURE 17.54 Abduction in the plane of the scapula. This is called the "full can" exercise because the shoulder is held in external rotation as if lifting a full can. **(A)** Front view. **(B)** Top view. If the shoulder is held in internal rotation, the exercise is called an "empty can" exercise.

also be performed in the prone position with the arm over the side of the table.

FOCUS ON EVIDENCE

EMG studies have confirmed that no one exercise isolates the action of the supraspinatus muscle from the other rotator cuff or deltoid muscles.[124,205] The supraspinatus muscle is effectively activated in both the "empty can" (humerus internally rotated)[97,223] and "full can"[95,124,205] exercises. It also contracts strongly with the military press-up[205] and horizontal abduction with external rotation exercises.[17,124,235] These findings appear to give the therapist several choices of exercises for strengthening the supraspinatus. However, several authors,[49,55,93,95,196] as well as the authors of this text, have suggested that the "empty can" exercise (scapular plane elevation with internal rotation of the humerus) should not be used for shoulder rehabilitation, because it can cause impingement of the suprahumeral tissues, especially as the arm approaches and elevates above 90°. In support of this, when compared to the "full can" exercise, the "empty can" exercise has been demonstrated to orient the scapula in greater amounts of internal rotation and anterior tilting, positions believed to increase the risk of subacromial impingement.[196] In contrast, the "full can" position minimizes the chance of impingement.[49,95,165]

Shoulder Flexion (Anterior Deltoid, Rotator Cuff, Serratus Anterior)

Patient position and procedure: Sitting, standing, or supine and elbow extended and thumb pointing forward. Have the patient move into forward flexion of the shoulder. If a free weight is used when supine, the greatest resistance is experienced at the beginning of the range; during standing, the greatest resistive force is encountered when the shoulder is flexed to the 90° position. Elastic resistance also can be used if secured under the patient's foot or a solid object on the floor.

- ***Military press-up.***

Patient position and procedure: Sitting, arm at the side in neutral to slight external rotation with elbow flexed and forearm in mid-position (thumb pointing posterior). Have the patient lift the weight vertically to the overhead position (Fig. 17.55).

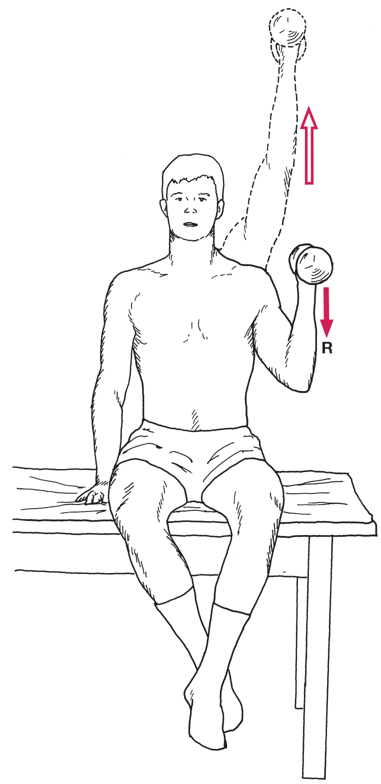

FIGURE 17.55 Military press-up. Beginning with the arm at the side in neutral to slight external rotation with elbow flexed and forearm in mid-position (thumb pointing posteriorly), the weight is lifted overhead.

Shoulder Adduction (Pectoralis Major, Teres Major, Latissimus Dorsi)

Patient position and procedure: Sitting or standing with the arm abducted. Have the patient pull down against a pulley force or elastic resistance tied overhead. The greatest resistance is when the line of the resistive force is at right angles to the patient's arm.

Shoulder Horizontal Adduction (Anterior Deltoid, Coracobrachialis, Pectoralis Major)

Patient position and procedure: Supine. Begin with one or both arms out to the side in horizontal abduction. Have the patient bring the arms forward into horizontal adduction until the arms are vertical.

Shoulder Extension (Posterior Deltoid, Latissimus Dorsi, Rhomboids)

- *Patient position and procedure:* Prone with the arm over the side of the table in 90° flexion. Have the patient lift the weight and extend the shoulder. Simultaneous elbow flexion while extending the shoulder is easier (shorter lever arm); maintaining elbow extension while extending the shoulder is more difficult (longer lever arm).
- *Patient position and procedure:* Sitting or standing with the arm flexed. A pulley or elastic resistance is secured overhead. Have the patient pull down against the resistance into extension.

Elbow Flexion (Biceps Brachii)

- ***Biceps curl.***

Patient position and procedure: Sitting or standing. Have the patient flex the elbow while holding a handheld weight and keeping the forearm supinated and the arm at the side or with the shoulder moving into slight extension (see Fig. 18.11).

NOTE: Because the biceps brachii is a two-joint muscle, the muscle not only serves to flex the elbow as its primary function, the long head assists the rotator cuff muscles by acting as an additional dynamic stabilizer of the GH joint by approximating the humeral head against the glenoid fossa and by depressing the head of the humerus as the arm elevates and the scapula upwardly rotates.[120] As such, the biceps brachii must be strengthened in a shoulder rehabilitation program.

Exercises Using Diagonal (PNF) Movement Patterns VIDEO 17.4.

Proprioceptive neuromuscular facilitation (PNF) patterns involve use of the entire upper extremity or address specific regions, such as the scapula. Apply resistance manually to emphasize specific muscles in the pattern by adjusting hand placement and resistance (see Chapter 6 for complete description of patterns). As control improves, teach the patient exercises in diagonal patterns using weights or elastic resistance (Fig. 17.56).

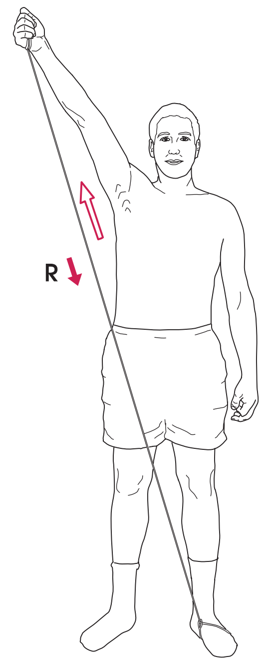

FIGURE 17.56 PNF pattern (D_2 flexion), emphasizing shoulder flexion, abduction, and external rotation against elastic resistance.

Functional Progression for the Shoulder Girdle

An essential element of a shoulder rehabilitation and injury prevention program is a sequence of carefully progressed exercises and activities designed to achieve necessary and desired functional outcomes. The final section of this chapter provides a summary of key components of a functional progression for the shoulder. This progression typically includes a variety of open- and closed-chain exercises in combined movement patterns that simulate functional activities and further improve strength, power, and muscular endurance. Integrated into the functional progression are activities for balance, coordination, and skill and aerobic conditioning. A few examples of activities are presented here. Refer to Chapter 23 for further examples of activities for advanced functional training.

Exercises Using Combined Movement Patterns with Functional Activities

Exercises in combined movement patterns typically require coordination between the stabilizing and dynamic functions of the scapular and glenohumeral muscles and involve control of the entire upper extremity and trunk and sometimes lower extremity control. Some of the strengthening exercises already presented in this chapter resist combined movement.

Component motions in functional activities, such as pulling, pushing, lifting, lowering, and carrying, involve combined movement patterns and should be practiced under progressively challenging conditions. Several examples follow.

- ***Rowing.***

Patient position and procedure: Long-sitting. Secure elastic resistance under the feet or around a solid object. Grasp both ends of the elastic material, and pull backward with the arms in a rowing action (Fig. 17.57). Vary the grip width. For a greater challenge, perform the rowing motion while seated on an unstable surface, such as a Swiss ball. As an alternative, a weight-cable system can be used for resistance.

- ***"Lawnmower pull."***

Patient position and procedure: Standing with hips partially flexed and holding onto a table or chair for balance with the hand of the sound upper extremity. Have the patient reach diagonally across the midline and grasp a piece of elastic tubing that is secured under the foot of the sound side or attached to the leg of a couch or bed. Then have the patient pull diagonally and upward as if starting a lawnmower (see Fig 18.18). This combined movement pattern may also be simulated with a free weight.

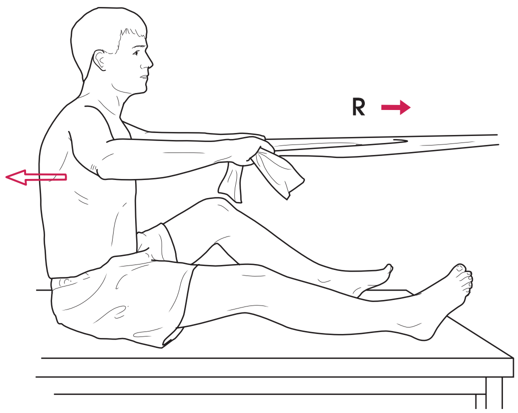

FIGURE 17.57 Simulated rowing motion against elastic resistance.

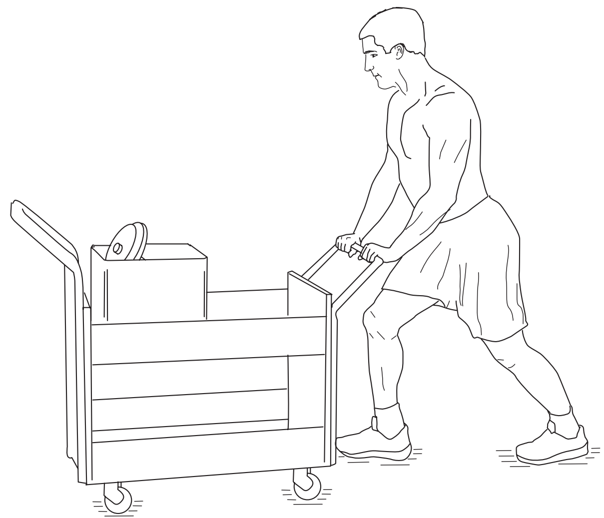

FIGURE 17.58 Pushing a weighted cart to simulate a functional activity and incorporate proper body mechanics.

- ***Pushing a weighted cart.***

Patient position and procedure: Standing with a stable base of support. Begin by pushing the cart on a flat surface with light loads on the cart (Fig 17.58). Emphasize proper body mechanics. Initially use both arms to push; then progress by pushing with one hand or by pushing heavier loads on uneven surfaces. Vary the activity by adjusting the width of the grip, the position of the arms, or by alternating between pushing and pulling.

Equipment

A variety of exercise devices can be used or adapted for shoulder girdle strengthening using combined movement patterns. Creativity in adapting equipment and exercises to meet progressive upper extremity challenges without exacerbating or causing recurrence of symptoms is a must. Examples of equipment and potential uses are identified in Table 17. 7. Many of the activities noted are described and shown in detail in Chapter 23.

TABLE 17.7 Exercise Devices and Potential Uses for Shoulder Girdle Rehabilitation

Exercise Device	Potential Use
BodyBlade™	Move the arm in anatomical and diagonal planes of movement, in circular (clockwise or counter-clockwise) patterns, or while moving the blade away from or toward the body, as if pushing or pulling.
Rowing machine	Use as designed for endurance training and upper extremity and trunk strengthening. Emphasizes scapular retraction and trunk stabilization when pulling backward.
Upper body ergometer	Forward or backward cycling (pushing or pulling movements) against progressive resistance over an extended time period for muscular and cardiopulmonary endurance. For a patient with an impingement syndrome, place emphasis on backward cycling for scapular retraction and to target weak or underused posterior shoulder structures and minimize action of tight and overused anterior structures.
Foam roll, small ball, balance equipment (rocker or wobble board or BOSU™)	Stabilization exercises or perturbation training in prone-propping or quadruped positions on one or both hands. Emphasize upper extremity weight shifting or alternating arm or leg movements.
Stepping machine	While kneeling, perform upper extremity “climbing” motions by pushing with the hands on the steps. Emphasizes scapular protraction during pushing.
Treadmill	Kneel at the end of the treadmill and perform forward and backward hand-walking.
ProFitter™	While kneeling on the floor next to the device, place hands on the platform and slide the platform side-to-side or forward-backward using quick changes of direction

Integration of Functional Activities

Functional progression in a shoulder rehabilitation program must integrate principles of task-specific training by including a sequence of simple and easy to perform activities then progressing to complex and challenging functional activities. It is important to have the patient use the actual patterns and types of muscle contraction that occur in the desired outcomes.

First, simulated activities should be performed with supervision and the therapist's guidance to avoid painful positions or faulty mechanics during movements of the shoulder. Then the activity can be performed independently at home or work. For example, begin by having the patient simulate the motions involved in unloading a dishwasher and placing the dishes on a low shelf or washing windows using small circular motions. If catching and throwing or swinging a bat or golf club are necessary, total body patterns are practiced.

An individual who has a sedentary lifestyle may require postural adaptations and ergonomic analysis of his or her home environment or workstation to change repetitive stress. In contrast, an athlete or industrial worker, who must perfom high-demand activities over an extended time period, may require muscular and cardiopulmonary endurance or high-intensity training, such as plyometric exercises, to develop power and skill.

Independent Learning Activities

Critical Thinking and Discussion

1. Describe how the scapulothoracic and GH musculature function as dynamic stabilizers of the shoulder.
2. Which factors may alter normal upward rotation of the scapula, and how does inadequate upward rotation of the scapula adversely affect elevation of the arm?
3. Describe the relationships among cervical and thoracic posture, scapula orientation, and elevation of the arm.
4. Which mechanisms and structures could be sources of pain in extrinsic impingement syndrome?
5. How are impingement and instability related to each other in secondary impingement syndrome?
6. Describe the differences and similarities between atraumatic and traumatic instability of the GH joint.
7. A patient experienced a traumatic shoulder injury when falling down five cement steps 2 weeks ago. She now has a capsular pattern, decreased joint play, and muscle guarding with passive GH motions. She does not actively use the extremity because of pain. You observe edema in the hand. What potential complications could develop if left untreated? Design an exercise program for this patient at her present level of involvement. What would you teach the patient about her symptoms, impairments, and parameters for recovery?
8. An individual with a history of diabetes has developed a frozen shoulder. She has had shoulder discomfort for several months, but she did not seek treatment until 1 week ago when she was unable to wash or fix her hair with her left hand. Describe your intervention plan and instructions for this patient. Explain how you will determine the level of aggressiveness with which to address her ROM loss.
9. For patients with a history of recurrent anterior dislocation of the GH joint, what types of functional activities (ADL, work-related, or sport-related) should initially be avoided or modified during the early and intermediate stages of a rehabilitation program? What would differ with a patient with a history of recurrent posterior dislocation of the GH joint?
10. What criteria should patients with each of the following shoulder diagnoses meet before progressing to *overhead* exercises and functional activities: primary impingement syndrome; anterior GH instability; frozen shoulder; S/P rotator cuff repair?

Laboratory Practice

1. With your laboratory partner, review and practice key tests and measurements that you might need to do to determine what is causing shoulder pain and/or diminished upper extremity function. What does each of those tests indicate?
2. Mobilize the scapula with manual techniques.
3. Mobilize the GH joint capsule with manual techniques; practice the mobilization with movement techniques for the shoulder.
4. Teach your partner a series of self-mobilization techniques for the GH joint capsule.
5. Using appropriate stabilization, manually stretch all major muscle groups of the shoulder.
6. Teach your partner effective self-stretching techniques for each of these muscle groups.
7. Practice a sequence of exercises to strengthen the muscles of the scapula using manual resistance (applied by the therapist). Use open-chain and closed-chain positions.
8. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop stability and dynamic control of the scapula. Apply perturbation techniques that will challenge the ability of the scapulothoracic muscles to stabilize the scapulothoracic articulation.
9. Teach your partner a progressive sequence of strengthening exercises that he or she could do in a home exercise program to develop strength, stability, and endurance of the GH muscles. Have your partner perform each exercise

for a specified number of repetitions and at a specified level of resistance.

- Describe faulty postures or motions that you will be looking for as your partner executes each exercise.
- Describe the signs of fatigue that you may observe and the indicators of poor exercise technique.

10. Develop a series of functional activities to complement the self-stretching and self-strengthening exercises you have taught your partner.

Case Studies

1. A patient referral states: Evaluate and treat shoulder pain S/P Motor Vehicle Accident. She was the driver of the car in a head-on collision. The patient describes shoulder pain whenever reaching overhead. She is a nurse and finds symptoms worsen when placing solutions on an IV pole, a frequent activity for her. Examination reveals painful resisted scapular protraction, elbow extension, and shoulder extension with pain on palpation of the long head of the triceps near its insertion on the inferior glenoid as well as pain in the serratus anterior in the axilla. Other impairments include weak rhomboids and lower trapezius muscles (4-/5).
   - Explain the potential mechanism of injury to these muscles from this type of accident.
   - Explain why this patient's reaching tasks would perpetuate these symptoms.
   - Outline a treatment plan that manages the acute symptoms and progresses to a therapeutic exercise program.
   - Identify a measurable functional outcome goal and interventions you would use to reach the goal.
   - As the patient's symptoms subside, how would you progress her exercise program?
2. Your patient describes pain whenever reaching overhead. He likes to play volleyball in a weekend league but otherwise has a sedentary lifestyle. On examination, you observe moderate atrophy in the infraspinous fossa, a protracted scapula, and thoracic kyphosis with forward head. You have him assume the quadruped position in anticipation of instruction in closed-chain rhythmic stabilization and scapular protraction exercises and note significant winging of the scapula.
   - Describe what muscles are likely to test weak based on these observations.
   - How would you adapt the quadruped exercise to develop control and strength in the involved muscles at a safe resistance level?
   - Based on your assumptions of muscle involvement, develop an intervention plan for this patient that includes a home exercise program. Indicate parameters (frequency, repetitions), positions, safety, and progressions.
3. You have received a referral to "evaluate and treat" a 62-year-old patient who underwent total shoulder arthroplasty for osteoarthritis 2 weeks ago. The patient has been wearing a sling to support and protect the operated shoulder but has been allowed to remove the sling for daily pendulum exercises and active ROM of the elbow, wrist, and hand.
   - Prior to initiating your examination and developing an exercise program, what additional information would you like to learn from the surgeon?
   - What information do you want to gather from the patient?
   - What examination procedures would you wish to perform during the patient's initial visit?
   - Develop, implement, teach, and then progress a series of exercises over a period of six visits with the patient.
4. Six months ago your patient underwent surgery for repair of a Bankart lesion and stabilization of the anterior capsule (capsular shift) after a traumatic anterior dislocation of the GH joint. The patient now has full ROM and 90% strength in the shoulder after a program of rehabilitation. Your patient wants to return to recreational sports, such as tennis, softball, and volleyball, but is apprehensive that the shoulder might dislocate during these activities. Design an advanced rehabilitation program to gradually return the patient to the desired recreational activities.

CHAPTER

18

The Elbow and Forearm Complex

A freely mobile but strong and stable elbow complex is required for normal upper extremity function. The design of the elbow and forearm adds to the mobility of the hand in space by shortening and lengthening the upper extremity and by rotating the forearm. The muscles provide control and stability to the region as the hand is used for various activities, from eating, dressing, and grooming to pushing, pulling, turning, lifting, throwing, catching, and reaching for objects to coordinated use of equipment, tools, and machines.[39,50,65,68] Most activities of daily living require a 100° arc of flexion and extension at the elbow, specifically between 30° and 130° as well as 100° of forearm rotation, equally divided between pronation and supination.[65] Tasks, such as drinking and eating, primarily require elbow flexion, whereas a task, such as reaching to tie shoelaces, requires substantial elbow extension.

Injury or disease of boney, articular, or soft tissue structures of the elbow and forearm can cause pain and compromised mobility, strength, stability, and functional use of the upper extremity. Loss of active or passive elbow flexion interferes with grooming and eating, whereas loss of elbow extension restricts a person's ability to push up from a chair or reach out for objects. In general, loss of terminal flexion of the elbow contributes to greater limitation of function than loss of terminal extension.[65]

The anatomical and kinesiological relationships of the elbow and forearm are outlined in the first section of this

chapter. Chapter 10 presents information on principles of soft tissue healing and management; the reader should be familiar with that material before establishing a therapeutic exercise program to improve function of the elbow and forearm.

Structure and Function of the Elbow and Forearm

The distal end of the humerus has two articular surfaces: the trochlea, which articulates with the ulna, and the capitulum, which articulates with the head of the radius (Fig. 18.1). Flexion and extension occur between these two joint surfaces. The radius also articulates with the radial notch on the ulna and is called the proximal radioulnar joint. This joint participates in pronation and supination along with the distal radioulnar joint. The capsule of the elbow encloses the humeroulnar, humeroradial, and proximal radioulnar articulations. The distal radioulnar joint is structurally separate from the elbow complex even though its function is directly related to the proximal radioulnar joint.

Joints of the Elbow and Forearm

There are four joints involved in elbow and forearm function: the humeroulnar, humeroradial, proximal radioulnar, and distal radial ulnar joints.

Elbow Joint Characteristics and Arthrokinematics

The elbow is a compound joint with a lax joint capsule, supported by two major ligaments—the medial (ulnar) and lateral (radial) collateral—which provide medial and lateral stability, respectively.[44,67,68]

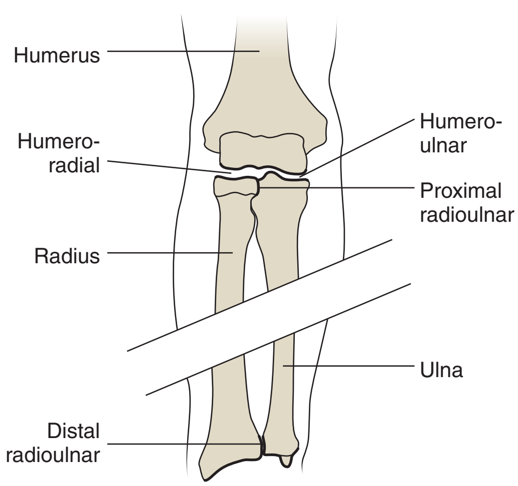

FIGURE 18.1 Bones and joints of the elbow and forearm.

Humeroulnar Articulation

Characteristics. The humeroulnar (HU) articulation is a modified hinge joint. The medially placed hourglass-shaped trochlea at the distal end of the humerus is convex. It faces anteriorly and downward 45° from the shaft of the humerus. The concave trochlear fossa on the proximal ulna faces upward and anteriorly 45° from the ulna (see Fig. 5.27). The primary motions at this articulation are flexion and extension.

Arthrokinematics. During flexion/extension the concave fossa slides in the same direction in which the ulna moves, so with elbow flexion, the fossa slides around the trochlea in an anterior and distal direction. With elbow extension, the fossa slides in a posterior and proximal direction.

There is also slight medial and lateral sliding of the ulna, allowing for full elbow range of motion (ROM); it results in a valgus angulation of the joint with elbow extension and a varus angulation with elbow flexion. When the bone moves in a medial/lateral direction, the trochlear ridge provides a convex surface, and the trochlear groove provides a concave surface—so with varus the ulna slides in a lateral direction and with valgus the ulna slides in a medial direction.

The arthrokinematics are summarized in Box 18.1.

BOX 18.1 Summary of Joint Arthrokinematics of the Elbow and Forearm Joints

Physiological Motion	Roll	Slide
Humeroulnar articulation	***Motion of ulnar joint surface***	
Flexion	Anterior	Distal/anterior
Extension	Posterior	Proximal/posterior
Humeroradial articulation	***Motion of radial joint surface***	
Flexion	Anterior	Anterior
Extension	Posterior	Posterior
Forearm varus	***Motion of proximal forearm*** **Medial**	Lateral
Forearm valgus	***Motion of proximal forearm*** Lateral	Medial
Proximal radiounlar joint	***Motion of rim of radial head***	
Pronation	Anterior	Posterior (dorsal)
Supination	Posterior	Anterior (volar)
Distal radioulnar joint	***Motion of distal radial joint surface***	
Pronation	Anterior	Anterior
Supination	Posterior	Posterior

Humeroradial Articulation

Characteristics. The humeroradial (HR) articulation is a hinge-pivot joint. The laterally placed, spherical capitulum at the distal end of the humerus is convex. The concave boney partner, the head of the radius, is at the proximal end of the radius. Flexion/extension and pronation/supination occur at this articulation.

Arthrokinematics. As the elbow flexes and extends, the concave radial head slides in the same direction as the bone motion, so with elbow flexion, the concave head slides anteriorly, and with elbow extension, it slides posteriorly. With pronation and supination of the forearm, the radial head spins on the capitulum (see Box 18.1).

Ligaments of the Elbow

Medial (ulnar) collateral ligament. The medial collateral ligament complex consists of bundles of fibers that may be differentiated into anterior, posterior, and transverse portions (Fig. 18.2 A). Various portions of the ligament are taut in different ROMs, providing medial support to the elbow against valgus stresses and limiting end-range elbow extension. The ligament also keeps the joint surfaces in approximation.[67,68] Activities, such as throwing and golfing, impose significant stresses on the medial collateral ligament complex.

Lateral (radial) collateral ligament. The lateral collateral ligament complex, a fan-shaped ligament on the lateral surface of the elbow, is composed of the lateral collateral ligament, the lateral ulnar collateral ligament, and the annular ligament.[68] This complex provides stability to the lateral aspect of the elbow against varus and supination forces, stabilizes the humeroradial joint, resists longitudinal distraction, and prevents posterior translation of the radial head (Fig. 18.2 B).

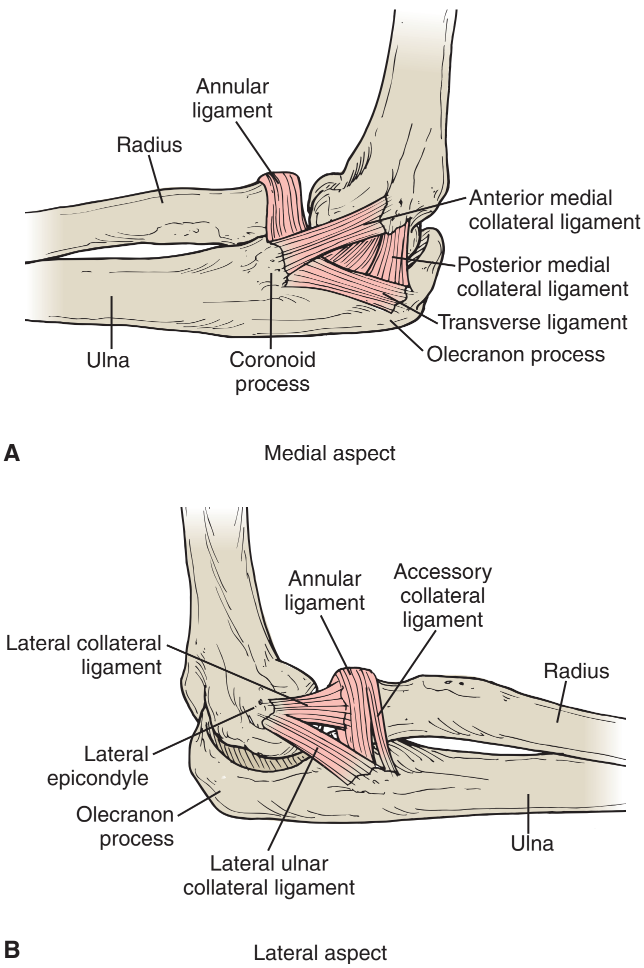

FIGURE 18.2 (A) The three parts of the medial (ulnar) collateral ligament are shown on the medial aspect of the right elbow. The musculature and joint capsule have been removed to show the ligament's attachments. **(B)** The lateral collateral ligament complex includes the lateral (radial) collateral ligament, lateral ulnar collateral ligament, and annular ligament. The musculature and joint capsule have been removed to show the ligaments' attachments. *(From Norkin,[68] p. 277, with permission.)*

Forearm Joint Characteristics and Arthrokinematics

Both the proximal and distal radioulnar joints are uniaxial pivot joints that function together to produce pronation and supination (rotation) of the forearm.[44,67,68]

Proximal (Superior) Radioulnar Articulation

The proximal radioulnar (RU) articulation is within the capsule of the elbow joint but is a distinct articulation.

Characteristics. The convex rim of the radial head articulates with the concave radial notch on the ulna and the annular ligament. This ligament encircles the rim of the radial head and stabilizes it against the ulna. The primary motion is pronation/supination.

Arthrokinematics. As the forearm rotates into pronation and supination, the convex rim of the radial head slides opposite the bone motion, so with pronation, the head slides posteriorly (dorsally) on the radial notch, and with supination, it slides anteriorly (volarly). It also slides in the annular ligament (see Fig. 18.2), and the proximal surface spins on the capitulum (see Box 18.1).

Distal (Inferior) Radioulnar Articulation

Characteristics. The distal RU joint is an anatomically separate joint at the distal end of the radius and ulna. The concave ulnar notch on the distal radius articulates with the convex notch on the head of the ulna. The distal RU joint, along with the proximal RU joint, participates primarily in pronation/supination.

Arthrokinematics. As the forearm rotates, the concave radius slides in the same direction as the physiological motion. It slides anterior (volar) with pronation and posterior (dorsal) with supination (see Box 18.1).

Muscle Function at the Elbow and Forearm

Muscles in the elbow region not only affect the function of the elbow and forearm, but also wrist and finger function.

Primary Actions at the Elbow and Forearm

Elbow Flexion

Brachialis. The brachialis is a one-joint muscle that inserts close to the axis of motion on the ulna, so it is unaffected by the position of the forearm or the shoulder; it participates in all flexion activities of the elbow.[67,68]

Biceps brachii. The biceps is a two-joint muscle that crosses both the shoulder and elbow and inserts close to the axis of motion on the radius, so it also acts as a supinator of the forearm. It functions most effectively as a flexor of the elbow between 80° and 100° of flexion. For the optimal length-tension relationship, the shoulder extends to lengthen the muscle when it contracts forcefully for elbow and forearm function.[67,68]

Brachioradialis. With its insertion a great distance from the elbow on the distal radius, the brachioradialis mainly functions to provide stability to the joint. However, it also participates as the speed of flexion motion increases and a load is applied with the forearm from mid-supination to full pronation.[67,68]

Elbow Extension

Triceps brachii. The long head of the triceps brachii crosses both the shoulder and elbow; the other two heads are uniaxial. The long head functions most effectively as an elbow extensor if the shoulder simultaneously flexes. This maintains an optimal length–tension relationship in the muscle.[67,68]

Anconeus. The anconeus muscle stabilizes the elbow during supination and pronation and assists in elbow extension.[67,68]

Forearm Supination

Supinator. The proximal attachment of the supinator at the annular and lateral collateral ligaments may function to stabilize the lateral aspect of the elbow. Unlike the biceps brachii, its effectiveness as a supinator is not influenced by the elbow position.[80]

Biceps brachii. The biceps muscle acts as a supinator if the elbow simultaneously flexes or if resistance is given to supination when the elbow is in extension.[10]

Brachioradialis. The brachioradialis contributes to pronation and supination only as an accessory muscle when resistance is provided to the motion.[10] It cannot function alone as a rotator or stabilizer of the forearm joints when other forearm muscles are paralyzed.

Forearm Pronation

Pronator teres. The pronator muscle pronates as well as stabilizes the proximal radioulnar joint and helps approximate the humeroradial articulation.[68]

Pronator quadratus. The pronator quadratus is a one-joint muscle and is active during all pronation activities.

Relationship of Wrist and Hand Muscles to the Elbow

Many muscles that act on the wrist and hand are attached on the distal portion (epicondyles) of the humerus. This allows for effective movement of the fingers and wrist, whether the forearm is in pronation or supination. The muscles provide stability to the elbow but contribute little to motion of the elbow. The position of the elbow affects the length-tension relationship of the muscles during their actions on the wrist and hand.[68] See Chapter 19 for information on the function of the wrist and hand.

Wrist flexor muscles. The flexor carpi radialis, flexor carpi ulnaris, palmaris longus, and flexor digitorum superficialis and profundus originate on the *medial epicondyle*.

Wrist extensor muscles. The extensor carpi radialis longus and brevis, extensor carpi ulnaris, and extensor digitorum originate on the *lateral epicondyle*.

Referred Pain and Nerve Injury in the Elbow Region

For a detailed description of referred pain patterns and injuries to the peripheral nerves coursing through the elbow and forearm region, see Chapter 13. Table 13.1 summarizes the muscle involvement and functional loss that occur with each of the nerve injuries.

Common Sources of Referred Pain into the Elbow Region

Symptoms referred from the C5, C6, T1, and T2 nerve roots cross the elbow region but are not usually isolated in the elbow.

Nerve Disorders in the Elbow Region

Ulnar nerve. The ulnar nerve courses posteromedial to the olecranon process in the cubital tunnel, which is the most common site for compression of this nerve in the elbow region.

Radial nerve. The radial nerve pierces the lateral muscular septum anterior to the lateral epicondyle and passes under the origin of the extensor carpi radialis brevis and then divides into a superficial and deep branch. Entrapment of the deep branch may occur under the edge of the extensor carpi radialis brevis, or injury may occur with a radial head fracture. The superficial branch may receive direct trauma as it courses along the lateral aspect of the radius.

Median nerve. The median nerve courses the elbow region deep in the cubital fossa, medial to the tendon of the biceps and brachial artery, where it is well protected. The

nerve then progresses between the ulnar and humeral heads of the pronator teres muscle and dips under the flexor digitorum profundus muscle. Entrapment may occur between the heads of the pronator muscle, mimicking carpal tunnel syndrome.

Management of Elbow and Forearm Disorders and Surgeries

In order to make sound clinical decisions when treating patients with elbow and forearm disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting structural and functional impairments, activity limitations, and participation restrictions (functional limitations and possible disabilities). In this section, pathologies and surgical procedures are presented and related to the corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[3] (Table 18.1). Conservative and postoperative guidelines for managing these conditions are described in this section.

Joint Hypomobility: Nonoperative Management

Related Pathologies and Etiology of Symptoms

Pathologies, such as rheumatoid arthritis (RA), juvenile rheumatoid arthritis (JRA), and degenerative joint disease (DJD), as well as acute joint reactions after trauma, dislocations, or fractures affect this joint complex. Postimmobilization contractures and adhesions develop in the joint capsule and surrounding tissues any time the joint is immobilized in a cast or splint. This typically occurs after dislocations and fractures of the humerus, radius, or ulna. The reader is referred to Chapter 11 for background information on arthritis and fractures.

TABLE 18.1 Elbow and Forearm Pathologies/Surgical Procedures, and Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Pattern and Associated Impairments[3]
■ Arthritis (rheumatoid arthritis, traumatic arthritis, osteoarthritis) ■ Postimmobilization arthritis (stiff joint) ■ Joint instability (subluxation, dislocation) ■ Overuse syndromes (lateral epicondylalgia, medial epicondylalgia) ■ Myositis ossificans (heterotopic bone formation)	■ Pattern 4D—impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
■ Acute arthritis ■ Acute “pulled elbow,” distal subluxation of radius	■ Pattern 4E—impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
■ Fracture (nondisplaced distal humerus, proximal radius, proximal ulna fractures—closed reduction)	■ Pattern 4G—impaired joint mobility, muscle performance, and ROM associated with fracture
■ Total elbow arthroplasty—linked and unlinked ■ Excision of the radial head with prosthetic implant ■ Interposition arthroplasty	■ Pattern 4H—impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
■ Open reduction and internal fixation of displaced/comminuted elbow fracture-dislocations ■ Resection of the radial head without implant ■ Synovectomy ■ Ligament repair/reconstruction ■ Capsulotomy ■ Arthrodesis	■ Pattern 4I—impaired joint mobility, motor function, muscle performance, and ROM associated with boney or soft tissue surgery
■ Median, ulnar, or radial nerve entrapment or injury in the elbow/forearm region	■ Pattern 5F—impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

Common Structural and Functional Impairments

Acute stage. When symptoms are acute, joint effusion, muscle guarding, and pain restrict elbow flexion and extension, and there usually is pain at rest. If pronation and/or supination are restricted after an acute injury, other conditions, such as fracture, subluxation, or dislocation, may be present.[23] These conditions require medical intervention.

Subacute and chronic stages. A capsular pattern usually exists in the subacute or chronic stages of tissue healing. Elbow flexion is more restricted than extension. There is a firm end-feel and decreased joint play. In long-standing arthritis of the elbow, pronation and supination also become restricted with a firm end-feel and decreased joint play in the proximal RU joint.[23] Arthritis of the distal RU joint results in pain on overpressure.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Difficulty turning a doorknob or key in the ignition
- Difficulty or pain with pushing and pulling activities, such as opening and closing doors
- Restricted hand-to-mouth activities for eating and drinking and hand-to-head activities for personal grooming and using a telephone
- Difficulty or pain when pushing up from a chair
- Inability to carry objects with a straight arm
- Limited reach

Joint Hypomobility: Management—Protection Phase

See 'Guidelines for Management Related to the Stages of Tissue Healing' in Chapter 10, Box 10.1.

Educate the Patient

- Inform the patient regarding the anticipated length of acute symptoms and teach methods of joint protection and how to modify activities of daily living. For example, the patient should avoid activities that involve lifting or pushing off with the involved upper extremity.
- Instruct the patient to avoid excessive fatigue by performing exercises frequently during the day but limiting the number of repetitions during each bout (set) of exercises.

Reduce Effects of Inflammation or Synovial Effusion and Protect the Area

- Immobilization in a sling provides rest to the part, but complete immobilization can lead to joint hypomobility, contractures, and limited motion; therefore, frequent periods of controlled movement within a pain-free range should be performed.

CLINICAL TIP

When immobilizing the elbow, position in relative extension (20° to 30° flexion) and use a posterior splint bubbled out around the cubital tunnel to prevent or treat ulnar neuropathy. Splinting in this position is used to minimize pressure on the ulnar nerve, which may be at risk from joint swelling in the cubital tunnel.[12]

- Gentle grade I or II joint distraction and oscillation techniques in the resting position may inhibit pain and move synovial fluid for nutrition in the involved joints (see Chapter 5 for principles of application and techniques).

Maintain Soft Tissue and Joint Mobility

- Passive or active-assistive ROM within limits of pain, including flexion/extension and pronation/supination
- Multiple-angle muscle setting of elbow flexors, extensors, pronators, supinators, and wrist flexors and extensors in pain-free positions

Maintain Integrity and Function of Related Areas

- Shoulder, wrist, and hand ROM and activities should be encouraged within the tolerance of the individual.
- If edema develops in the hand, the arm should be elevated whenever possible. Apply massage as described in Chapter 25.

Joint Hypomobility: Management—Controlled Motion Phase

If joint hypomobility exists, ROM is increased by utilizing joint mobilization techniques as well as passive stretching and muscle inhibition techniques following the principles described in Chapters 4 and 5. Box 18.2 highlights several important precautions if joint restrictions are related to trauma.

Increase Soft Tissue and Joint Mobility

Initiate stretching cautiously and note the joint and tissue response. Vigorous stretching should not be undertaken until the chronic stage of healing. As noted in Box 18.2, high-intensity stretching of the elbow flexors is contraindicated following trauma because of the potential for development of heterotopic bone formation.

- ***Passive joint mobilization techniques.*** Because several articulations are involved with each motion at the elbow, it is important to identify which of the articulations have reduced joint play prior to applying grade III sustained or grade IV oscillation techniques. For specific techniques to use, see Figures 5.28 through 5.33 and their descriptions in Chapter 5. Progress each technique by positioning the joint at the end of its available range before applying the mobilization technique.

BOX 18.2 Precautions Following Traumatic Injury to the Elbow

- If the brachialis muscle is injured, ossification of the injured tissue is a potential complication, and stretching is contraindicated.
- After healing of fractures in the forearm, malunion is not unusual, preventing full range of pronation or supination. A boney block end-feel or an abnormal appearance of the forearm should alert the therapist to the cause of this impairment. Radiographical imaging is helpful in verifying the problem. No amount of stretching or mobilizing changes the patient's range. Indiscriminate stretching may lead to hypermobility of related joints, which could cause additional trauma and pain.

CLINICAL TIP

To progress joint mobility in the terminal ranges of flexion and extension, it may be necessary to emphasize the accessory motions of varus and valgus, respectively. This is accomplished with medial and lateral gliding techniques or with a varus or valgus physiological stretch at the elbow.

- ***Manipulation to reduce a "pushed elbow."*** Proximal subluxation of the radius may result from falling on an outstretched hand. The radial head is pushed proximally in the annular ligament and impinges against the capitulum. This injury sometimes accompanies a fracture of the distal radius (Colles' fracture) or scaphoid and is not identified as an impairment until after the fracture has healed and the cast is removed. It is often overlooked because there is considerable soft tissue and joint restriction caused by the period of immobilization. Bilateral palpation of the joint spaces reveals the decreased space on the involved side. There may be limited flexion or extension of the elbow, limited wrist flexion, and limited pronation.

CLINICAL TIP

For an acute "pushed elbow" (and no fracture), apply a distal traction to the radius to reposition the radial head. If chronic, repetitive stretching with sustained grade III distal traction to the radius is necessary (see Fig. 5.29) in addition to the soft tissue stretching and strengthening techniques needed for increasing motion.

- ***Manipulation to reduce a "pulled elbow."*** Distal subluxation of the radius is usually seen as an acute injury in children and is sometimes labeled "tennis elbow" when it occurs in adults. It occurs as a result of a forceful pull on the hand such as would occur when a child jerks away from a parent or caregiver or a person tries to pick up a heavy object with a jerking motion on the handle. The force causes the radius to move distalward with respect to the ulna. The head of the radius is unable to slide proximally in the annular ligament when supination is attempted, resulting in the person holding the forearm in pronation. Either supination is restricted, or the patient guards against the motion.

CLINICAL TIP

A quick, compressive manipulation (high-velocity thrust) with supination is applied to the radius (see Fig. 5.31) to reposition the radial head when there is a "pulled elbow." If it is an initial injury, there may be soft tissue trauma from the injury, which is treated with cold and compression.

- ***Manual stretching and self-stretching.*** Use manual stretching and inhibition techniques to increase the flexibility of any periarticular tissues that are restricting mobility. Use of a cuff weight placed around the distal forearm with the patient carefully positioned for an effective stretch provides a low-intensity, long-duration stretch and is an alternative to manual passive stretching (see Fig. 18.7 in the exercise section). If elbow ROM does not steadily improve after acute symptoms have subsided, the patient may need to begin wearing an adjustable, dynamic splint that applies a low-intensity stretch force over an extended period of time. These stretching interventions are described in Chapter 4.
- ***Home instructions.*** Teach the patient self-stretching maneuvers followed by active exercise that utilizes the new range. Suggestions are provided in the last section of this chapter.

Improve Joint Tracking of the Elbow

A mobilization with movement (MWM) technique consisting of a lateral glide combined with the active movement of flexion or extension and pain-free passive overpressure may improve articular surface tracking by allowing the muscles to move the joint in a pain-free manner.[66] (Refer to the principles of MWM in Chapter 5.)

- *Patient position and maneuver*: Supine with elbow either flexed or extended to the end of the available range. A mobilization belt is secured around the proximal forearm and your hips. Stabilize the distal humerus at the olecranon process with one hand and support the forearm with the other. Apply a gentle lateral glide to the proximal ulna with the belt by moving your hips. Have the patient produce an active elbow flexion or extension movement and apply a passive overpressure stretch at the end of the range (Fig. 18.3). This should not elicit any pain.

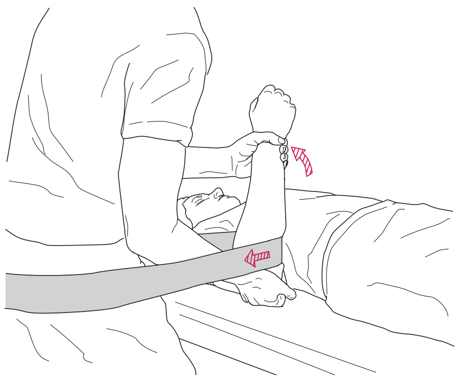

FIGURE 18.3 Mobilization with movement (MWM) to improve elbow flexion. A lateral glide is applied to the proximal ulna while the patient actively flexes, followed by a passive end-range stretch.

Improve Muscle Performance and Functional Abilities

Initiate active and low-load resistance exercises in open- and closed-chain positions to develop control, muscular endurance, and strength in the muscles of the elbow and forearm. As the patient improves, adapt the exercises to progress toward functional activities. Specific exercises are described in the exercise section of this chapter. Include the shoulder girdle, wrist, and hand in the exercise program as their flexibility and strength has an influence on the recovery of elbow function.

Joint Hypomobility: Management—Return to Function Phase

Improve Muscle Performance

Progress strengthening exercises as the joint tissue tolerates. Teach the patient safe progressions and exercise strategies that promote return to function. To prepare the joints and muscles for specific tasks, use exercises that replicate the repetitions and demands of daily activities, such as pushing, pulling, lifting, carrying, and gripping.

Restore Functional Mobility of Joints and Soft Tissues

If restrictions remain, use vigorous manual or mechanical stretching and joint mobilization techniques.

Promote Joint Protection

Chronic arthritic conditions may require modification of high-load activities to minimize deforming stresses on the involved joints.

Joint Surgery and Postoperative Management

Intra-articular or extra-articular surgical intervention is often necessary for management of severe fractures or dislocations that affect the joints of the elbow and surrounding soft tissues. These injuries may require open reduction with internal fixation or arthroscopic or open excision of bone fragments. In adults, the most common fracture in the elbow region is a fracture of the head and neck of the radius. This type of fracture accounts for approximately one-third of all elbow fractures.[9,71] This injury usually occurs when a person falls on an outstretched hand when the elbow is extended, causing a posterior dislocation and fracture of the radial head coupled with injury of elbow ligaments.[31]

If the proximal radius is displaced and the radial head fracture is comminuted, either open or occasionally arthroscopically assisted reduction with internal fixation or a radial head excision (resection) with or without prosthetic implant are surgical options.[31,59,60,71] It has been suggested that rigid internal fixation (screws or plate fixation) of radial head fractures is indicated in the young, active adult, whereas excision of the radial head is more appropriate for the low-demand patient or if the fracture is severely comminuted and fixation is not possible.[40] Box 18.3 summarizes the advantages and disadvantages of surgical options for management of displaced fractures of the radial head. Radial head fractures in children, however, are relatively uncommon. When they do occur, closed reduction is preferred.[78]

BOX 18.3 Surgical Options for Displaced Fractures of the Radial Head

Open Reduction and Internal Fixation
- *Advantages:* Achieves stabilization and fixation of multiple fracture fragments with normal or near-normal alignment; ability to repair significant ligamentous damage; early postoperative motion permissible unless reconstruction of ligaments required
- *Disadvantages:* Extensive soft tissue disruption and arthrotomy required; not amenable to nonreconstructible fractures and less practical than radial head excision for severely comminuted fractures

Arthroscopic or Arthroscopically Assisted Reduction and Internal Fixation
- *Advantages:* Allows arthroscopic evaluation of the joint and débridement of fracture debris; if fully arthroscopic, no arthrotomy, less soft tissue disturbance, less postoperative pain, better cosmetic outcome
- *Disadvantages:* Limited to reduction and fixation of no more than two-part displaced fractures; not appropriate for radial neck fractures; if fully arthroscopic, fixation techniques more technically difficult (e.g., use of percutaneous screw fixation) than open procedure

Excision of the Radial Head
- *Advantages:* Only option for severely comminuted, nonreconstructible fractures; no potential for mechanical blockage of joint motion from malalignment of fracture fragments or internal fixation; early ROM permissible
- *Disadvantages:* Requires arthrotomy; may compromise joint stability if a prosthetic implant is not used

Small osteochondral defects of one or more of the articular surfaces of the elbow complex occur in the skeletally mature and immature individual (often in the throwing athlete) as the result of repetitive trauma. Such defects, depending on their size, characteristics, and location, may require surgical intervention, such as removal or internal fixation of a fragment, microfracture, or autologous osteochondral or chondrocyte implantation, if nonoperative measures have been ineffective.[72]

Early-stage or long-standing joint disease (RA, JRA, posttraumatic arthritis) associated with synovial proliferation and destruction of articular surfaces of the elbow joints and leading to pain, limitation of motion, and impaired upper extremity function also may need to be managed with extra-articular or intra-articular surgery. For example, with early-stage RA in which synovial proliferation is present but joint surfaces are still in good condition, *arthroscopic* or *open synovectomy* is the procedure of choice for relief of pain if medications have not controlled the disease.[14,32,43,47] Occasionally, advanced arthritis is managed surgically by *interposition arthroplasty* (only in the young patient on a selective basis),[21,32,73] *resection of the radial head* with or without prosthetic implant and concomitant synovectomy,[20,28,56,60] or *arthrodesis* (as a salvage procedure).[73] However, today, the most common surgical procedure used to manage severe destruction of the elbow joint is *total elbow arthroplasty*.[14,20,21,32,48,61,73] Table 18.2 summarizes how the severity of joint disease and the extent of soft tissue involvement influence the choice of surgical procedure for the elbow complex.[14,21,28,32]

The goals of surgery of the elbow joint complex and postoperative rehabilitation include[21,73]: (1) relief of pain, (2) restoration of boney alignment and joint stability, and (3) sufficient strength and ROM to allow functional use of the elbow and upper extremity. Surgical procedures done to relieve pain and improve elbow stability tend to be more successful than procedures done solely to increase ROM. Heterotopic bone formation, which leads to joint stiffness, is often a complication of elbow fractures, dislocations, and elbow joint surgery.[57] Therefore, the single goal of improving ROM is rarely an indication for surgery.[21]

Radial Head Excision or Arthroplasty

Indications for Surgery

The following are frequently cited indications for radial head excision or arthroplasty.

- Severely comminuted fracture or fracture-dislocations of the head or neck of the radius that cannot be reconstructed and stabilized with internal fixation[54,56,59,71]
- Chronic synovitis and mild deterioration of the articular surfaces associated with arthritis of the HR and proximal RU joints resulting in joint pain at rest or with motion, possible subluxation of the head of the radius, and significant loss of upper extremity function[21,28,60]

CONTRAINDICATIONS: Radial head excision is contraindicated in the growing child.[78] Excision without replacement of the radial head is not an appropriate option in the presence of a damaged lateral ulnar collateral ligament complex.[56] As with other joints, arthroplasty also is contraindicated with active infection.

Procedure

Background

Selection of procedure. Depending on the integrity of the ligaments and stability of the elbow complex, a radial head excision may be selected or implant arthroplasty may be the better choice. The use of a prosthetic implant is indicated when there is clinical instability of the elbow as the result of disruption of the supporting ligaments.[49,56,60]

Implant designs, materials, and fixation. Radial head implants originally were flexible and made of silicone (Silastic® material).[21,60] However, this material is no longer used because it has been associated with fatigue failure, particulate debris, and the development of adverse biological reactions, specifically inflammatory arthrosis (synovitis) of the HU joint.[84] Currently used implants are one-piece or two-piece (modular) designs that more closely replicate the normal biomechanics of the elbow and are made of metal (cobalt-chrome and titanium), ceramics, or ultra-high molecular weight polyethylene.[36,56,59,60] The use of pyrolytic

TABLE 18.2 Severity of Elbow Joint Disease and Selection of Surgical Procedure

Severity of Joint Disease	Selection of Surgical Procedure
■ Mild synovitis: joint surfaces normal or minimally deteriorated; osteoporosis	■ Nonoperative/medical management
■ Moderate synovitis; some loss of articular cartilage; narrowing of joint space but joint contour maintained	■ Arthroscopic synovectomy or resection of the radial head with synovectomy
■ Moderate to severe synovitis; loss of articular cartilage; loss of joint space; intact collateral ligaments	■ Resurfacing total elbow arthroplasty or, possibly in a growing child, an interpositional arthroplasty
■ Severe synovitis; destruction of articular cartilage; complete loss of joint space (bone-to-bone articulation); significant joint instability; bone loss; ankylosis	■ Semiconstrained total elbow arthroplasty

carbon as an implant material also is being investigated.[56] However, the optimal radial head implant has yet to be designed and fabricated. Cemented or cementless fixation is an option with total elbow arthroplasty (TEA).

Overview of Operative Procedure

A lateral or posterolateral triceps-sparing incision at the elbow and forearm is made into the joint (arthrotomy) just anterior to the lateral collateral ligament. The radial head is exposed, and a radial osteotomy is performed at the level of the annular ligament to resect the head. For a severe fracture, some of the neck of the radius also may need to be excised. When exposing the operative field, effort is made not to detach intact ligaments. A concomitant synovectomy is done if proliferative synovitis is present (typically seen in RA and JRA).

If an implant is to be inserted, the medullary canal of the radius is prepared to accept the stem of the prosthesis. If the elbow is unstable, ligamentous structures are repaired. If the lateral ulnar collateral ligament (LUCL) is insufficient, it may be reinforced with a palmaris longus autograft or allograft. To prevent injury to the ulnar nerve or if symptoms of compression are present, ulnar nerve transposition is also performed.[28,56,59,60]

Complications

Intraoperative complications. Damage to the posterior interosseous nerve is a concern during surgical excision of the radial head regardless of whether a radial head replacement is included in the procedure.[56] If an implant is inserted, malpositioning or inaccurate sizing can cause postoperative pain and HR instability, compromise ROM, and eventually contribute to premature implant wear.

Postoperative complications. Postoperatively complications of excision with or without implant may include delayed wound closure, infection, limited ROM of the elbow and/or forearm, cubital laxity, persistent pain, and a sense of instability. Slight proximal migration of the radius may occur if resection does not include implantation of a prosthetic radial head. This complication may or may not be associated with elbow or wrist pain. Following excision for a severe radial head fracture, osteoarthritis of the HR joint also may develop over time.[56,59]

As with all types of implant arthroplasty, aseptic loosing or long-term implant wear and breakage are complications that may occur, necessitating revision arthroplasty. Although not unique to elbow surgery, complex regional pain syndrome may develop in rare instances.

Postoperative Management

The goals and interventions, the rate of progression, and the length of the rehabilitation program, as well as final outcomes, are highly dependent on the extent of damage to soft tissues from injury or chronic inflammation, the integrity of repaired soft tissues particularly the supporting ligaments of the elbow complex, the philosophy of the surgeon, and the patient's expectations of the surgery and response to treatment.

Immobilization

The elbow is immobilized continuously in a well-padded posterior resting splint in a position of 90° of flexion and mid-position of the forearm after surgery.[59,60] When elbow motion is permissible (often as early as 1 to 3 days after surgery or longer if significant reconstruction of ligaments was necessary), the splint is removed for exercise but is replaced after exercise and worn at night for an extended period of time to protect healing tissues. If the stability of the elbow is in question, the patient may need to wear a dynamic (hinged) splint for ROM exercises.

Exercise: Maximum Protection Phase

Goals and interventions. The first phase of rehabilitation, which extends for about the first 6 weeks after surgery, focuses on patient education that emphasizes wound care, control of pain and peripheral edema, and exercises to offset the adverse effects of immobilization while protecting repaired soft tissues that maintain the stability of the elbow. The arm is elevated for comfort and to control edema distally. The following goals and exercise-related interventions typically are included in this initial phase.[9,51,59,60,91]

- ***Maintain mobility of unoperated joints.*** Active ROM exercises of the shoulder, wrist, and hand immediately after surgery.
- ***Maintain mobility of the elbow and forearm.*** When permitted, have the patient remove the splint several times daily for self-ROM (passive or active-assisted) of the elbow and forearm within pain-free ranges. Active ROM is allowed within a week after exercises are initiated. As noted previously, some patients must wear a hinged splint for additional stability during ROM exercises.

CLINICAL TIP

Some specific motions initially may need to be restricted to prevent excessive stress on reconstructed ligaments. Restrictions vary depending on the extent of ligament disruption and which ligaments were repaired. For example, if the lateral collateral complex was repaired, supination is limited to 20° during the early weeks of rehabilitation.[31]

- ***Minimize muscle atrophy.*** Submaximal, pain-free, multiple-angle setting exercises of elbow and forearm musculature.

Exercise: Moderate and Minimum Protection Phases

Goals and interventions. The intermediate phase of rehabilitation begins when wound healing is satisfactory and active movements of the elbow are relatively pain-free. This phase and the final phase of rehabilitation are characterized by continued efforts to restore nearly full or at least sufficient ROM for functional activities while maintaining stability of the elbow. Exercises to improve upper extremity strength and muscular endurance and use of the involved elbow for light functional activities are introduced and progressed.[9]

NOTE: It is important to note that some surgeons and therapists prefer to improve strength and muscular endurance solely through ADL without the use of specific resistance exercises.[51,59,60]

- ***Increase ROM,*** particularly if contractures were noted preoperatively.
  - Gentle (low-intensity) manual stretching, hold-relax techniques (PNF stretching), or self-stretching
  - Grade II joint mobilization techniques initially, followed by grade III mobilizations after 6 weeks when the joint capsule is well healed

CONTRAINDICATION: When applying joint mobilization techniques, do not perform valgus/varus stretches in terminal extension/flexion, particularly if the radial head was not replaced with a prosthetic implant or if the integrity of the supporting ligaments and stability of joints are questionable.

  - Low-load, long-duration, dynamic splinting or alternating use of static splints in maximum flexion and extension
- ***Improve functional strength and muscular endurance.***
  - Low-load resistance exercises (maximum 1 to 2 lb), emphasizing high repetitions
  - Use of the operated upper extremity for *light* ADL

Resumption of recreational and work-related activities. Patient education is a key element of helping the patient return safely to physical activities. Following excision of the radial head with or without a prosthetic implant, a patient must permanently refrain from high-demand or high-impact, work-related or recreational activities regardless of the underlying pathology that necessitated surgery.[51] Be certain the patient knows to avoid using the involved upper extremity for moving or holding heavy objects or refrain from participating in recreational activities that impose significant stress across the elbow complex, such as racquet sports.

Outcomes

The anticipated outcomes after resection of the radial head for a severely displaced and comminuted fracture or advanced arthritis are a stable elbow and pain-free movement (flexion/extension and pronation/supination) within functional ranges.[31,59,60] Short-term, postoperative outcomes of excision arthroplasty with and without implant are similar with regard to relief of pain and functional motion. However, patients with preoperative instability necessitating an implant and those with a tenuous repair of ligamentous structures have less satisfactory results than those with a stable elbow. If preexisting contractures exist, ROM does not necessarily improve.

Some patients may develop a slight increase (about 5° to 10°) in valgus laxity of the elbow, without complaints of instability during functional activities if ligaments are intact prior to surgery or repaired at the time of surgery. Others may experience pain and instability associated with the increased laxity, thus compromising outcomes. In a study by Hall and co-investigators,[37] posterolateral rotary instability associated with a deficient lateral ulnar collateral ligament was identified at a mean of 44 months in only 16.6% of patients (7 of 42) who reported lateral elbow pain and a sense of instability or weakness after radial head resection (without implant).

Many of the long-term studies of excision with prosthetic implant have evaluated the results of procedures using flexible components made of silicone, which as previously noted, have been shown to be associated with material fatigue or inflammatory responses and have led to premature failure.[60] Short-term and a few long-term outcomes after current-day procedures, using rigid implants but involving relatively small numbers of participants, are gradually being reported in the literature.[56] Results of these studies are promising including pain relief, stability, and sufficient elbow and forearm ROM for functional activities leading to relatively high patient satisfaction.

Total Elbow Arthroplasty

When nonoperative management or previous surgical procedures have been unsuccessful, total elbow arthroplasty (TEA) has been considered a treatment option primarily for the older individual (over 60 to 65 years of age) with debilitating, late-stage elbow arthritis whose physical demands are relatively low.[11,73] However, since the first cemented TEA was introduced several decades ago,[24] the indications for this procedure have broadened considerably as the design of prosthetic implants and surgical techniques have evolved.[88] TEA is now considered for the younger patient. One resource, for example, has suggested that any individual, older than age 30, might be an appropriate candidate for TEA depending on their expected postoperative demands.[32] A long-term follow-up of patients, who had undergone TEA at or before the age of 40 for various types of elbow arthritis, showed that 93% continued to have good to excellent outcomes at a mean duration of 91 months after surgery.[16]

In addition to management of advanced arthritis, TEA now is considered a preferred surgical alternative to open reduction and internal fixation for management of severely comminuted, intra-articular distal humeral fractures sustained by elderly patients.[53,75]

Indications for Surgery

The following are currently accepted indications for TEA.

- Debilitating pain and loss of functional use of the upper extremity as the result of moderate to severe joint pain and articular destruction of the HU and HR joints.[11,21,32,73,75] Underlying diseases managed with TEA include RA (by far the most common pathology),[28,34,61,63] JRA,[20] and post-traumatic degenerative arthritis or primary OA.[32,62,77]
- Gross instability of the elbow[11,31,41,74,75]
- Acute comminuted, intra-articular fracture[18,53] and nonunion fracture of the distal humerus[58,64]
- Failed interposition arthroplasty or radial head resection[76]
- Marked bilateral limitation of motion of the elbows[21,22,58]

CONTRAINDICATIONS: Absolute and relative contraindications for TEA are identified in Box 18.4.[11,22,32,48,61,75] It is important to note, however, with the exception of active infection, there is lack of agreement as to which contraindications are absolute versus relative.

Procedure

Background

The complex structural relationships among the HU, HR, and proximal RU joints have made developing a prosthetic elbow joint a challenging task. Following introduction and use of early cemented elbow replacements,[24] incremental improvements in design, materials, fixation, and surgical technique have contributed to increasingly predictable and successful outcomes.[21,73] Elbow replacement systems include a humeral and an ulnar implant (Fig. 18.4), and some designs also include replacement of the head of the radius.[48,58,61]

Implant design and selection considerations. Early designs were *hinged (linked, articulated)* and *fully constrained* metal-to-metal humeral and ulnar implants that allowed only flexion and extension of the elbow joint.[21,32,73] These designs made no allowances for normal varus and valgus and rotational movements, and hence, the implants rapidly loosened at the bone-cement interface. Metal fatigue at the linkage of the prosthetic components and joint dislocation also were common complications.[7,35] As more accurate information about the biomechanical characteristics of the elbow joint became known, the design of prosthetic replacements evolved. In addition to an arc of flexion and extension, contemporary designs provide 5° to 10° of varus and valgus and a small degree of rotation (Fig. 18.5).[61]

The designs of total elbow replacement can be classified into two broad categories: *linked* (articulated) and *unlinked* (nonarticulated).[7] Rather than being fully constrained, as the early components were, linked humeral and ulnar implants are now loosely constrained and, as such, are referred to as *semiconstrained* designs.[34,58,61,77] Designs classified as unlinked are composed of two separate, nonarticulated implants and are often called *resurfacing* replacements.[7,22,32,48] The most recent advance in implant design is the *hybrid* prosthesis, which can be inserted as either a linked or unlinked replacement system. Use of a hybrid replacement enables the surgeon to determine the more appropriate design based on intraoperative observations and evaluation.[7]

The criteria for use of a linked or unlinked TEA are based in part on the characteristics of these designs with respect to

BOX 18.4 Contraindications to Total Elbow Arthroplasty

Absolute
- The presence of active (acute or subacute) infection
- Neurological dysfunction leading to paralysis and inadequate control of elbow musculature, particularly the elbow flexors

Relative
- History of previous elbow infection
- Irreparable supporting ligaments
- Inadequate control of elbow extensors
- Heterotopic ossification or pain-free ankylosis
- Insufficient bone stock
- The younger patient, particularly one who must lift heavy loads (>10 lb) after TEA

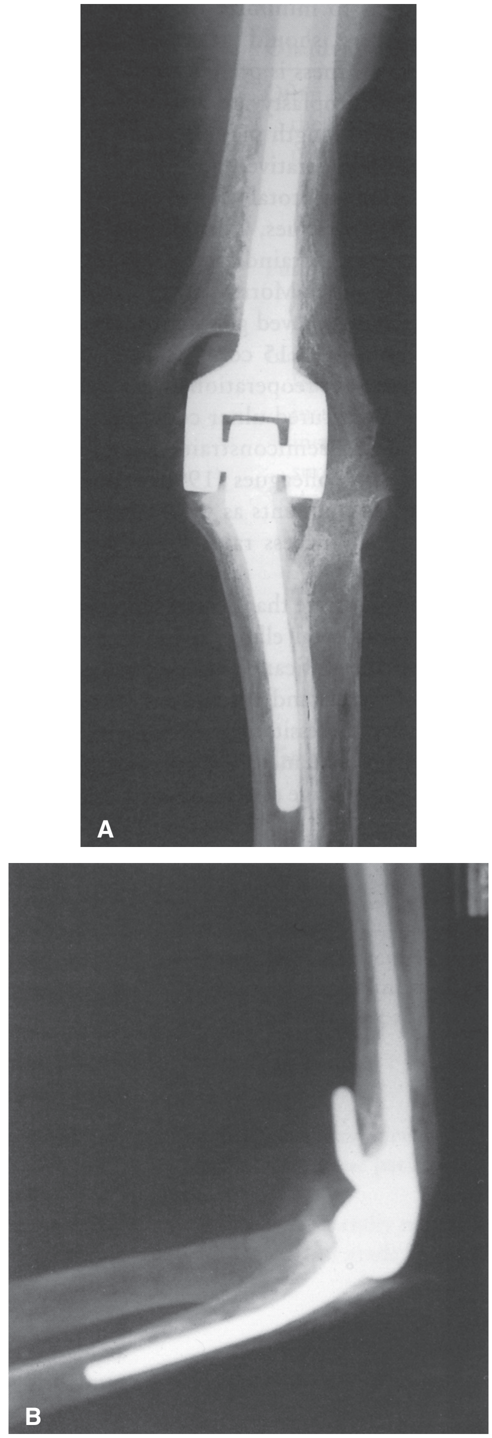

FIGURE 18.4 **(A)** Anteroposterior and **(B)** lateral radiographs following placement of a Conrad-Morrey (linked/semiconstrained) total elbow arthroplasty. *(From Field and Savoié,[31] with permission.)*

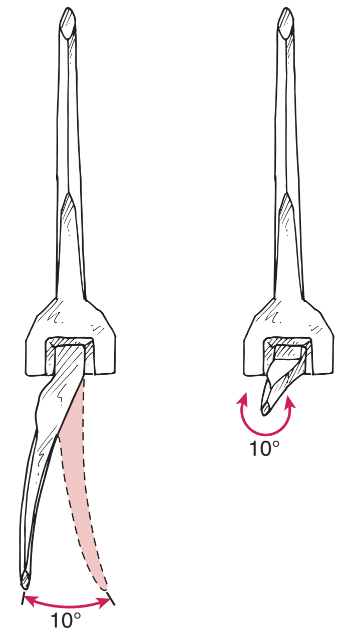

FIGURE 18.5 A linked, semiconstrained design is characterized by varus-valgus and axial rotation tolerances of several degrees at the articulation. *(From Morrey, BF [ed]: The Elbow and Its Disorders, ed. 3. Philadelphia: WB Saunders, 2000, p 617, with permission from the Mayo Clinic Foundation.)*

stability. Linked designs derive inherent stability from one or two pins, which couple the humeral and ulnar components.[58] In addition, some semiconstrained designs have an anterior flange to enhance joint stability and decrease the risk of posterior dislocation.[61] Unlinked implant systems, although sometimes referred to as nonconstrained,[32] actually have varying degrees of constraint built into their designs based on the degree of congruency of the articulating surfaces.[22,48] The less constraining the articular surfaces of the implants, the more reliant the replacement system is on the surrounding soft tissues, particularly the collateral ligaments, for joint stability.

Overall, linked designs, because of their inherent stability, are considered appropriate for use with a broader spectrum of patients, including those with unstable elbows, than unlinked designs.[32] Although both linked and unlinked designs derive some degree of stability from the supporting capsuloligamentous structures and elbow musculature, the integrity of these soft tissues is far more critical for successful use of unlinked than linked designs.[7,58]

In addition to considerations related to stability, the etiology and extent of joint destruction, the degree of deformity, the quality of the available bone stock, and the training and experience of the surgeon are factors that influence the type of replacement system used.

Materials and fixation. A stemmed titanium humeral component that has a cobalt-chrome alloy articulating surface interfaces with a high-density polyethylene articulating surface of a stemmed ulnar component.[7,21] Currently, prosthetic components are cemented in place with polymethyl methacrylate, an acrylic cement. Some designs also have a porous-coated extramedullary flange for osseous ingrowth. To date, all-cementless fixation has not yet been developed for total elbow arthroplasty.[21,73]

Operative Overview

The following is a brief overview of typical elements involved in a TEA.[11,22,32,48,58,61,77] A longitudinal incision is made at the posterior aspect of the elbow, either slightly lateral or medial to the olecranon process. The ulnar nerve is isolated, temporarily displaced, and protected throughout the procedure. The distal attachment of the triceps is detached and reflected laterally with a *triceps-reflecting approach* or split longitudinally and retracted along the midline with a *triceps-splitting approach*.[22,61] The more recently developed *triceps-sparing (triceps-preserving) approach* is also an option. It involves incisions on the medial and lateral aspects of the elbow joint. This approach preserves the attachment of the triceps tendon on the olecranon but makes insertion of the implants more technically challenging.[8,32]

As the procedure progresses, ligaments and other soft tissues are released as necessary; the posterior aspect of the capsule is incised and retracted; and the joint is dislocated. In preparation for the implants, small portions of the distal humerus and proximal ulna are resected. Depending on the status of the radial head, the integrity of the collateral ligaments, and the design of the prosthesis, the head of the radius may or may not be excised. Then the intramedullary canals of the humerus and ulna and possibly the radius are prepared, and trial components are inserted. The available ROM and stability of the prosthetic joint are checked intraoperatively and x-rays are taken to confirm proper alignment of the implants. The components are then cemented in place, and the capsule and any ligaments that had ruptured prior to surgery or were released during the procedure are repaired to the extent possible or necessary based on the design of the prosthesis and the quality of the structures. If detached or split, the extensor mechanism is securely reattached or meticulously repaired. Following possible anterior transposition and careful placement of the ulnar nerve in a subcutaneous pocket, the incision is closed, and a sterile compressive dressing and posterior and/or anterior splint are applied to immobilize the elbow and forearm. The arm is elevated to control peripheral edema.

Complications

Although the incidence of complications has declined steadily over the past few decades as selection of patients, prosthetic design, and surgical technique have improved, complications after TEA continue to occur more frequently than after total hip, knee, or shoulder arthroplasty.[8,88]

FOCUS ON EVIDENCE

In the mid-1990s,[35] a comprehensive review of the literature indicated that the overall rates of complications following TEA ranged from 20% to 45%. A recent systematic review of the results of subsequent studies (published from 1993 to 2009), however, indicated that the mean overall rate of complications after contemporary, primary TEA (semiconstrained and nonconstrained designs) was 24.3% (±5.8%).[88]

Complications are categorized as intraoperative and postoperative—early or late (before or after 6 weeks).[70]

Intraoperative complications. Intraoperative complications, such as fracture and component malpositioning, can significantly affect short- and long-term outcomes. Ulnar damage or irritation, either transient or permanent, also can occur intraoperatively from handling or during the early weeks after surgery from compression as well,[8,35,70,88] typically causing paresthesia but not weakness.[32,75]

Postoperative complications. Deep infection, a concern after any surgery, is reported to occur in an average of 3.3% (±2.9%) of cases following current-day TEA.[88] This rate is higher for TEA than large joint arthroplasties, owing to the thin layer of soft tissues covering the elbow joint and because the majority of patients undergoing TEA have inflammatory arthritis and a compromised immune system due to medication.[75,88]

Other postoperative complications, including joint instability, wound healing problems, and triceps insufficiency, are of particular concern during the early and intermediate phases of rehabilitation. Despite continuing improvements in implant design and fixation and surgical techniques, some complications develop several months or even years after surgery. These complications include aseptic (biomechanical) loosening of the prosthetic implants over time at the bone-cement interface (the most common long-term complication and reason for revision arthroplasty), periprosthetic fracture, and mechanical failure or premature wear of the components.[8,30,32,75,88]

It is important for a therapist to be familiar with the incidence and possible causes of complications after TEA in order to effectively structure and progress a postoperative rehabilitation program that decreases at least some of the risk factors associated with these complications. The incidence and characteristics of selected postoperative complications (joint instability, triceps insufficiency, prosthetic loosening) after TEA and factors that contribute to these complications are summarized in Box 18.5.[8,35,70,74,75,88] Precautions to reduce the risk of these and other complications are addressed in the following section on postoperative management.

BOX 18.5 Analysis of Three Potential Complications after Total Elbow Arthroplasty

Joint Instability

- *Incidence.* One of the more common complications after TEA; predominantly a problem in unlinked arthroplasty;[8,88] overall rate of dislocation and symptomatic instability of contemporary TEA, an average of 3.3% (± 2.9%).[88]
  - Higher incidence with prior radial head resection[76]
  - Higher rate in unlinked implants (reported at 4% to 15%, mean 8%)[48] than in linked implants (reported at 0% to 14%, mean 3.5%).[34,45,77]
- *Characteristics.* Early or late onset; associated with pain and loss of function.
  - Disruption of a repaired LCL complex → posterolateral, rotary, and varus instability; disruption of a repaired MCL complex → posteromedial and valgus instability.
  - Disruption of triceps mechanism → diminished dynamic compressive forces across the joint.
- *Contributing factors.* Excessive release or inadequate or failed soft tissue repair → deficient static or dynamic stabilizers (possibly due to inadequate postoperative immobilization and excessive postoperative stresses across the elbow, particularly during the early postoperative period before soft tissue repairs have healed), malpositioning of implants, and long-term polyethylene wear of the ulnar component increase the risk of instability.[8,48,70]

Triceps Insufficiency

- *Incidence.* Primarily occurs after surgical approaches that disrupt the triceps mechanism; occurs in both linked and unlinked arthroplasty, usually during the first postoperative year.[75] Examples of rates of occurrence reported in separate retrospective studies: 1.8% of 887 elbows,[15] 4% of 78 elbows,[34] and 11% of 28 elbows[45] and 2.4% (± 2.4%) of 2,938 elbows reported in a recent systematic literature review of contemporary TEA.[88]
  - Higher overall risk in patients with previous elbow surgery before TEA.[15]
- *Characteristics*. Partial or complete rupture, or avulsion, of the extensor mechanism (during the early or late postoperative period) → weakness (particularly in terminal extension), often posterior elbow pain, and difficulty with pushing activities and overhead functions, such as combing one's hair.
- *Contributing factors*. Occasionally postoperative trauma but most commonly a failed surgical reattachment or repair of a poor quality tendon; premature or excessive ROM or loads on the extensor mechanism during early rehabilitation or during long-term functional use of the arm.[48]

Implant Loosening

- *Incidence.* The most common postoperative complication, occurring in linked (semiconstrained) more than unlinked (nonconstrained) implants. Overall rates are lower with contemporary TEA designs (mean, 5.1%, ± 3.4%)[88] than earlier designs[35] but remain higher than after hip, knee, and shoulder arthroplasty.[70] The more constrained the design, the greater the risk of loosening.
  - Rate of clinical loosening reported in individual studies of contemporary implants up to a 6-year follow-up has been reported to range from 0% to 6%.[35,45,63,77]
  - Rates of 0% reported in patients with RA over a mean follow-up of 3.8 years[63] and in patients with posttraumatic arthritis with a mean follow-up of 5 years.[77]
  - The incidence of radiological loosening is consistently higher than clinical loosening (when the patient becomes symptomatic).
- *Characteristics.* Aseptic (biomechanical) loosening, a late complication, occurs at the bone–cement interface typically of the ulnar component;[32] clinical loosening is associated with pain. Excludes loosening caused by infection.[8]
- *Contributing factors.* Inadequate cementing technique, implant malpositioning, and lack of adherence to postoperative activity modification. High-load, high-impact activities place patient at higher risk of loosening.

Postoperative Management

The overall goal of rehabilitation after TEA is to achieve pain-free ROM of the elbow joints as well as strength of the upper extremity sufficient for functional activities while minimizing the risk of early or late postoperative complications. This goal is best achieved with an individualized rehabilitation program based on a thorough examination of each patient's postoperative status.

Immobilization

As noted previously, a soft compression dressing is applied at the close of surgery. A well padded posterior or anterior splint is used to immobilize the elbow and maintain stability and protect structures as they heal. Recommendations for the positions and duration of immobilization vary.

Position. The position of immobilization is based on a number of factors, including the surgical approach, the implant design, and which soft tissues were repaired and require protection.[6,22,28,51] If, for example, a triceps-reflecting approach was used for a linked TEA, full or almost full elbow extension typically will be selected to protect the reattached triceps tendon and a neutral position of the forearm.[6,22,58,61] In contrast, with an unlinked TEA, which typically requires repair of the lateral ligament complex because of preoperative damage or release for operative exposure of the joint, the position of immobilization is a moderate degree of flexion with limitation of full forearm supination to lessen stress on the repaired ligaments.[6,70] If a patient had a significant preoperative elbow flexion contracture that was surgically released, an anterior splint may be selected with the elbow placed in the available amount of extension. An extended position is also indicated if symptoms of ulnar neuropathy are present to alleviate pressure in the cubital tunnel.[58,61,70]

Duration. The period of continuous immobilization after surgery, which is kept as short as possible to avoid stiffness, also varies widely, ranging from 1 to 2 days to several weeks. This time period depends on the design of the prosthesis, the surgical approach, the integrity of ligamentous structures, intraoperative observations by the surgeon, and the integrity of the skin and subsequent wound healing. In general, unlinked/resurfacing designs, which have little inherent stability, require a longer period of immobilization than linked/semiconstrained designs.[8,28,51]

If there is increased risk of delayed wound healing because of poor skin quality or a patient's history of diabetes, smoking, or use of steroids, the elbow may be continuously maintained in extension for 10 to 14 days postoperatively to limit stress on the posterior incision.[58,61,70] Even after it is permissible to remove the splint for exercise or self-care, the patient is advised to continue to wear the splint at night for protection for up to 6 weeks.[6,51] If there was a preoperative flexion contracture, an adjustable splint that maintains the elbow in extension is worn periodically during the day for a prolonged stretch, and a static (resting) splint is worn at night to hold the arm in a comfortably extended position. This regimen may be followed for 8 to 12 weeks postoperatively to prevent recurrence of the contracture.[51,58,61]

Exercise Progression

The progression of a postoperative exercise program after TEA varies considerably based on many factors. Key factors and their impact on postoperative rehabilitation are identified in Table 18.3.[6,22,51,91] The rehabilitation process proceeds most rapidly when a triceps-sparing approach is used to insert a linked replacement in a patient whose incision is healing well.

TABLE 18.3 Factors That Influence the Progression of Exercise After Total Elbow Arthroplasty

Factors	Impact on Rehabilitation
▪ Design of prosthesis: linked/semiconstrained vs. unlinked/resurfacing	▪ Earlier ROM and use of the operated upper extremity for light ADL with linked/semiconstrained replacements, which typically do not require ligament repair for joint stability ▪ More protected, controlled motion during exercise and delayed use for ADL with unlinked/resurfacing replacements, which typically require repair of supporting ligaments for stability
▪ Surgical approach: triceps-sparing vs. triceps-splitting or triceps-reflecting	▪ Initial postoperative ROM permissible through a greater range of flexion and earlier active antigravity elbow extension, low-load resistance exercise, and light ADL with triceps-sparing approach
▪ Preoperative and postoperative status of supporting ligaments of the elbow	▪ Earlier and less protected motion during exercise, less protected use during ADL, and less time in splint during the day and at night if ligaments were intact preoperatively and did not undergo a release and repair during arthroplasty
▪ Wound healing	▪ Longer duration of immobilization of the elbow in an extension splint or delayed end-range flexion if posterior skin quality is poor and healing of the incision is likely to be delayed
▪ Ulnar neuropathy	▪ May require extended immobilization in an extension splint or delay of exercises to regain elbow flexion
▪ Surgical release of a preoperative elbow flexion contracture	▪ May require use of extension splint at night for a prolonged period of time

On the other end of the spectrum, in which rehabilitation must progress most cautiously, is the use of a triceps-reflecting approach for an unlinked replacement, requiring release and repair of the lateral ligament complex in a patient with poor skin quality.

Just as the progression of exercise is based on the unique features of each patient's surgery, precautions are determined in a similar manner. It is particularly important for the therapist to know the status of repaired soft tissues to incorporate the necessary precautions into the exercise program. Information in the operative report and close communication with the surgeon are the best sources for these details. Specific precautions for exercise and functional use of the operated upper extremity are summarized in Box 18.6.[6,11,51,58,75,91] Patient education about these precautions should occur throughout the rehabilitation program. A patient's adherence to precautions ensures more positive outcomes and lessens the likelihood of short- or long-term postoperative complications related to exercise and use of the operated arm for functional activities.

Exercise: Maximum Protection Phase

The focus during the first phase of rehabilitation, which extends approximately over a 4-week period, includes control of inflammation, pain, and edema with use of medication as needed, application of cold and regular elevation of the operated arm. Emphasis is also placed on careful inspection of the wound, protection of repaired soft tissues as they begin to heal, and early ROM exercises to offset the adverse effects of immobilization without jeopardizing the stability of the prosthetic joint. Assisted ROM as tolerated and within the ranges achieved intraoperatively typically is initiated 2 to 3 days after linked TEA and a few days later after unlinked TEA if the elbow is stable.[6,51,91]

CLINICAL TIP

If there was significant preoperative instability of the elbow or if the repair of ligaments released during surgery is in question, elbow ROM typically is delayed for more than a week. When motion is initiated, the patient may need to wear a hinged splint for 4 to 5 weeks that allows only flexion and extension and restricts rotation of the forearm.[6,51]

Goals and interventions. The goals and exercise interventions during this first phase include the following.[6,19,25,48,51,58,61,91]

- ***Maintain mobility of the shoulder, wrist, and hand.***
  - Active ROM of these regions during the immediate postoperative period. This is particularly important for the patient with RA or JRA involving these joints.
- ***Regain motion of the elbow and forearm.***
  - After a linked TEA or if the elbow is stable after an unlinked TEA, start with gentle self-assisted elbow flexion/extension and pronation/supination with the elbow comfortably flexed and the forearm in mid-position, progressing to active ROM as tolerated. As acute symptoms subside, have the patient maintain the end-range position to apply a very low-intensity stretch.
  - If the triceps mechanism was reflected and repaired, limit assisted flexion to 90° to 100° for the first 3 to 4 weeks to avoid excessive stretch on the repaired triceps tendon. Perform active elbow flexion/extension in a seated or standing—rather than supine—position for the same time frame to avoid antigravity extension, which also could cause excessive stress to the reattached triceps mechanism and subsequent insufficiency.[6,19,51]

BOX 18.6 Specific Precautions After Total Elbow Arthroplasty

ROM Exercise

- Perform ROM exercises only within the arc of motion achieved during surgery.
- To reduce postoperative stress on a repaired triceps mechanism, avoid end-range flexion during assisted ROM and active, antigravity elbow extension for 3 to 4 weeks.
  - Also avoid early, end-range elbow flexion to decrease stress on the incision and reduce the risk of compromising wound healing.[75]
- If elbow stability is questionable after an unlinked TEA, limit full extension of the elbow and rotation of the forearm, particularly supination past neutral, to avoid overload on repaired lateral ligaments for 4 weeks. With an unlinked replacement, the greatest risk of instability is when the elbow is extended beyond 40° to 50°.[6]
- If symptoms of ulnar nerve compression are noted, avoid prolonged positioning or stretching into end-range flexion.[2,12]

Strengthening Exercises

- Postpone resisted elbow extension for 6 weeks (or as long as 12 weeks) if a triceps-reflecting approach was used.
- When strengthening the shoulder, apply resistance above the elbow to eliminate stresses across the elbow joint.
- Weight training using moderate and high-loads is not appropriate after TEA.

Functional Activities

- Avoid lifting or carrying any objects with the operated extremity for 6 weeks or objects greater than 1 lb for 3 months.
- If the triceps mechanism was detached and repaired, avoid pushing motions, including propelling a wheelchair, pushing up from a chair, and using a walker, crutches (other than forearm platform design), or a cane, for at least 6 weeks or as long as 3 months.
- If an unlinked replacement was implanted, do not lift weighted objects during daily tasks with the elbow extended to avoid shear forces across the lateral ligament repair, which could contribute to posterolateral instability.
- Limit repetitive lifting to 1 lb for the first 3 months, 2 lb for the first 6 months, and no more than 5 lb thereafter. Never lift more than 10 to 15 lb in a single lift.[6,22,48,51,61]
- Do not participate in recreational activities, such as golf, volleyball, and racquet sports, that place high-loads or impact across the elbow.

While sitting and standing, elbow extension is gravity-assisted; extension is controlled by an eccentric contraction of the elbow flexors.
- If a linked replacement was implanted using a triceps-sparing approach, there is little to no risk of early postoperative instability or disruption of the triceps mechanism. Therefore, active ROM in all planes of motion is permissible immediately.

NOTE: Some sources recommend that after linked arthroplasty involving a triceps-reflecting approach—and if secure reattachment of the triceps tendon was achieved—ROM exercises progress as tolerated without restriction.[31,61]

- ***Minimize atrophy of upper extremity musculature.***
  - Gentle, pain-free muscle-setting exercises of elbow musculature (against no resistance) while in the splint and later, multiple-angle setting exercises when the splint can be removed.
  - Low-intensity, isometric resistance exercises of the shoulder, wrist, and hand.
  - Use of the hand for light functional activities as early as 1 to 2 weeks postoperatively if a linked replacement was inserted but several weeks later after an unlinked TEA.[58,61]

Exercise: Moderate and Minimum Protection Phases

By about 4 to 6 weeks postoperatively, soft tissues have healed sufficiently to withstand increasing stresses. By 12 weeks, barring complications, only minimum protection is necessary; therefore, a patient typically can resume most functional activities with some imposed restrictions (see Box 18.6). However, the recommended timeline for return to a reasonably full level of activity varies from 6 weeks[22,48,58] to 3 to 4 months.[6,25,51]

Goals and interventions. The focus of rehabilitation during the intermediate and final phases is to improve ROM to the extent achieved intraoperatively, regain strength and endurance of elbow musculature, and use the operated arm for gradually demanding functional activities. However, these goals must be reached without disrupting repaired soft tissues and compromising the stability of the prosthetic elbow. Strength and muscular endurance usually continue to improve up to 6 to 12 months postoperatively by cautious use of the operated arm for functional activities.

Patient education, especially with regard to the resumption of functional activities, is ongoing until the patient is discharged from therapy. The following goals and interventions are added during the moderate and minimum protection phases of rehabilitation.[6,25,51]

- ***Increase ROM of the elbow.***

NOTE: It is the opinion of the authors that use of joint mobilization techniques to increase ROM of the elbow or forearm is inappropriate after TEA, particularly with linked implants or if the stability of the elbow is questionable. If selected as a stretching technique, it should be implemented only after specific consultation with the surgeon to determine its appropriateness. It is a more prudent choice to forego full elbow motion than to jeopardize the stability of the joint.

  - Low-intensity, manual self-stretching.
  - Low-load, long-duration dynamic splinting,[13,38,51,83] as described and illustrated in Chapter 4 (see Fig. 4.13), or alternating use of static splints, each fabricated in maximum but comfortable extension and flexion.

PRECAUTIONS: Emphasize end-range extension before end-range flexion to protect the posterior capsule and the triceps mechanism. If symptoms of cubital tunnel syndrome are present (aching along the medial forearm and hand, paresthesia, or hyperesthesia due to compression or entrapment of the ulnar nerve), avoid prolonged or repeated end-range positioning or stretching to increase elbow flexion.[2,11]

- ***Regain functional strength and muscular endurance of the operated extremity.***

NOTE: Some sources advocate progressive use of the operated upper extremity to regain strength and muscular endurance rather than an exercise program.[31,48,58,61]

  - Resisted, multiple-angle isometric exercises at 5 weeks if not initiated previously.
  - *Light* ADL (initially <1 lb of weight) performed with the arm positioned along the side of the trunk and the elbow flexed. If a triceps-reflecting approach was used, incorporate activities that require elbow flexion before elbow extension. Initially modify activities to avoid those that require lifting with the elbow extended and pushing motions, such as pushing up from a chair or using a walker, axillary crutches, or a cane.
  - Dynamic, open-chain resistance exercises no earlier than 6 weeks and often later using a light-weight (1 lb) or light-grade elastic resistance. Emphasize gradually increasing repetitions rather than resistance.
  - Repetitive lifting during exercise and functional activities limited to 1 lb for the first 3 months and 2 lb for the next 3 months. Permanently limit repetitive lifting to no more than 5 lb and a single lift to no more than 10 to 15 lb.[6,22,48,51,58,61] (See Box 18.6 for additional restrictions to strengthening exercises and functional activities.)
  - Low-load, closed-chain activities, such as wall push-ups after 6 weeks or later (when the triceps mechanism and posterior capsule have healed).
  - Upper extremity ergometry.

CONTRAINDICATIONS: High-load progressive resistive exercise (PRE), heavy lifting during home- and work-related activities, and recreational activities that place high-loads or impact on the upper extremities (e.g., racquet and throwing sports or golf) are not allowed after TEA. These activities must be permanently avoided to reduce the risk of complications, such as elbow instability, implant loosening, and polyethylene wear.[6,17,25,48,51,61]

Outcomes

Although the results of the early use of TEA during the 1970s were unsatisfactory, improvements in prosthetic design and fixation, surgical techniques, postoperative management, and criteria for patient selection have made this procedure a reliable means for relieving pain, restoring joint stability, improving physical function, and preventing eventual disability.

The outcomes of TEA and postoperative rehabilitation typically are assessed by a combination of patient self-report instruments that address pain relief, function, and quality of life (e.g., the Patient Related Elbow Evaluation form or the Disabilities of the Arm, Shoulder, and Hand [DASH] questionnaire), and physician-administered tools (e.g., the American Shoulder and Elbow Surgeons Questionnaire or the Mayo Elbow Performance Score, which also include measurements of ROM, strength, and specific shoulder and elbow functions).[5] Because of the variety of tools used, direct comparison among studies is often difficult.

Pain relief and patient satisfaction. Complete or nearly complete relief of pain is the most consistently positive and predictable outcome after elbow arthroplasty, occurring in more than 85% to 95% of patients.[20,34,48]

As noted at the beginning of this discussion on TEA, although the indications have broadened over the past four decades, elbow arthroplasty continues to be used most frequently in patients with RA followed by patients with posttraumatic arthritis. Follow-up studies of patients with these and other underlying pathologies who have undergone linked or unlinked TEA indicate an overall high rate of patient satisfaction, with 80% to 100% of patients reporting "good" or "excellent" results after linked[16,34,45,74,77] and unlinked[22,48] TEA.

ROM and functional use of the upper extremity. Improvements in elbow ROM after TEA are less significant than relief of pain. In addition, maintaining stability of the prosthetic elbow postoperatively is a higher priority than gaining full ROM. However, results of most studies of linked[34,45,55,62] and unlinked[81,82] arthroplasty indicate some increase in the arc of elbow extension/flexion and forearm rotation in patients with late-stage posttraumatic,[62,77] rheumatoid,[34,45,81,82] and juvenile[17] arthritis. Anecdotal evidence suggests that most gains are achieved within 6 to 12 weeks but occasionally up to 6 months postoperatively. Patients with little active movement of the elbow because of preoperative instability have exhibited marked improvement of active motion postoperatively.[41,74]

Many resources suggest or report supporting preoperative and postoperative data to show that greater improvement occurs in elbow flexion than extension after TEA.[22,45,48,77,81,82] Some examples of the arc of extension/flexion achieved after TEA are 26° to 131°,[34] 19° to 140°,[45] and 27° to131°.[77] Remember that arcs of 100° (from 30° to 130° of extension/flexion and 50° each of pronation/supination) are necessary for most functional activities.[65] Therefore, in all of these studies, functional ROM for extension and flexion was achieved.

It is important to note that, when reviewing the literature for this summary of outcomes, there were no studies found that compared outcomes after different approaches to rehabilitation.

TEA survival rates. "Survival rate" (the point at which revision arthroplasty is necessary) following current-day TEA appears to depend more on a patient's underlying pathology than on the type of prostheses implanted.[32] Relatively recent long-term studies of patients with RA, for example, have indicated that the survival rate of implants is 94% at a mean of 7.6 years[45] and 92.4% at a minimum of 10 years[34] after linked (semiconstrained) arthroplasty and 87% at a mean of 12 years[82] and 90% at 16 years[81] after unlinked arthroplasty. Overall prosthetic survivorship rates tend to be lower and the risk of revision arthroplasty higher in patients with posttraumatic arthritis or primary OA than in patients with RA. This may be because of generally higher activity levels—and therefore, greater loads placed across the elbow—in those with posttraumatic arthritis than in those with inflammatory disease.[30,88]

Regardless of underlying pathology, the survival rates are dramatically better for contemporary designs than those for the early, constrained implants in which upward of 70% failed within 10 years and are even better than the 82% survival rate of 5.5 years reported in an analysis of studies published worldwide from 1986 to 1992.[35] There is general consensus that for the best long-term results, a patient must be selective in the type of work-related or recreational activities performed, modifying some activities and eliminating those that impose high-loads and high impact on the elbow.

As with all types of total joint arthroplasty, TEA survival rates deteriorate over time regardless of underlying pathology, type of implant, and the extent of stress placed on the elbow. For example, in a large follow-up study of patients who underwent TEA between 1995–2005, the survival rates of the implants were 92% and 85% at 5 and 10 years respectively regardless of patient's underlying diagnosis or if a semiconstrained or nonconstrained prosthetic design was used.[30]

Myositis Ossificans

The terms *myositis ossificans* and *heterotopic* or *ectopic bone formation* are often used interchangeably to describe the formation of bone in atypical locations of the body. Some resources[39,54,57] use the term myositis ossificans to denote only ossification of muscle. More often, the term is used generally to characterize heterotopic bone formation in the muscle-tendon unit, capsule, or ligamentous structures. In this text,

the terms myositis ossificans and heterotopic bone formation are used synonymously.

Etiology of Symptoms

Although not a common phenomenon, the sites most frequently involved are the elbow region and thigh. In the elbow, heterotopic bone formation most often develops in the brachialis muscle or joint capsule as the result of trauma, such as a comminuted fracture of the radial head, a fracture-dislocation (supracondylar or radial head fracture) of the elbow, or a tear of the brachialis tendon.[23,39,57,59] Patients with neurological impairments, specifically traumatic brain injury or spinal cord injury, and patients with burns to the extremities are also prone to develop this complication.[57] It also may develop as the result of aggressive stretching of the elbow flexors after injury and a period of immobilization.[23]

Myositis ossificans is distinguished from traumatic arthritis of the HU joint in that passive extension is more limited than flexion; resisted elbow flexion causes pain; flexion is limited and painful when the inflamed muscle is pinched between the humerus and ulna; and resisted flexion in mid-range causes pain in the brachialis muscle. Palpation of the distal brachialis muscle is tender.[23,39] After the acute inflammatory period, heterotopic bone formation is laid down in muscle between, not within, individual muscle fibers or around the joint capsule within a 2- to 4-week period. This makes the muscle extremely firm to touch. Although this condition can permanently restrict elbow motion, in most cases, the heterotopic bone, is largely reabsorbed over several months, and motion usually returns to near normal.[54]

Management

Massage, passive stretching, and resistive exercise are contraindicated if the brachialis muscle is implicated after trauma. The elbow should be kept at rest in a splint, which should be removed only periodically during the day for active, pain-free ROM. Rest should continue until the boney mass matures and then resorbs. If the capsule also is involved, surgical excision of heterotopic bone from muscle or TEA is necessary only in rare instances.[54,57]

Overuse Syndromes: Repetitive Trauma Syndromes

Overuse can occur in any musculotendinous structure in the elbow region, including the flexors and extensors of the elbow, but it most commonly occurs in the muscles attached to the lateral or medial epicondyles in response to repetitive stressful wrist motions. Problems anterior or posterior to the elbow frequently are caused by excessive extension or flexion strain in sporting activities.[4] Discussion in the literature as to whether overuse syndromes have an inflammatory component or are primarily degenerative in response to repetitive trauma lead to questions on use of terminology.[27,46,85]

Overuse of the medial and lateral musculotendinous structures causing microscopic tears and inflammation is commonly termed *epicondylitis* (medial and lateral epicondylitis), and overuse of the distal biceps and triceps tendons is called tendonitis.[23,85] *Tendinosis* or *tendinopathy* refers to degenerative changes in the collagen tissue without signs of inflammation. These changes include immature fibroblastic and vascular elements and weakening of the tendinous structure.[27,85]

Related Pathologies

Lateral Elbow Tendinopathy (Tennis Elbow)

Tennis elbow is commonly called lateral epicondylitis, lateral epicondylalgia, or lateral epicondylosis depending on whether inflammation is present or not.[79,85] Symptoms include pain in the common wrist extensor tendons along the lateral epicondyle and HR joint with gripping activities. Activities requiring firm wrist stability, such as the backhand stroke in tennis, or repetitive work tasks that require repeated wrist extension, such as computer keyboarding or pulling weeds in a garden, can stress the musculotendinous unit and cause symptoms. The most frequent location of involvement is in the musculotendinous junction of the extensor carpi radialis brevis,[23,26,27,39,69,85] although the extensor communis is also involved in many patients.[27] Symptoms also occur when the annular ligament is stressed.

Positive tests of provocation include palpation tenderness on or near the lateral epicondyle, pain with resisted wrist extension performed with the elbow extended, pain with resisted middle finger extension performed with the elbow extended, and pain with passive wrist flexion with the elbow extended and forearm pronated.[23,89]

NOTE: Pulled elbow, pushed elbow, rotated elbow, radial head fracture, pinched synovial fringe,[68] meniscal lock, radial tunnel syndrome, tendinosis,[46] and periosteal bruise are also possible sources of pain at the elbow and are sometimes erroneously called tennis elbow.[49]

Medial Elbow Tendinopathy (Golfer's Elbow)

Golfer's elbow, also known as medial epicondylitis, medial epicondylalgia, or medial epicondylosis, involves the common flexor/pronator tendon at the tenoperiosteal junction near the medial epicondyle. It is associated with repetitive movements into wrist flexion, such as swinging a golf club, pitching a ball, or work-related grasping, shuffling papers, and lifting heavy objects. Concomitant ulnar neuropathy is often an associated finding.[33,39]

Positive tests of provocation include palpation tenderness on or near the medial epicondyle, pain with resisted wrist flexion performed with the elbow extended, and pain with passive wrist extension performed with the elbow extended.

Etiology of Symptoms

The most common cause of epicondylalgia is excessive repetitive use or eccentric strain of the wrist or forearm muscles. The result is microdamage and partial tears, usually near the musculotendinous junction when the strain exceeds the strength of the tissues and when the demand exceeds the repair process. Initially there may be signs of inflammation followed by the formation of granulation tissue and adhesions.[69] With repetitive trauma, fibroblastic activity and collagen weakening occurs. Recurring problems are seen because the resulting immobile or immature scar is re-damaged when returning to activities before there is sufficient healing or mobility in the surrounding tissue.

Hypersensitivity over the radial and ulnar nerves has been reported to occur in women with lateral epicondylalgia, indicating a possible link between mechanical irritation and nerve sensitization.[29]

Common Structural and Functional Impairments

- Gradually increasing pain in the elbow region after excessive activity of the wrist and hand
- Pain when the involved muscle is stretched or when it contracts against resistance
- Decreased muscle strength and endurance for the demand
- Decreased grip strength, limited by pain
- Tenderness with palpation at the site of inflammation, such as over the lateral or medial epicondyle, head of the radius, or in the muscle belly

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- Inability to participate in provoking activities, such as racket sports, throwing, or golf.
- Difficulty with repetitive forearm/wrist tasks, such as sorting or assembling small parts, typing on a keyboard or using a computer mouse, gripping activities, using a hammer, turning a screwdriver, shuffling papers, or playing a percussion instrument.

Nonoperative Management of Overuse Syndromes: Protection Phase

Utilize the following management guidelines and interventions when signs of acute or chronic inflammation are present.

Decrease Pain, Inflammation, Edema, or Spasm

- ***Immobilization.*** Rest the muscles by immobilizing the wrist in a splint such as a cock-up splint in which the elbow and fingers are free to move.
- ***Patient instruction.*** Instruct the patient to avoid all aggravating activities, such as strong or repetitive gripping actions.
- ***Cryotherapy.*** Use ice to help control edema and swelling.

Develop Soft Tissue and Joint Mobility

- ***Multiple-angle muscle setting (low-intensity isometrics).*** Have the patient remove the splint several times a day and perform gentle multiple-angle setting techniques to the involved muscle followed by ROM within the pain-free range.
  - ***Technique for wrist extensor muscles.***

Patient position and procedure: Sitting with the elbow flexed, forearm pronated and resting on a table, and the wrist in extension. Begin with gentle isometric contractions with the wrist extensors in the shortened position. Resist wrist extension, hold the contraction to the count of 6, relax, and repeat several times; then move the wrist toward flexion and repeat the isometric resistance. Do not move into the painful range or provide resistance that causes a painful contraction.

When full wrist flexion is obtained without pain in the lateral epicondyle region, progress by placing the elbow in greater degrees of extension and repeat the isometric resistance sequence to the wrist extensors. Progress until gentle resistance can be applied to the wrist extensors in the position of elbow extension and wrist flexion. It may take several weeks to reach this position.

- ***Technique for wrist flexor muscles.***

Patient position and procedure: Sitting with the elbow flexed, forearm resting on a table, and the wrist in flexion. Begin with gentle isometric contractions with the wrist flexors in the shortened position. Resist wrist flexion, hold the contraction to the count of 6, relax, and repeat several times; then move the wrist toward extension and repeat the isometric resistance. Do not move into the painful range or provide resistance that causes a painful contraction.

When full wrist extension is obtained without pain in the medial epicondyle region, progress by placing the elbow in greater degrees of extension and supination and repeat the isometric resistance sequence to the wrist flexors. As stated above, it may take several weeks to reach the full range of elbow extension, forearm supination, and wrist extension and to be able to tolerate gentle resistance.

- ***Cross-fiber massage.*** Apply gentle cross-fiber massage within tolerance at the site of the lesion. Teach the patient to self-administer the submaximal isometric and cross-fiber massage techniques in a home exercise program.
- ***Neuromobilization.*** If increased symptoms occur with nerve tension testing, use neuromobilization techniques as described in Chapter 13.

Maintain Upper Extremity Function

- ***Active ROM.*** Have the patient perform ROM to joints not immobilized to maintain the integrity of the rest of the upper extremity.

- ***Resistive exercises.*** Have the patient perform shoulder and scapular ROM and stabilization exercises with resistance applied proximal to the elbow.

Nonoperative Management: Controlled Motion and Return to Function Phases

Utilize the following management guidelines and interventions when there are no signs of inflammation.

Increase Muscle Flexibility and Scar Mobility

- ***Manual stretching techniques.*** Use agonist contraction, hold-relax, and passive stretching techniques to elongate the tight muscle to the end of its range (principles for application of these techniques are described in Chapter 4). Use an intensity of muscle contraction and stretch that causes a stretching sensation but not increased pain.
  - For both the wrist flexors and wrist extensors, the elbow must be extended.
  - To stretch the wrist extensors, pronate the forearm, flex and ulnarly deviate the wrist, and flex the fingers.
  - To stretch the wrist flexors, supinate the forearm, extend and radially deviate the wrist, and extend the fingers.
- ***Self-stretching techniques.*** The patient may use a wall (see Fig. 18.10) and slide the hand along the wall until a stretch force is experienced, or the patient may use the opposite hand to apply the stretch force. These techniques are described in the self-stretching section later in the chapter.
- ***Cross-fiber (friction) massage.*** Palpate to localize the scar, and then apply pressure and cross-fiber massage. Increase the intensity of massage as tolerated.

Restore Joint Tracking at the RU Joint

- ***Mobilization with movement (MWM).*** These techniques are used to restore normal tracking of the radius on the capitulum, so the forearm muscles can be strengthened without painful symptoms.[66] Several researchers have reported decreased pain and increased grip strength during or shortly after MWM at the elbow.[55,86,87] One researcher observed decreased shoulder rotation in patients with lateral epicondylalgia and demonstrated significant improvement in shoulder range after MWM at the elbow. He proposed that the mechanism was mediated neurophysiologically.[1] Refer to Chapter 5 for principles of application. The following techniques are used if the patient experiences pain when making a fist or with resisted wrist extension.
  - *Patient position and procedure:* Supine with the forearm pronated. Place a mobilization belt around the patient's proximal forearm and across your shoulders and stabilize the distal humerus with one hand. Apply a lateral glide to the forearm through the belt and then have the patient do repeated wrist extension against manual resistance applied by your other hand (Fig. 18.6 A).
  - *Alternative method:* Apply the lateral glide force against the proximal forearm with your distal hand and have the patient do repeated gripping by squeezing a ball or inflatable bulb (Fig. 18.6 B). Both the lateral glide force and the muscle contraction must be pain-free.
  - ***Self-MWM.*** The patient stands with the humerus of the involved elbow stabilized against a doorframe and the forearm in the opening and then applies lateral glide force against the proximal forearm with the contralateral hand. The patient then does repetitive gripping or squeezing against a resistive force, such as a pneumatic bulb or squeezable ball (Fig. 18.6 C).

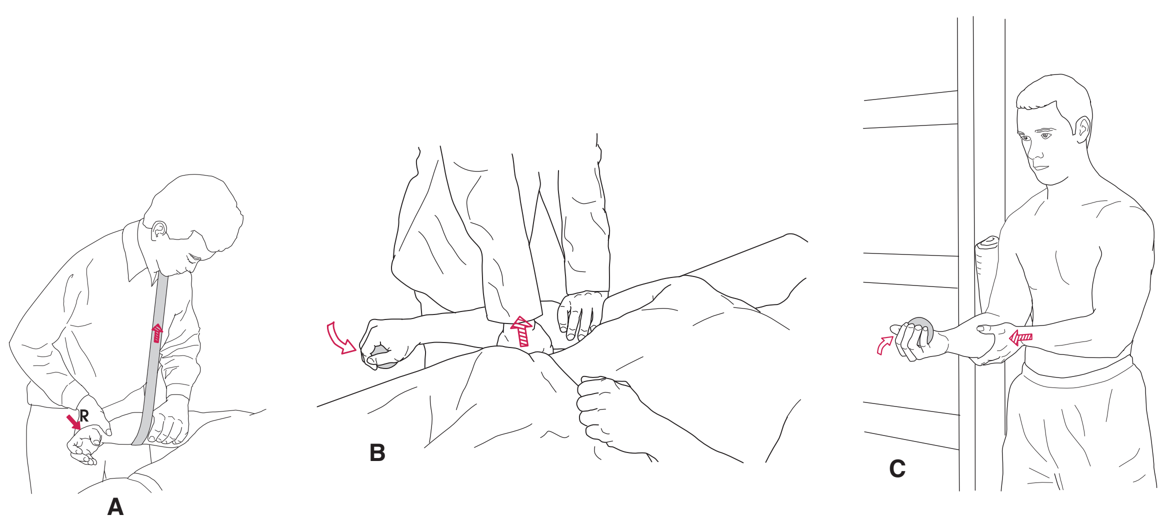

FIGURE 18.6 MWM for lateral epicondylitis. Lateral glide is applied to the proximal forearm **(A)** with resistance added to wrist extension, **(B)** with patient squeezing a ball to bring in the wrist extensors, and **(C)** with self-treatment.

Improve Muscle Performance and Function

- ***Counter force elbow sleeve or strap.*** Use an elbow orthosis to help reduce the load on the musculotendinous unit. This type of orthosis has been shown to have the immediate effect of improving pain-free grip strength in individuals with lateral epicondylosis.[42]
- ***Isometrics.*** Progress the isometric exercises by applying resistance in various pain-free positions with emphasis on the lengthened position.
- ***Dynamic resistance exercise.*** Progress to dynamic exercises against manual or elastic resistance or free weights through pain-free ranges. Initially, use low-intensity resistance with multiple repetitions for muscular endurance, then progress to more intense resistance to strengthen the muscles in preparation for functional demands.
  - ***Eccentric training:*** Incorporate a progression of eccentric contractions of the involved musculotendinous unit, first within a comfortable wrist ROM against a low-intensity load, at a slow speed, and preferably with the elbow in a relatively extended position.[79] Use of an isokinetic dynamometer enables the patient to perform repetitive, eccentric-only contractions.[19] If elastic resistance or a free weight is used, have the patient lift the weight or lengthen the elastic band with the sound hand when returning to the starting position of wrist extension.[52]
  - ***Progressions:*** Progress to faster speeds before increasing the resistance. When resistance is increased, return to a slow speed and then again work up to a faster speed before increasing the resistance and so on. Gradually perform the eccentric contractions through a full, pain-free ROM.

FOCUS ON EVIDENCE

Eccentric resistance training (typically combined with a program of static stretching) often is recommended in the literature and implemented in the clinical setting to reduce pain associated with epicondylalgia/epicondylitis of the elbow, improve grip strength, and gradually restore physical functioning of the upper extremity. Although there is evidence demonstrating positive changes over time for patients participating in eccentric strengthening programs, these studies typically do not include control groups or direct comparisons of different treatment approaches.[19,27] Furthermore, if provided, details about the eccentric training programs often are limited or vary considerably from study to study, making it difficult to replicate the training programs. Consequently, the results of a systematic literature review[92] indicated that there is insufficient evidence from high-quality studies (prospective randomized trials) at this time to support the efficacy of eccentric exercise for management of elbow epicondylalgia compared with other active exercise interventions, such as a program of concentric training. The need for more well-designed studies is consistently emphasized.

- ***Functional patterns.*** As flexibility and strength improve and the pain is brought under control, incorporate functional training, utilizing functional patterns into the exercises. Emphasize control of the resistance through the pattern. If pain or deviation of the pattern with substitute motions occurs, have the patient rest before resuming additional repetitions. Exercises simulating the desired activity are progressed from slow, controlled motions to high speeds with low resistance to improve timing (see Fig. 18.22).
- ***General strengthening and conditioning.*** Incorporate any unused or underused part of the extremity or trunk into the training program prior to returning to the stressful activity.[27,90]
- ***Plyometric exercises.*** Add plyometrics to the program if the patient's goals include returning to sports or occupational activities that require elbow and forearm power. Suggestions include the following and are described and shown in Chapter 23.[27,90]
  - Dribbling a weighted ball against the wall or the floor
  - Flipping and catching a weighted ball
  - Bouncing a tennis ball on a short-handled racquet, progressing to a long-handled racquet
  - Rapid eccentric/concentric elbow and forearm motions against elastic resistance
  - Rapid chest passes or overhead passes using a weighted plyometric ball
- ***Activity modification.*** It may be necessary to modify the patient's activity or technique before he or she returns to the repetitive or stressful activity. For example, it may require taking tennis lessons to correct improper tennis techniques, adapting use of a hammer or other equipment, or making ergonomic modifications of a computer workstation.[26,27,39,69,89]

NOTE: Information on ergonomic recommendations for computer workstations are described in Chapter 14.

Patient Education

- Education includes advice and techniques on prevention, recognition of provoking factors, and identification of warning symptoms.
- Teach the patient how to reduce the overload forces that caused the problem and retrain the patient in proper techniques.[26,27,39]
- In addition to exercises, include home instructions on the application of friction massage and stretching the involved muscle prior to using it.

FOCUS ON EVIDENCE

In a descriptive study of 60 subjects with lateral epicondylalgia who were followed for 6 months after initiating physical therapy intervention, Waugh and associates[89] reported that 80% of the participants continued to improve, but only 33% had complete resolution of symptoms. The therapy intervention consisted of 8 weeks of ultrasound, deep transverse friction massage, and a stretching/strengthening program for the wrist extensor muscles; 37% of the participants also received

treatment for the cervical spine or shoulder. Altogether, 50% continued with some form of therapeutic intervention after the initial 8 weeks. Those with poorer outcomes had repetitive work duties, with 92% of the repetitive duties involving computer work.

This study also reported that women who have positive cervical signs as well as repetitive job duties involving computer usage had a poorer prognosis. This was observed at both 8 weeks and 6 months. Ergonomic recommendations for postural adaptations when using a computer included having forearm support, smooth movements, and relaxed shoulders.[89]

Exercise Interventions for the Elbow and Forearm

Exercise Techniques to Increase Flexibility and Range of Motion

Prior to initiating a muscle stretching program, be sure the joint capsule is not restricting motion. Techniques to increase joint play in the elbow and forearm articulations are discussed earlier in the chapter. Principles and techniques for applying joint mobilization techniques are presented in Chapter 5.

In addition to the description of principles and techniques of stretching presented in Chapter 4, manual, mechanical, and self-stretching techniques directed to the elbow are described in this section. When teaching the patient self-stretching, emphasize the importance of maintaining a low-intensity, prolonged stretch and not applying a ballistic stretch force (bouncing at the end of the range).

Manual, Mechanical, and Self-Stretching Techniques

To Increase Elbow Extension

CLINICAL TIP

Of the three muscles that flex the elbow, only the biceps brachii crosses the shoulder; it also rotates the forearm. Therefore, to fully elongate the biceps brachii, the shoulder must be extended and forearm pronated in addition to extending the elbow.

Mechanical Stretch: Mild Flexion Contracture

Patient position and procedure: Supine with the arm supported on the treatment table and a folded towel under the distal humerus as a fulcrum. Place a cuff weight around the distal forearm. Position the forearm in pronation, mid-position, and then supination to affect each of the three flexor muscles. Have the patient stabilize the proximal humerus with the other hand or place a sandbag or belt across the proximal humerus to stabilize it. Instruct the patient to maintain the stretch for an extended period of time.[90]

Self-Stretch: Mild Flexion Contracture

Patient position and procedure: Sitting with arm supported on the treatment table and a folded towel under the distal humerus as a fulcrum. Using the opposite hand, have the patient apply the stretch force against the distal forearm positioned in pronation, mid-position, and then supination to affect each of the flexor muscles.

Mechanical Stretch: Dynamic Splinting

Apply a low-intensity, long-duration mechanical stretch force with a dynamic splint to reduce a long-standing elbow flexion contracture by affecting the soft tissue properties of creep and stress-relaxation.[13,38]

FOCUS ON EVIDENCE

Ulrich and colleagues[83] carried out a prospective study to investigate the effectiveness of a patient-directed stretching program based on the principles of static progressive stretch and stress-relaxation (see Fig 4.7 B) with 37 patients (37 elbows) with posttraumatic contractures of the elbow. Patients with any degree of heterotopic bone formation were excluded from the study. Patients performed a 30-minute stretching protocol one to three times per day in a dynamic elbow orthosis over a period of time (mean, 10 weeks; range, 2 to 25 weeks). The intensity of the stretch was controlled by the patient.

At the conclusion of the study, the mean gain in overall elbow ROM was significant (26°, range 2° to 60°) as were gains in range of elbow flexion and extension individually. Prior to the splinting program, overall elbow ROM was 81° and 107° at the conclusion of the program. During the course of the study, overall patient satisfaction was good, and no patients required anti-inflammatory medication. The authors concluded that daily use of a dynamic splint and applying the principles of stress-relaxation over a relatively short period of time was an effective means of increasing elbow ROM.

Manual Stretch: Biceps Brachii

Patient position and procedure: Prone with the elbow in end-range but comfortable extension and forearm in pronation. Stabilize the scapula and passively extend the shoulder.

Mechanical Stretch: Biceps Brachii

Patient position and procedure: Supine with a cuff weight around the distal forearm and the elbow in extension and forearm in pronation. Have the patient stabilize the proximal

humerus with the opposite hand and then place the arm over the side of the table. Allow the elbow and shoulder to extend as far as possible and sustain the stretch position for an extended period of time (Fig. 18.7 A).

Self-Stretch: Biceps Brachii

Patient position and procedure: Standing at the side of a table. Have the patient grasp the edge of the table and walk forward, causing shoulder extension with elbow extension (Fig. 18.7 B). It is important to note that this stretching position does not include forearm pronation.

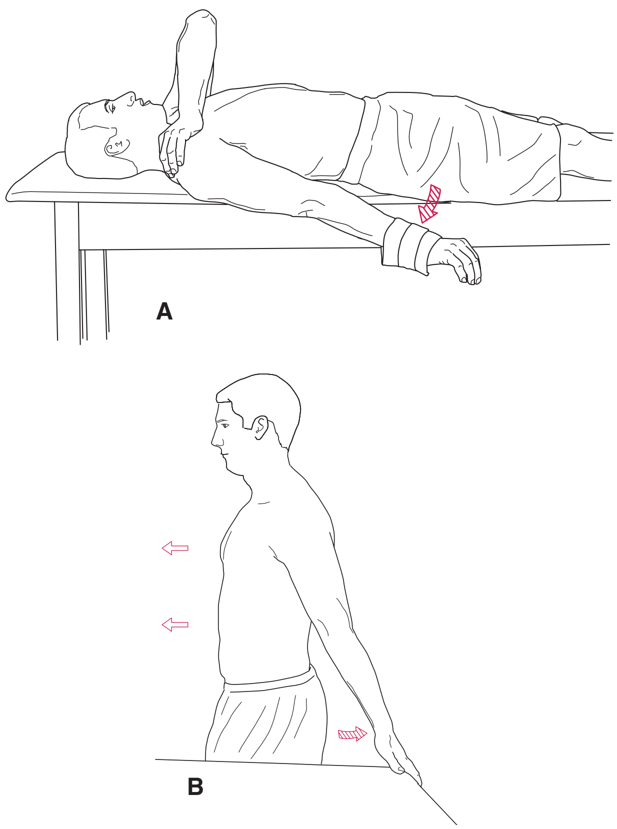

FIGURE 18.7 Self-stretching the biceps brachii musculotendinous unit includes stretching the long head across the shoulder joint **(A)** supine and **(B)** standing.

To Increase Elbow Flexion

Self-Stretch: Mild Extension Contracture

- *Patient position and procedure:* Prone-lying and propped up on elbows with forearms resting on the exercise mat. Have the patient lower the chest as far as elbow flexion allows and maintain the position as long as tolerated.
- *Patient position and procedure:* Sitting with elbow flexed as far as possible. Have the patient press against the distal forearm with the opposite hand to provide the stretch force into flexion. Alternatively, with the forearm supported on a table or arm rest of a chair, have the patient lean forward flexing the humerus against the stabilized forearm and maintaining the position as long as tolerated.

Self-Stretch: Long Head of Triceps

Patient position and procedure: Sitting or standing. Have the patient flex the elbow and shoulder as far as possible. The other hand can either push on the forearm to flex the elbow, or push the shoulder into more flexion (Fig. 18.8). Hold the stretch position as long as tolerated.

FIGURE 18.8 Self-stretching the triceps brachii musculotendinous unit includes stretching the long head across the shoulder joint.

To Increase Forearm Pronation and Supination

Patient position: Sitting with the elbow flexed to 90° and the elbow resting on a padded table or stabilized against the side of the trunk.

Self-Stretch to Increase Pronation

Have the patient grasp the dorsal surface of the involved forearm so the heel of the uninvolved hand is against the dorsal aspect of the radius just proximal to the wrist and so the fingers wrap around the ulna. Then have the patient pronate the forearm and sustain the stretch as long as tolerated. The force is applied against the radius, so there is no trauma to the wrist.

Self-Stretch to Increase Supination

Have the patient place the heel of the uninvolved hand against the volar aspect of the involved radius just proximal to the wrist, supinate the forearm, and sustain the stretch as long as tolerated (Fig. 18.9).

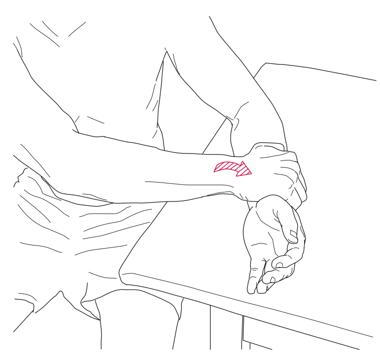

FIGURE 18.9 Self-stretching the forearm into supination. It is important that the stretch force is against the radius, not the hand.

Self-Stretching Techniques: Muscles of the Medial and Lateral Epicondyles

To Stretch the Wrist Extensor Muscles (From the Lateral Epicondyle)

- *Patient position and procedure:* Sitting or standing with the elbow extended and forearm pronated. While holding this position have the patient ulnarly deviate the wrist and flex the wrist and fingers; then apply a gentle stretch force against the dorsum of the hand. The patient should feel a stretching sensation along the lateral epicondyle or proximal forearm.
- *Patient position and procedure:* Standing with elbow extended, forearm pronated, and back of the hand against a wall (fingers pointing down). Have the patient then slide the back of the hand up the wall (Fig. 18.10). For additional stretch, have the patient actively flex the fingers.

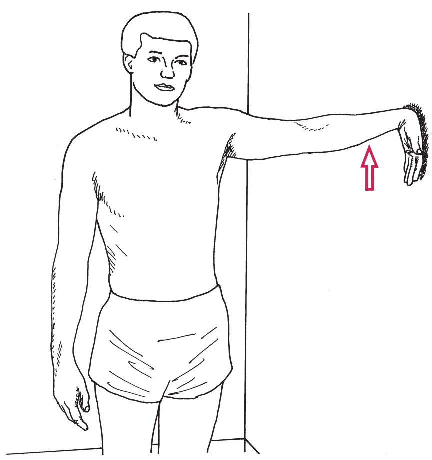

FIGURE 18.10 Self-stretching of the muscles of the lateral epicondyle.

To Stretch the Wrist Flexor Muscles (from the Medial Epicondyle)

- *Patient position and procedure:* Sitting or standing with the elbow extended and forearm supinated. While holding this position, have the patient radially deviate and extend the wrist and apply a gentle stretch force with the other hand against the palm of the hand. A stretch sensation should be felt along the medial epicondyle or proximal forearm.
- *Patient position and procedure:* Standing with the elbow extended and forearm supinated. Have the patient place the palm of the hand against a wall, fingers pointing down, and then move the hand up the wall until a stretch sensation is felt in the wrist flexor muscles.

Exercises to Develop and Improve Muscle Performance and Functional Control

In addition to the conditions already described in this chapter, imbalances in length and strength of muscles crossing the elbow and forearm can be the result of a variety of causes, such as nerve injury or after surgery, trauma, disuse, or immobilization. Appropriate exercises to develop neuromuscular control, increase strength, and improve muscular endurance for return to functional activities can be selected from the following exercises as well as the techniques described in Chapters 6 and 23.

For patients with elbow impairments, exercises for the regions above (shoulder girdle) and below (wrist and hand) also should be incorporated into the therapeutic exercise program to prevent complications and restore proper function of the entire upper quarter. The general principles of managing acute soft tissue lesions are discussed in Chapter 10. The exercises described in this section are for use during the controlled motion and return to function phases of intervention when tissues are in the subacute and chronic stages of healing and require only moderate to minimum protection.

Isometric Exercises

Multiple-Angle Isometric Exercises

Use manual or mechanical resistance at various positions throughout the available ROM of elbow flexion and extension and forearm rotation. Isolate the key musculature. Apply resistance at the distal forearm, not at the hand, to avoid forces across the wrist joints.

Angle-Specific Training

During isometric exercises, emphasize joint positions that simulate use of the elbow for anticipated functional activities. For example, to simulate carrying large boxes close to the chest, strengthen the elbow flexors in a 70° to 90° position with the forearm in mid-position and supination. Emphasize holding objects for extended periods of time to increase muscular endurance for sustained control.

Alternating Isometrics and Rhythmic Stabilization

Open-Chain Exercises

Apply manual resistance to alternating isometric contractions of antagonists at multiple angles of elbow flexion/extension and forearm pronation/supination. Stabilize the humerus and apply the resistance against the forearm.

When the patient is able to respond to the alternating resistance at various elbow and forearm positions and at varying speeds, progress to alternating isometrics using total upper extremity patterns. To further develop stability superimposed on movement (dynamic stability), have the patient hold a vibrating BodyBlade® in various positions of the elbow, forearm, and the entire upper extremity and then during a variety of movements.

Closed-Chain Exercises

Patient positions include standing with hands against a wall or table, in the quadruped position, or in the prone push-up position (with knees or toes as a fulcrum). Have the patient hold the desired elbow position and apply alternating isometrics and rhythmic stabilization by means of manual resistance against the shoulders and trunk.

Dynamic Strengthening and Endurance Exercises

Many muscles that cross the elbow joint are multijoint muscles, such as the biceps, long head of the triceps, and wrist flexors and extensors. It is particularly important to consider the position of the shoulder and forearm during resistance training at the elbow. Dynamic strengthening and endurance activities for the *prime movers* of the elbow, forearm, and wrist using manual or mechanical resistance are noted in this section. Combined patterns of motion during open- and closed-chain activities are described in the final section describing a functional progression for the elbow and forearm.

Elbow Flexion

Muscles include the biceps brachii, brachialis, and brachioradialis.

- *Patient position and procedure:* Sitting or standing, with the humerus at the side of the chest (arm perpendicular to the floor). Have the patient hold a weight or grasp a piece of elastic band or tubing (secured under the foot or to the floor), and flex and extend the elbow. This strengthens the elbow flexors concentrically and eccentrically throughout the available ROM to simulate functional lifting and lowering. Perform this motion with the forearm supinated, pronated, and in mid-position.
- *Patient position and procedure:* Supine or prone, with the humerus supported on a treatment table. When the patient is supine, the resistive force from a free weight or gravity has a greater effect on the muscles near end-range extension and has little to no effect as the elbow reaches 90°. With the patient prone and the forearm over the side of the bed, use a pulley system or elastic resistance to provide resistance to the elbow flexors.
- *Patient position and procedure:* Standing or sitting while holding a weight with the forearm supinated. Have the patient extend the shoulder as the elbow flexes (Fig. 18.11). This combined motion elongates the biceps brachii over the shoulder as the muscle is shortening to move the elbow and thus most efficiently maintains optimal length for development of maximum tension in the *biceps.* This combined motion develops control for carrying objects at the side.

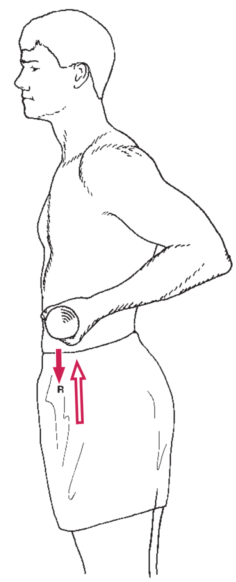

FIGURE 18.11 Resisting elbow flexion with emphasis on the biceps brachii. The shoulder extends as the elbow flexes with the forearm in supination. This combined action lengthens the proximal portion of the musculotendinous unit across the shoulder while it contracts to move the elbow, thus maintaining a more optimal length-tension relationship through a greater ROM.

Elbow Extension

Muscles include the triceps and anconeus.

- *Patient position and procedure:* Prone, humerus abducted to 90° and supported on a rolled towel on a treatment table. Have the patient extend the elbow while holding a weight. This position strengthens the elbow extensors from only 90° of flexion to terminal extension.
- *Patient position and procedure:* Supine with the shoulder flexed 90°, holding a weight in the hand. Have the patient begin with the elbow flexed and the weight either at the ipsilateral or contralateral shoulder (external or internal rotation of the shoulder); then extend and flex the elbow (lift and lower the weight) to strengthen the elbow extensors concentrically and eccentrically. To help maintain the shoulder in a stable position, have the patient stabilize the humerus in the 90° position with the opposite hand.

Long Head of Triceps with Elbow Extension

Patient position and procedure: Sitting or standing with the arm held overhead (shoulder flexed) and elbow flexed so the weight is near the shoulder (Fig. 18.12). Have the patient lift the weight overhead and then lower the weight for concentric and eccentric strengthening. The patient may support the humerus with the opposite hand. Perform this exercise only if the patient has sufficient control of the shoulder.

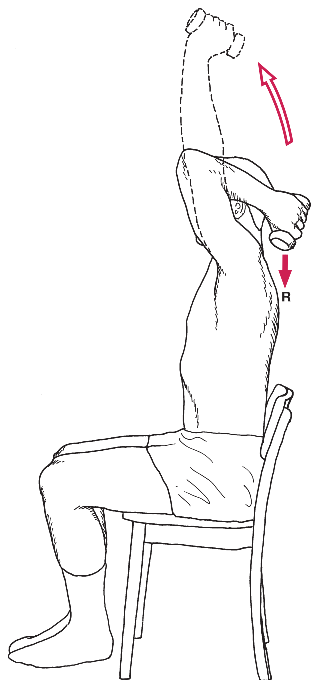

FIGURE 18.12 Resisting elbow extension, beginning with the long head of the triceps brachii on a stretch.

Pronation and Supination

Muscles of pronation are the pronator teres and quadratus; muscles of supination are the supinator and biceps brachii. *Patient position*: Sitting or standing with the elbow flexed to 90°. When sitting, the forearm may be on a table for support.

- ***Free weights.*** When using a free weight to strengthen the pronators and supinators, the weight must be placed to one side or the other of the hand (Fig. 18.13). If a dumb-bell is held, weight is equal on each side of the hand; therefore, one side of the weight is assistive and the other is resistive, in essence canceling out the resistive force. Note also the position of the thumb for each exercise, so it is not lifting the bar. The weight also can be turned through a downward arc by placing the resistance on the ulnar side of the hand.
- ***Elastic resistance.*** Have the patient grasp one end of the elastic resistance with the sound hand, or secure one end by standing on it. Have the patient grasp the other end with the involved extremity and turn the forearm against the resistance. For greater resistance, secure the elastic resistance around the end of a short rod, and have the patient pull against the resistance force.
- ***Functional activity.*** Have the patient stand, facing a door-knob with the arm kept at the side and the elbow flexed to 90° to avoid substituting with shoulder rotation. Have the patient turn the knob.

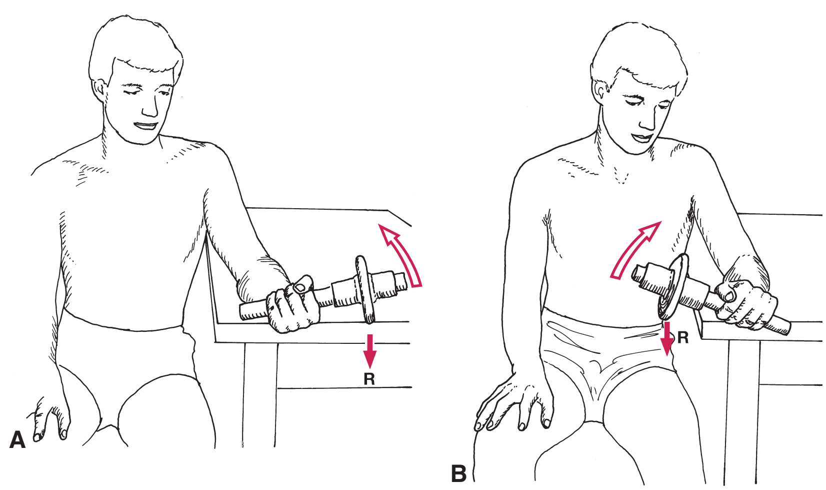

FIGURE 18.13 Mechanical resistance exercise using a small bar with an asymmetrically placed weight for strengthening **(A)** forearm pronators and **(B)** supinators. The bar also can be rotated through a downward arc to affect the other half of the range for each muscle by placing the weight on the ulnar side of the hand.

Wrist Flexion and Extension

Wrist flexion involves muscles of the medial epicondyle; extension involves muscles of the lateral epicondyle.

NOTE: In the following exercises, when the forearm is pronated, resistance is applied to the wrist extensors; when supinated, resistance is applied to the wrist flexors.

- ***Elastic resistance.***

Patient position and procedure: Tie the ends of an elastic band or tubing together. While sitting, have the patient place one end of the loop under one foot. Stabilize the forearm on the thigh and place the other end of the loop across the dorsum (Fig 18.14) or palm of the hand to resist the wrist extensors or flexors respectively. Placing the elastic band in this manner is useful for the patient with epicondylalgia if simultaneous gripping during resisted wrist motions is painful.
Progression: Perform the same resisted wrist motions while grasping one end of the elastic material as simultaneous gripping during resisted wrist motions becomes comfortable.

- ***Free weights.***

Patient position and procedure: Sitting, with forearm resting on a table and hand over the edge of the table holding a small weight (Fig. 18.15). Extend and flex the wrist against the resistance.

- ***Wrist roller.***

Patient position and procedure: Sitting or standing, with the elbows flexed or extended and the forearms pronated or supinated. Tie a 2- to 4-ft cord to the middle of a short rod and a weight to the other end of the cord. Have the patient hold each end of the rod and with an alternating wrist action, turn the rod causing the cord to wind around the rod and elevate the weight. The weight is then lowered with a reverse motion (Fig. 18.16).

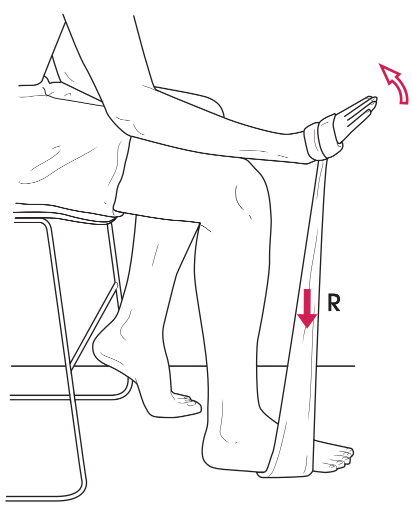

FIGURE 18.14 Resisted wrist extension to strengthen muscles of the lateral epicondyle without the use of grasp.

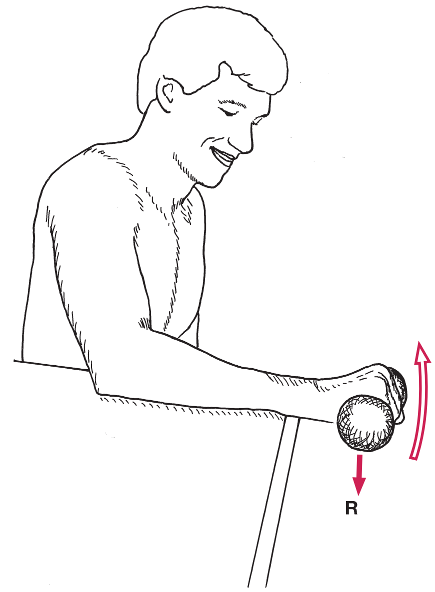

FIGURE 18.15 Strengthening the muscles of the lateral epicondyle (wrist extensors) while grasping a handheld weight for resistance.

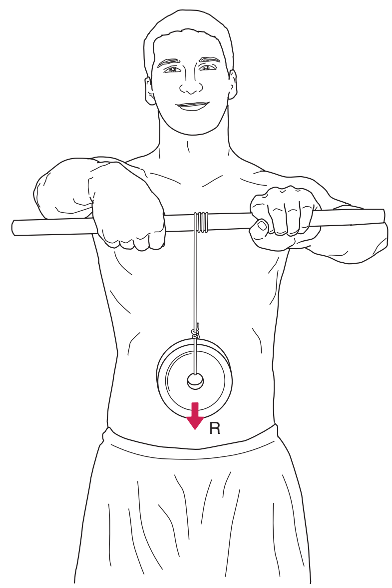

FIGURE 18.16 Wrist roller exercise to strengthen grip and develop muscles of the lateral epicondyle. This exercise requires stabilization in the shoulder girdle and elbow muscles. The elbows may be flexed or the forearms supinated to emphasize the elbow flexors or muscles of the medial epicondyle, respectively.

Functional Progression for the Elbow and Forearm

A comprehensive rehabilitation program for the elbow and forearm designed to achieve an individual's functional goals involves a sequence of carefully progressed exercise interventions designed to develop or restore sufficient mobility,

strength, stability, muscular endurance, and power. The final section of this chapter identifies integral components and examples of exercise interventions and simulated functional activities that often are included in a functional progression for the elbow and forearm. Refer to Chapters 17 and 23 for additional exercises and activities.

NOTE: Because the elbow primarily functions during activities that also involve the shoulder and hand, combined patterns of exercise that develop mobility and control the entire upper extremity should be implemented. Be careful that substitute motions do not occur to compensate for a weak link in the chain.

Diagonal Patterns

PNF patterns against manual or mechanical resistance. Use unilateral or bilateral diagonal patterns as described in Chapter 6. Use manual resistance, free weights, elastic resistance, a weight-pulley system, or an isokinetic dynamometer to provide the resistance as the patient moves through the diagonal patterns. Gradually increase resistance, speed (if appropriate with the choice of equipment), and repetitions.

Combined Pulling Motions

Elbow flexors are used in pulling, lifting, and carrying activities in open- and closed-chain activities. These upper extremity actions also require strength of the scapular retractors, shoulder extensors, and wrist and hand musculature. Many of the exercises that are described for the shoulder in Chapter 17 also involve resisted elbow flexion and therefore can be used to strengthen muscle groups during pulling motions. Suggestions include:

- Bilateral pull-ups against elastic resistance (Fig. 18.17).
- Closed-chain chin-ups or modified pull-ups on an overhead bar (Fig. 18.18).

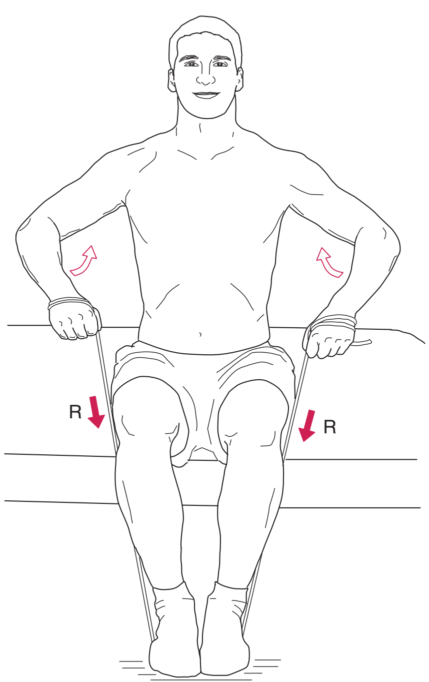

FIGURE 18.17 Bilateral pull-up against elastic resistance.

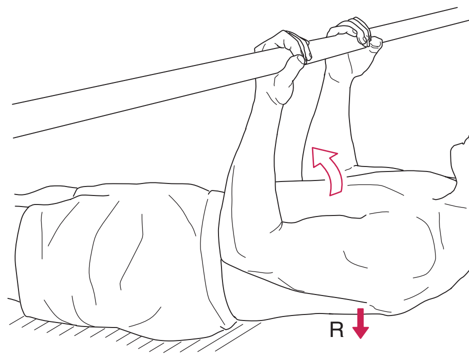

FIGURE 18.18 Closed-chain, modified chin-up using top half of body weight for resistance to strengthen the elbow flexors. This exercise may be performed in a bed with an overhead trapeze.

- Unilateral combined pulling pattern simulating starting a lawn mower (Fig. 18.19) or bilateral or unilateral rowing motions, such as using a rowing machine.
- Pulling a variety of weighted objects with one or both arms, emphasizing elbow flexion and proper body mechanics.

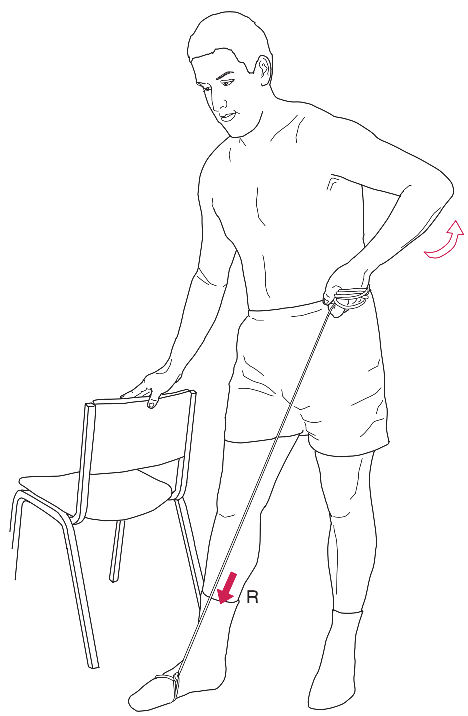

FIGURE 18.19 Simulation of a "lawn mower pull" for functional strengthening of the upper extremity.

Combined Pushing Motions

The triceps muscle is involved in pushing motions. Pushing also involves variations of shoulder flexion and scapular protraction or depression so that muscles controlling these motions are functioning with the triceps. Many of the exercises described in Chapter 17 for the shoulder and Chapter 23 also

involve resisted elbow extension and may be used to strengthen muscles groups involved in pushing patterns. Suggestions include:

- Military press-up (see Fig. 17.55).
- Bench press.
- Upper extremity ergometry (see Fig. 6.54).
- Wall push-ups, semi-prone or prone push-ups (Fig. 18.20 A).
- Push-ups from a chair or on parallel bars (Fig. 18.20 B).
- Stepping/stair-climbing machine with hands on the "steps." Emphasize elbow extension.
- Pushing a variety of weighted objects with one or both arms using dynamic elbow extension (Fig. 18.21).

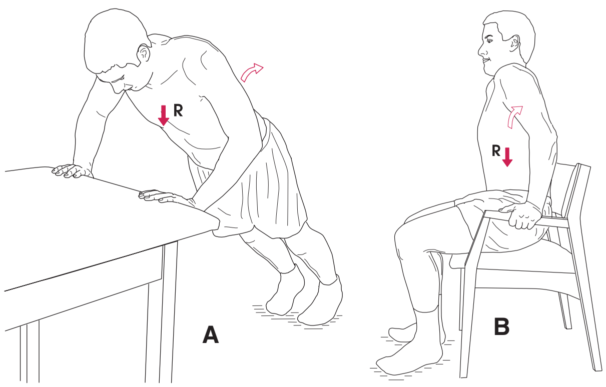

FIGURE 18.20 Closed-chain strengthening of the triceps. **(A)** Modified push-up. **(B)** Seated push-up.

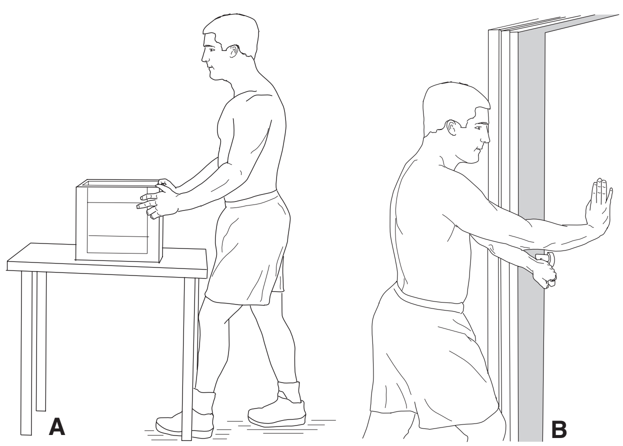

FIGURE 18.21 Strengthening the triceps with pushing activities. **(A)** Pushing weighted objects across a table. **(B)** Depressing a door handle and pushing open a door.

Plyometric Training (Stretch-Shortening Drills)

The following are suggestions for increasing power of the elbow musculature using plyometric exercises.[27,90] These advanced training activities are described in Chapter 23.

- Perform elbow flexion and extension exercises against elastic resistance, emphasizing rapid reversal between eccentric and concentric motions.
- Using a weighted ball, have the patient catch the ball and then quickly throw it back. Emphasize elbow motions with overhead passes, chest passes, and lateral passes.
- Bounce a ball against a wall or a tennis ball on a racquet with the forearm pronated and supinated.

Simulated Functional Tasks and Activities

Determine the component motions of the patient's desired functional activities as well as occupational or recreational tasks. Have the patient simulate these motions and practice the entire task. Activities could involve lifting, lowering, carrying, pushing, pulling, twisting, turning, catching, throwing, or swinging. For example, if the patient is recovering from repetitive trauma to the muscles of the lateral epicondyle when playing tennis, have the patient practice the various racquet strokes using a wall-pulley system (Fig. 18.22). Impose controlled forces to challenge the patient by increasing the time or repetitions, speed, or resistance.[27,90]

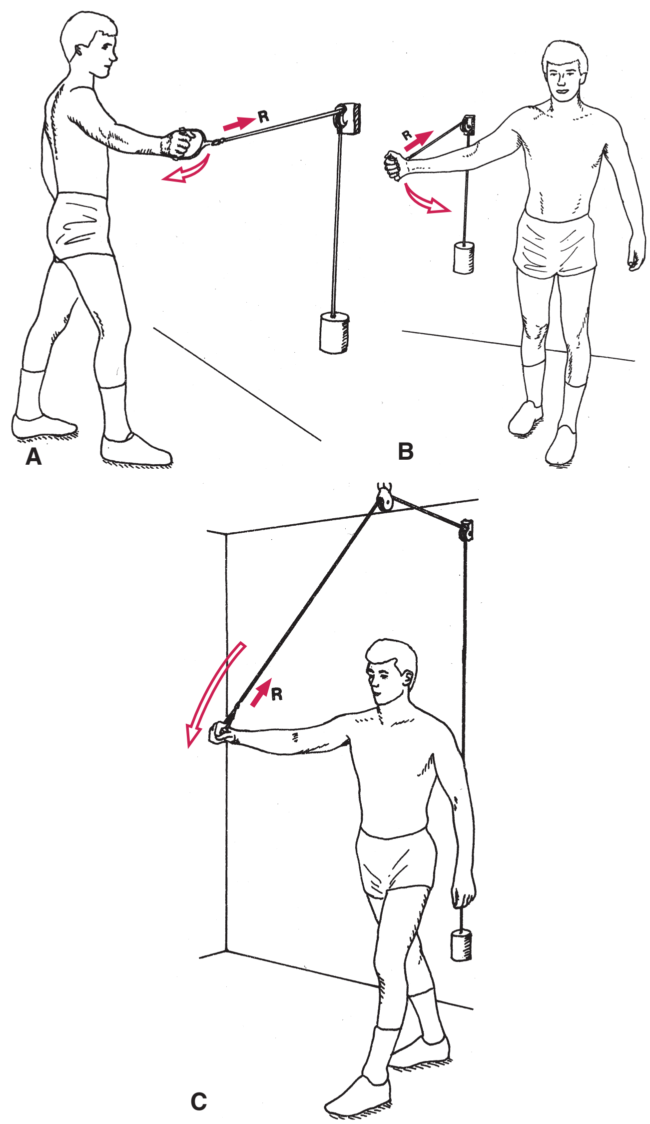

FIGURE 18.22 Mechanical resistance exercise using wall pulleys to simulate tennis swings. **(A)** Backhand stroke. **(B)** Forehand stroke. **(C)** Serve.

Independent Learning Activities

Critical Thinking and Discussion

1. Differentiate between the etiology, signs and symptoms, and management of lateral and medial epicondylalgia. Note the similarities and differences.
2. Develop, compare, and contrast the postoperative management (including an exercise progression and precautions) after two types of total elbow arthroplasty: (1) a semiconstrained implant/triceps-reflecting approach and (2) a resurfacing implant/triceps-splitting approach.
3. The goal is to increase muscle performance and function of the elbow flexors that are currently functioning at a 3/5 strength level and endurance of four repetitions. Identify exercises that could be used at each increment of strength, including exercises for strength, endurance, power, control, stability, and function. Identify parameters for progression of each exercise and any precautions.
4. Do the same sequence of analysis and identification to increase muscle performance and function of the elbow extensors.
5. Analyze the following household, occupational, or sports-related activities. Identify the components and sequence of motions related to each of these motor tasks; pay particular attention to elbow and forearm motions during these tasks. Design a sequence of upper extremity exercises and simulated activities that could be incorporated into a late-stage rehabilitation program to prepare a patient to return to the desired task after an elbow injury.
   - Housecleaning
   - Gardening
   - Grocery store stocking
   - Carpentry
   - Volleyball
   - Tennis
   - Throwing sports

Laboratory Practice

1. Apply mobilization techniques to a laboratory partner to increase the following elbow and forearm motions: mid- and end-range elbow flexion; mid- and end-range elbow extension; forearm pronation and supination (proximal and distal articulations).
2. Demonstrate passive stretching and hold–relax techniques to elongate the following muscles that cross the elbow: brachialis, brachioradialis, biceps, long head of the triceps, extensor communis digitorum, flexor carpi ulnaris, flexor carpi radialis.
3. Using the following pieces of resistance equipment demonstrate at least two methods (setups) to strengthen the elbow flexors/extensors and forearm rotators: free weights, weight-pulley system, and elastic resistance. Then demonstrate a progressive sequence of resistance exercise to strengthen the same muscle groups using self-resistance (body weight or manual resistance).

Case Studies

1. Describe the mechanical problem causing impairments in the elbow and forearm in the following scenario and what techniques could be used for intervention. A patient is referred to you 4 weeks after sustaining a fracture of the distal radius with immobilization in a cast following a fall on an outstretched arm and hand. She has limited elbow, forearm, and wrist motions. On palpation, you note a decreased space between the lateral aspect of the head of the radius and capitulum as well as decreased joint play at all articulations of the elbow, forearm, and wrist.
2. A 15-year-old patient with a 5-year history of polyarticular JRA just underwent open synovectomy and excision of the head of the radius with implant for late-stage joint disease of the elbow. Prior to surgery, the patient had severe pain in the elbow region, lacked full elbow flexion/extension and forearm rotation, and had limited use of the arm for functional activities. Continuous passive motion (CPM) was implemented during the patient's hospitalization (3 days). A day prior to discharge, the patient was referred to physical therapy for a home program. Design an exercise program for this teenager. Prioritize and describe each exercise you want the patient to do for the first week at home. Outline a program of exercises for later use in the rehabilitation process. The patient plans to return to school within a week of discharge from the hospital. Indicate whether you recommend outpatient therapy; if so, indicate the frequency and duration; justify the need for this recommendation.

CHAPTER

19

The Wrist and Hand

The wrist is the final link of joints that positions the hand for functional activities. It has the significant function of controlling the length-tension relationship of the multiarticular muscles of the hand as they adjust to various activities and grips.[6] The hand is a valuable tool through which we control and manipulate our environment and express ideas and talents. It also has an important function of providing sensory feedback to the central nervous system.

This chapter is divided into three major sections. The first section briefly reviews the rather complex structure and function of the wrist and hand—information that is important to know in order to effectively treat hand problems. The second section describes common disorders and guidelines for conservative and postoperative management. The last section describes exercise techniques commonly used to meet the goals of treatment during the stages of tissue healing and phases of rehabilitation.

Structure and Function of the Wrist and Hand

The bones of the wrist include the distal radius, scaphoid (S), lunate (L), triquetrum (Tri), pisiform (P), trapezium (Tm), trapezoid (Tz), capitate (C), and hamate (H). Five metacarpals and 14 phalanges make up the hand and the five digits (Fig. 19.1).

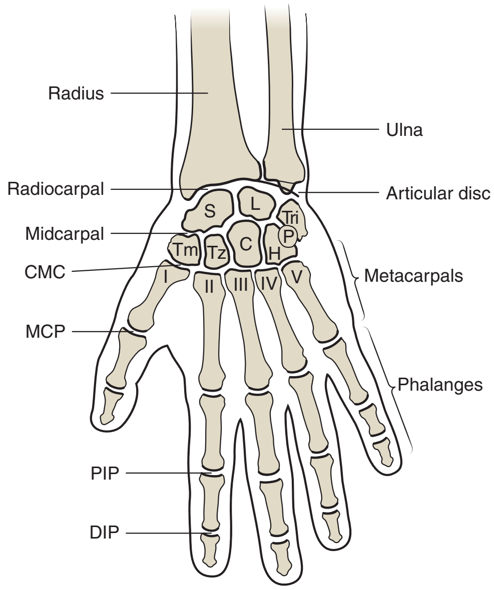

FIGURE 19.1 Bones of the wrist and hand complex.

Joints of the Wrist and Hand

Wrist Joint: Characteristics and Arthrokinematics

The distal radioulnar (RU) joint is not part of the wrist joint, although pain and impairments in this forearm articulation are often described by the patient as wrist pain. Structure and function of the RU joints are described in Chapter 18.

The wrist joint is multiarticular and is made up of two compound joints. It is biaxial, allowing flexion (volar flexion), extension (dorsiflexion), radial deviation (abduction), and ulnar deviation (adduction). Stability is provided by numerous ligaments: the ulnar and radial collateral, the dorsal and volar (palmar) radiocarpal, the ulnocarpal, and the intercarpal.

The pisiform is categorized as a carpal and aligned volar to the triquetrum in the proximal row of carpals. It is not part of the wrist joint per se but functions as a sesamoid bone in the flexor carpi ulnaris tendon.

Radiocarpal Joint

Characteristics. The radiocarpal (RC) joint is enclosed in a loose but strong capsule that is reinforced by the ligaments shared with the midcarpal joint. The biconcave articulating surface is the distal end of the radius and radioulnar disk (discus articularis); it is angled slightly volarward and ulnarward. The biconvex articulating surface is the combined proximal surface of the scaphoid, lunate, and triquetrum. The triquetrum primarily articulates with the disk. These three carpals are bound together with numerous interosseous ligaments.

Arthrokinematics. With motions of the wrist, the convex proximal row of carpals slides in the direction opposite the physiological motion of the hand. The arthrokinematics are summarized in Box 19.1.

Midcarpal Joint

Characteristics. The midcarpal joint is a compound joint between the two rows of carpals. It has a capsule that is also continuous with the intercarpal articulations. The combined distal surfaces of the scaphoid, lunate, and triquetrum articulate with the combined proximal surfaces of the trapezium, trapezoid, capitate, and hamate.

Arthrokinematics. The articulating surfaces of the capitate and hamate are, in essence, convex and slide on the concave articulating surfaces of a portion of the scaphoid, lunate, and triquetrum, so with flexion and extension, as well as radial and ulnar deviation, their combined surfaces slide opposite the physiological motion.

The articulating surfaces of the trapezium and trapezoid are concave and slide on the convex distal surface of the scaphoid so with flexion and extension their combined surfaces slide in the same direction as the physiological motion. Because the trapezoid is bound to the capitate, they cannot slide in opposite directions during radial and ulnar deviation. The trapezii (the trapezium and trapezoid), therefore, slide in a dorsal direction on the scaphoid during radial deviation and in a volar direction during ulnar deviation.[62]

Physiological motions of the wrist result in a complex motion between the proximal and distal row of carpals. Because the concave trapezii slide in a dorsal direction on the scaphoid and the convex capitate and hamate slide in a volar direction on the lunate and triquetrum during extension and radial deviation, the resulting motion is a supination twist of the distal row on the proximal row. A pronation twist occurs during flexion and ulnar deviation as the trapezii slide volarly and the capitate and hamate slide dorsally.[6]

These arthrokinematic relationships are summarized in Box 19.1.

Hand Joints: Characteristics and Arthrokinematics

Carpometacarpal Joints of Digits 2 through 5

Characteristics. The carpometacarpal (CMC) joints are enclosed in a common joint cavity and include the articulations of each metacarpal with the distal row of carpals and the articulations between the bases of each metacarpal.

The joints of digits 2, 3, and 4 are plane uniaxial joints; the joint of digit 5 is biaxial. They are supported by transverse and longitudinal ligaments. The fifth metacarpal is most mobile, with the fourth being the next most mobile. Flexion of the metacarpals and additional adduction of the fifth contribute to cupping (arching) of the hand, which improves the ability of the hand to grasp objects of various sizes. Extension of the metacarpals contributes to flattening of the hand, which improves the ability to release objects.

Arthrokinematics. The proximal surfaces slide in a volar direction with flexion and in a dorsal direction with extension motions in the hand (see Box 19.1).

BOX 19.1 Arthrokinematics of the Wrist and Hand Joints

Physiological Motion	Roll	Slide
Radiocarpal joint: Motion of proximal row of carpals		
Flexion of wrist	Volar	Dorsal
Extension of wrist	Dorsal	Volar
Radial deviation	Radial	Ulnar
Ulnar deviation	Ulnar	Radial
Midcarpal joints: Motion of distal row of carpals		
Flexion of wrist	Volar	C and H dorsal
	Tm and Tz volar	
Extension of wrist	Dorsal	C and H volar
		Tm and Tz dorsal
Radial deviation	Radial	C and H ulnar
		Tm and Tz dorsal
Ulnar deviation	Ulnar	C and H radial Tm and Tz volar
Carpometacarpal joints of digits 2–5: Motion of proximal phalanx		
Flexion (increased arch)	Volar	Volar
Extension (decreased arch)	Dorsal	Dorsal
Carpometacarpal joint of thumb: motion of 1st metacarpal		
Flexion	Ulnar	Ulnar
Extension	Radial	Radial
Abduction	Volar	Dorsal
Adduction	Dorsal	Volar
Metacarpophalangeal joints of digits 2–5: motion of phalanx		
Flexion	Volar	Volar
Extension	Dorsal	Dorsal
Abduction	Away from center of hand	
Adduction	Toward center of hand	
Interphalangeal joints and MCP joint of thumb: Motion of phalanx		
Flexion	Volar	Volar
Extension	Dorsal	Dorsal

Carpometacarpal Joint of the Thumb (Digit 1)

Characteristics. The CMC joint of the thumb is a saddle-shaped (sellar) biaxial joint between the trapezium and base of the first metacarpal. It has a lax capsule and wide range of motion (ROM), which allows the thumb to move away from the palm of the hand for opposition in prehension activities.

Arthrokinematics. For flexion/extension of the thumb (components of opposition/reposition, respectively) in the frontal plane, the surface of the trapezium is convex, and the base of the metacarpal is concave; therefore, its surface slides in the same direction as the angulating bone. For abduction/adduction in the sagittal plane, the trapezium surface is concave and the metacarpal is convex; therefore, the surface of the metacarpal slides in the opposite direction of the physiological motion (see Box 19.1).

Metacarpophalangeal Joints of Digits 2–5

Characteristics. The metacarpophalangeal (MCP) joints are biaxial condyloid joints. Each joint is supported by a volar and two collateral ligaments. The collaterals become taut in full flexion and prevent abduction and adduction in this position.

Arthrokinematics. The distal end of each metacarpal is convex and the proximal phalanx concave. The proximal surface of the proximal phalanx rolls and slides in the same direction as the physiological motion (see Box 19.1).

Interphalangeal Joints and MCP Joint of the Thumb

Characteristics. There is a proximal (PIP) and distal (DIP) interphalangeal joint for each digit, 2 through 5. The thumb

has only one interphalangeal joint, although the MCP joint of the thumb is uniaxial and therefore functions similarly to the IP joints. The MCP joint of the thumb differs in that it is reinforced by two sesamoid bones on the volar surface, which improve the leverage of the flexor pollicis brevis muscle. Each of these joints is a uniaxial hinge joint.

The capsule of each joint is reinforced with collateral ligaments, which are taut in extension. Going radial to ulnar in digits 2 through 5, there is increasing flexion/extension range in the joints. This allows for greater opposition of the ulnar fingers to the thumb and also causes a potentially tighter grip on the ulnar side of the hand.

Arthrokinematics. The articulating surface at the distal end of each phalanx is convex; the articulating surface at the proximal end of each phalanx is concave. Therefore, the proximal surface of each phalanx rolls and slides in the same direction as the physiological motion (see Box 19.1).

Hand Function

Muscles of the Wrist and Hand

The complex function of the hand occurs as a result of an intricate balance and control of forces between the extrinsic and intrinsic muscles of the wrist and hand. The primary and secondary actions of the wrist and hand muscles are summarized in Table 19.1 and depicted in Figure 19.2.

TABLE 19.1 Muscles of the Wrist and Hand

Action	Prime Movers	Secondary Movers
Wrist		
Flexion	Flexor carpi radialis Flexor carpi ulnaris Palmaris longus	Flexor digitorum superficialis Flexor digitorum profundus Flexor pollicis longus
Extension	Extensor carpi radialis longus Extensor carpi radialis brevis Extensor carpi ulnaris Extensor digitorum communis	Extensor indicis proprius Extensor digiti minimi Extensor pollicis brevis Abductor pollicis longus
Radial deviation	Flexor carpi radialis longus Extensor carpi radialis longus Extensor carpi radialis brevis	Flexor pollicis longus Extensor pollicis brevis Abductor pollicis longus
Ulnar deviation	Flexor carpi ulnaris Extensor carpi ulnaris	
Thumb (Digit 1)		
CMC opposition	Opponens pollicis	
CMC flexion	Opponens pollicis	
CMC extension	Abductor pollicis longus	Extensor pollicis longus
CMC abduction	Opponens pollicis Abductor pollicis longus Abductor pollicis brevis Extensor pollicis brevis	Flexor pollicis brevis (lateral head)
CMC adduction	Adductor pollicis (first volar interossei)	Flexor pollicis brevis (medial head) Extensor pollicis longus
MCP flexion	Flexor pollicis brevis	Flexor pollicis longus
MCP extension	Extensor pollicis brevis Extensor pollicis longus	Extensor pollicis longus
IP flexion	Flexor pollicis longus	
IP extension	Extensor pollicis longus	Abductor pollicis brevis and adductor pollicis to neutral through attachment to extensor tendon

Continued

TABLE 19.1 Muscles of the Wrist and Hand—cont'd

Action	Prime Movers	Secondary Movers
Digits 2 through 5 (function of these muscles varies with joint positions/motions)		
MCP flexion	Lumbricals Volar and dorsal interossei Flexor digitorum superficialis Flexor digitorum profundus	
MCP extension	Extensor digitorum Extensor digiti minimi Extensor indices	
MCP abduction	Dorsal interossei Abductor digiti minimi	(Note: Proximal wing tendons of the interossei have more influence on the MCP joint)[6]
MCP adduction	Volar interossei	
IP flexion	Flexor digitorum superficialis (PIP only) Flexor digitorum profundus (PIP and DIP)	
IP extension	Lumbricals, dorsal and volar interossei, and extensor digitorum via extensor mechanism	(Note: Distal wing tendons of the interossei have more influence on the IP joints)[6]

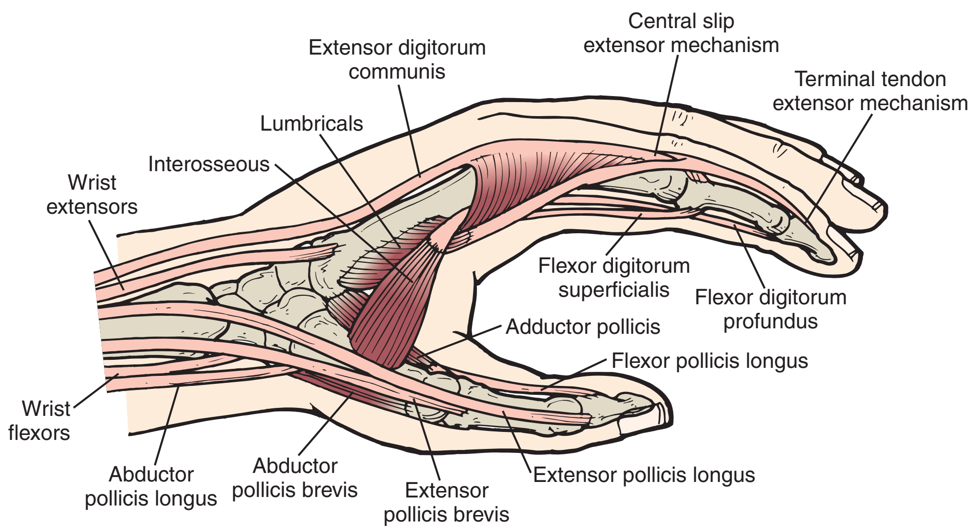

FIGURE 19.2 The extrinsic and intrinsic muscles of the wrist and hand create a balance of forces that affect hand function.

Length-Tension Relationships

The position of the wrist controls the length of the extrinsic muscles of the digits. As the fingers or thumb flex, the wrist extensor muscles must stabilize the wrist to prevent the flexor digitorum profundus and flexor digitorum superficialis or the flexor pollicis longus from simultaneously flexing the wrist. As the grip becomes stronger, synchronous wrist extension lengthens the extrinsic flexor tendons across the wrist and maintains a more favorable overall length of the musculotendinous unit for a stronger contraction.

For strong finger or thumb extension, the wrist flexor muscles stabilize or flex the wrist so the extensor digitorum communis, extensor indicis, extensor digiti minimi, or extensor pollicis longus muscles can function more efficiently. In addition, there is ulnar deviation; the flexor and extensor carpi ulnaris muscles are both active as the hand opens.

Extensor Mechanism

Structurally, the extensor hood (extensor expansion) is made up of the extensor digitorum communis tendon, its connective tissue expansion, and fibers from the tendons of the dorsal and volar interossei and lumbricals (Fig. 19.3).[6] Each structure that is a part of the hood has an effect on the extensor mechanism.

- An isolated contraction of the extensor digitorum produces clawing of the fingers—MCP hyperextension with IP

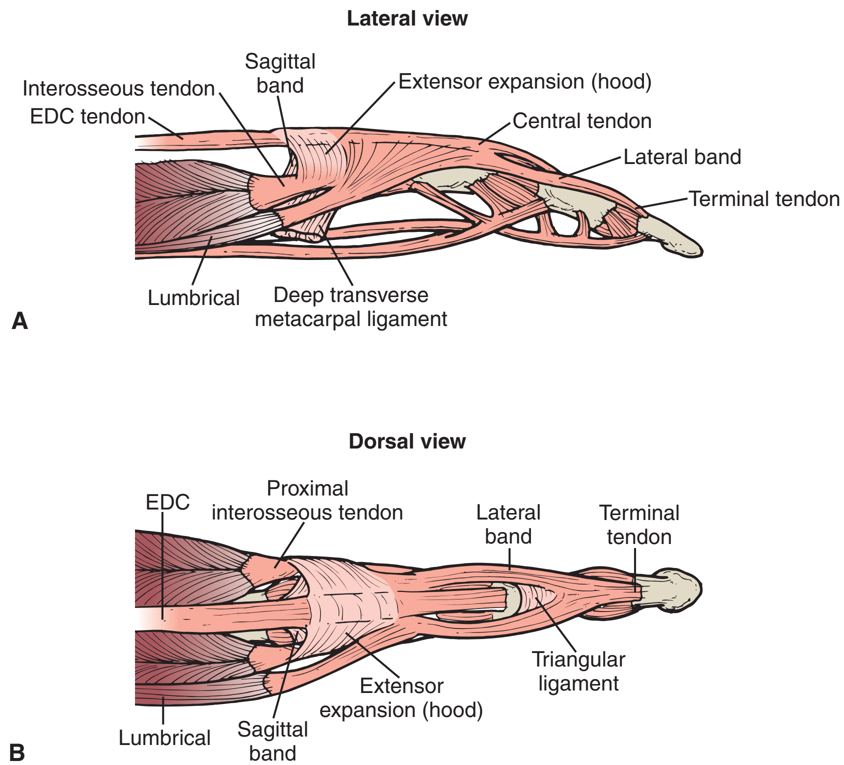

FIGURE 19.3 Anatomical structures of the extensor mechanism: **(A)** lateral view and **(B)** dorsal view. See text for description of functional relationships.

flexion from passive pull of the extrinsic flexor tendons, also called the hook position.
- PIP and DIP extension occurs concurrently and can be caused by the interossei or lumbrical muscles through their pull on the extensor hood.
- There must be tension in the extensor digitorum communis tendon for there to be interphalangeal extension. This occurs either by active contraction of the muscle, causing MCP extension concurrently as the intrinsic muscles contract, or by stretch of the tendon, which occurs with MCP flexion.

Control of the Unloaded (Free) Hand

Anatomical factors, muscular contraction, and viscoelastic properties of the muscles influence finger motion.[6]

- When only the extrinsic muscles contract, clawing motions occur in the digits.
- Closing motions can occur only with extrinsic muscle contractions but also require the viscoelastic force of the biarticular interossei.
- Opening motions require synergistic contraction of the extrinsic extensor and the lumbrical muscles.
- Reciprocal motion of MCP flexion and IP extension is caused by the interossei. The lumbrical removes the viscoelastic tension from the profundus tendon and assists IP extension.

Grips and Prehension Patterns

The nature of the intended activity dictates the type of grip used.[6,61,71,85,86]

Power Grips

Description. Power grips involve clamping an object with partially flexed fingers against the palm of the hand and with counter pressure from the adducted thumb. Power grips are primarily isometric functions. The fingers are flexed, laterally rotated, and ulnarly deviated. The amount of flexion varies with the object held. The thumb reinforces the fingers and helps make small adjustments to control the direction of the force. Varieties include cylindrical grip, spherical grip, hook grip, and lateral prehension.

Muscle control. The muscles primarily function with isometric contractions.[6,86]

- Extrinsic finger flexors provide the major gripping force.
- The extensor digitorum provides a compressive force to the MCP joints, which increases stability and also provides a balancing force for the flexors.
- Interossei rotate the first phalanx for positioning to compress the external object and also flex the MCP joint.
- With the exception of the fourth lumbrical, lumbricals do not participate in the power grip (except the fourth).
- The thenar muscles and adductor pollicis provide compressive forces against the object being gripped.

Precision Patterns

Description. Prehension patterns involve manipulating an object that is not in contact with the palm of the hand between the opposing abducted thumb and fingers. The muscles primarily function isotonically. The sensory surfaces of the

digits are used for maximum sensory input to influence delicate adjustments. With small objects, precise handling occurs primarily between the thumb and index finger. Varieties include pad-to-pad, tip-to-tip, and pad-to-side prehension.

Muscle control. The primary dynamic function of the muscles includes the following.[6,86]

- Extrinsic muscles provide the compressive force to hold the objects between the fingers and thumb.
- For manipulation of an object, the interossei abduct and adduct the fingers; the thenar muscles control movement of the thumb; and the lumbricals help move the object away from the palm of the hand. The amount of participation of each muscle varies with the amount and direction of motion.

Combined Grips

Description. Combined grips involve digits 1 and 2 (and sometimes 3) performing precision activities, whereas digits 3 through 5 supplement with power.

Pinch. Pinch requires holding an object between the thumb and index or middle finger, as in precision handling, but may require primarily an isometric hold. The thenar eminence muscles, the adductor pollicis, the interossei, and the extrinsic flexors provide compression between the thumb and fingers. The lumbricals also participate.

Major Nerves Subject to Pressure and Trauma at the Wrist and Hand

For a detailed description of peripheral nerve injuries and entrapments in the wrist and hand region, as well as complex regional pain syndromes (including reflex sympathetic dystrophy) and their management, see Chapter 13.

Nerve Disorders in the Wrist

Median nerve. The most common site for compression of the median nerve is the carpal tunnel.

Ulnar nerve. The most common site for compression of the ulnar nerve is in the ulnar tunnel (also called Guyon's canal).

Referred Pain and Sensory Patterns

The hand is the terminal point for the C6, C7, and C8 nerve roots coursing through the median, ulnar, and radial nerves (see Figs. 13.5, 13.6, and 13.7). Injury or entrapment of these nerves may occur anywhere along their course, from the cervical spine to their termination. What the patient perceives as pain or a sensory disturbance in the hand may be from injury of the nerve anywhere along its course, or the pain may derive from irritation of tissue of common segmental origin, such as the zygapophyseal facet joints of the spine. For treatment to be effective, it must be directed to the source of the problem, not to the site where the patient perceives the pain or sensory changes. Therefore, a thorough history is taken and examination of the entire upper quarter must be done, including the cervical spine when referred pain patterns or sensory changes are reported by the patient.[37,74]

Management of Wrist and Hand Disorders and Surgeries

To make sound clinical decisions when treating patients with wrist and hand disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting structural and functional impairments, activity limitations (functional limitations), and possible participation restrictions (disabilities). In this section, common pathologies and surgeries are presented and are related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[3] (Table 19.2). Conservative and postoperative management of these conditions is also described in this section.

Joint Hypomobility: Nonoperative Management

Pathologies, such as rheumatoid arthritis (RA) and degenerative joint disease (DJD), affect the joints of the wrist and hand and may have a significant effect on the functional abilities of an individual as a result of pain, impaired mobility, and potential joint deformities. Impaired joint, tendon, and muscle mobility also occurs any time joints are immobilized due to fractures, trauma, or surgery. Chapter 11 describes the etiology and general guidelines for management of impairments due to these joint pathologies. This section focuses on specific interventions for the wrist and hand.

Common Joint Pathologies and Associated Impairments

Rheumatoid Arthritis

The following is a summary of signs, symptoms, and resulting impairments typically seen in the wrist and hand with RA.[4,13,87,94,121]

Acute stage. There is pain, swelling, warmth, and limited motion from synovial inflammation (synovitis) and tissue proliferation, most commonly in the MCP, PIP, and wrist joints bilaterally. There is also inflammation (tenosynovitis) and synovial proliferation in the extrinsic tendons and tendon sheaths. In addition:

- Progressive muscle weakness and imbalances in length and strength between agonists and antagonists and between intrinsic and extrinsic muscles occur.

TABLE 19.2 Wrist and Hand Pathologies/Surgical Procedures and Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Pattern and Associated Impairments[3]
■ Arthritis (osteoarthrosis, rheumatoid arthritis, posttraumatic arthrosis) ■ Synovitis ■ Postimmobilization arthrosis (stiffness) ■ Tendon adhesions	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
■ Acute arthritis, capsulitis, synovitis, tenosynovitis ■ Acute sprain, tendonitis	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
■ Interposition arthroplasty (flexible silicone spacer, soft tissue implant) ■ Surface (total joint) replacement arthroplasty	Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
■ Synovectomy and tenosynovectomy ■ Repair, reconstruction, or transfer of a ruptured or lacerated tendon ■ Soft tissue release (capsule, ligament, or tendon) ■ Open reduction and internal fixation of a fracture or fracture-dislocation ■ Bone resection (distal styloidectomy of the ulna, proximal row carpectomy) ■ Arthrodesis	Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with boney or soft tissue surgery
■ Carpal tunnel syndrome (median nerve) ■ Tunnel of Guyon syndrome (ulnar nerve)	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury.

- Carpal tunnel syndrome may occur in conjunction with tenosynovitis due to compression of the median nerve from the swollen tissue.
- General systemic as well as muscular fatigue occurs.

Advanced stages. Joint capsule weakening, cartilage destruction, bone erosion, and tendon rupture, as well as imbalances in musculotendinous forces, lead to joint instabilities, subluxations, and deformities (Fig. 19.4). Typical deformities and the pathomechanics in the hand include:

- *Volar subluxation of the triquetrum on the articular disk and ulna.* The extensor carpi ulnaris tendon displaces volarly and causes a flexor force at the wrist joint.
- *Ulnar subluxation of the carpals.* This causes radial deviation of the wrist.
- *Ulnar drift of the fingers and volar subluxation of the proximal phalanx.* There is stretching or rupture of the collateral ligaments at the MCP joints and a bowstringing effect from the extrinsic tendons.[13]
- *Swan-neck deformity*. Laxity of the PIP joint with an overstretched palmar plate and bowstringing of the lateral bands of the extensor hood result in hyperextension of the PIP and flexion of the DIP joints (Fig. 19.5A). Tight or overactive interossei muscles pulling on the extensor tendon reinforces the hyperextension of the hypermobile PIP joints, and increased passive tension in the flexor digitorum profundus tendon causes flexion of the DIP joint.

FIGURE 19.4 Joint deformities seen in the hand of a patient with rheumatoid arthritis. Note the hypertrophy of the IP joints, rheumatoid nodules, and volar subluxation of the triquetrum. This patient had fusion of the wrist joints due to pain and complete destruction of the joints, which has helped prevent the deforming, bowstringing effect of the extrinsic tendons on the MCP joints. *(Courtesy of Turtle Services Limited, www.turtleserviceslimited.org/.)*

- *Boutonnière deformity.* Rupture of the central band (central slip) of the extensor hood results in the lateral bands of the extensor apparatus (extensor hood) slipping in a volar direction to the PIP joint, causing PIP flexion and DIP extension (Fig. 19.5B).

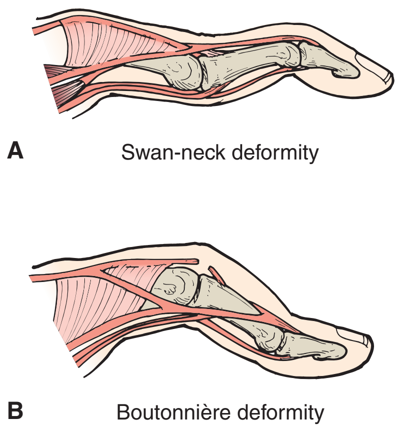

FIGURE 19.5 (A) Swan-neck and **(B)** Boutonnière deformities. See text for description of the pathomechanics.

- *Zigzag deformity of the thumb.* Muscle imbalances and ligamentous laxity lead to metacarpal dislocation of the thumb and deformities similar to swan-neck or boutonnière deformity. Tightness in the adductor pollicis contributes to deformities in the thumb.[87]

Degenerative Joint Disease/Osteoarthritis and Posttraumatic Arthrosis

Age and repetitive joint trauma lead to degenerative cartilaginous and boney changes in susceptible joints. DJD, or osteoarthritis (OA), most commonly involves the trapezioscaphoid articulation, CMC joint of the thumb, and DIP joints of the digits, although the effects of trauma can occur in any joint.

Posttraumatic arthrosis can develop in any joint of the wrist or hand as the result of a severe intra-articular fracture or fracture-dislocation. For example, at the wrist, deficiency of the scapholunate interosseous ligament as the result of a severe wrist sprain can alter joint alignment, which can cause articular degeneration over time. In the fingers, the PIP joint is a common site of articular fracture and subsequent joint degeneration.

The following is a summary of signs, symptoms, and resulting impairments commonly seen in DJD or posttraumatic arthrosis.[126]

Acute stage. During the early stages of DJD, symptoms include achiness and feelings of stiffness, which abate with movement. Following stressful activities or trauma, joint swelling, warmth, and restricted and painful motion occur.

Advanced stages. With degeneration, there is capsular laxity resulting in hypermobility or instability; with progression, contractures and limited motion develop. Affected joints may become enlarged or sublux (Fig. 19.6). Limitation of both flexion and extension with a firm capsular end-feel develops in the affected joints. There is general muscle weakness, weak grip strength, and poor muscular endurance. Pain may also be a limiting factor in pinch and gripping activities.

FIGURE 19.6 Advanced-stage osteoarthritis of the hands of an 86-year-old pianist. Note the carpometacarpal (CMC) joint subluxation at the base of each thumb. Atrophy of the first dorsal interossei, nodules, and joint enlargements are apparent, but the individual is still functional.

PRECAUTION: After trauma, the therapist must be alert to signs of a fracture in the wrist or hand because small bone fractures may not show on radiographs for as many as 2 weeks. Signs include swelling, muscle spasm when passive motion is attempted, increased pain when the involved bone is stressed (e.g., deviation toward the involved bone), and tenderness on palpation over the fracture site.[37,80]

Postimmobilization Hypomobility

Immobilization may be necessary following a fracture, surgery, or trauma, or it may be used to rest a part when an individual sustains repetitive stress. Structural and functional impairments may occur from the lack of motion and muscle contraction, including:

- Decreased ROM and decreased joint play with firm end-feel and pain on overpressure.
- Tendon adhesions as the result of inflammation in a tendon or its sheath.
- Decreased muscle performance including muscle weakness, weak grip strength, decreased flexibility, and decreased muscle endurance.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

When joint pathology is acute, many prehension activities are painful, interfering with activities of daily living (ADL and IADL), such as dressing, eating, grooming, and toileting or almost any functional activity that requires pinching, gripping, and fine-finger dexterity, including writing and typing.

Depending on which joints are involved; the amount of restricted movement and residual weakness, fatigue, or dexterity loss; and the type of grip or amount of precision handling required, functional loss may be minor or significant.

Joint Hypomobility: Management—Protection Phase

General guidelines for managing acute joint lesions are described in Chapter 11, with special concerns for patients with RA and OA summarized in Boxes 11.2 and 11.4, respectively.

Control Pain and Protect Joints

Patient education. Teach the patient how to protect involved joints and control pain with activity modification, ROM exercises, and appropriate use of a splint.

Pain management. In addition to physician-prescribed medications or nonsteroidal anti-inflammatory medications and modalities, gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition in the involved joints.

Splinting. Use a splint to rest and protect the involved joints. Instruct the patient to remove the splint for brief periods of nonstressful motion throughout the day.

Activity modification. Analyze the patient's daily activities and recommend adaptations or assistive devices to minimize repetitive or excessive stresses on the joints. This is particularly important for patients with chronic arthritic disorders to prevent repetitive trauma and to minimize joint-deforming forces. Examples are summarized in Box 19.2.

Maintain Joint and Tendon Mobility and Muscle Integrity

Passive, assistive, or active ROM. It is important to move the joints as tolerated, because immobility of the hand quickly leads to muscle imbalance and contracture formation or further articular deterioration. Aquatic therapy is an effective method of combining nonstressful, nonweight-bearing exercises with therapeutic heat.

Tendon-gliding exercises. Have the patient perform full motion in the uninvolved joints and as much motion as possible in the involved joints to prevent adhesions between the long tendons or between the tendons and their synovial sheaths.[52] Tendon-gliding exercises are described in the exercise section of this chapter.

Multiple-angle muscle setting exercises. Perform gentle isometrics of all wrist and hand musculature. Resistive ROM exercises usually are not tolerated if there is joint effusion or inflammation; therefore, isometric resistance within the tolerance of pain is performed.

BOX 19.2 Joint Protection in the Wrist and Hand

Purpose. Performance of daily activities with minimal pain, stress to joints, and energy expenditure. Most of these principles are applicable to any arthritic problem in the hand but are especially important in the hand affected by rheumatoid arthritis.[94,95]

Respect pain. Monitor activities; stop when fatigue or discomfort begins to develop. Modify or discontinue any activity or exercise that causes pain that lasts longer than 1 hour after stopping the activity.

Maintain strength and ROM. Integrate exercises into daily activities.
- Look for early signs of muscle tightness in the intrinsic muscles. If tight, initiate stretching. One cause of swan-neck deformity is tight interossei muscles pulling on the extensor tendon, leading to hyperextension of hypermobile PIP joints.
- Strengthen radial deviation of the MP joints of the fingers to counter the ulnar drifting of the fingers that occurs in many functional activities.

Balance activity level and rest. More rest than normal is required during the active phases of RA. Conserve energy and perform activities in the most economic way or do the most important activities first.

Avoid deforming positions or one position for prolonged periods.

Avoid using strong grasping activities that facilitate the deforming force. Typical joint deformities with RA include radial deviation and extension of the wrist and ulnar deviation and volar subluxation of the MPC joints. Adaptive suggestions include:
- Open jars with the left hand or with an assistive device.
- Cut food with the blade of the knife protruding from the ulnar side of the hand.
- Stir food with spoon on the ulnar side of the hand.
- Build up the handles of eating utensils.
- Use stronger, larger joints whenever feasible. For example, carry items in a shoulder bag or over the forearm or with two hands rather than with one hand.
- Avoid twisting or wringing motions with the fingers. Press water out of a rag by opposing the palms of both hands together.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

With joint pathology, increase ROM by utilizing joint mobilization techniques to stretch the capsule[97] as well as passive stretching and muscle inhibition techniques to elongate the periarticular connective tissue and musculotendinous units following the principles described in Chapters 4 and 5. It is also critical to determine if scar tissue has formed in the long tendon sheaths in the hand and if so, attempt to re-establish smooth tendon gliding.

Increase Joint Play and Accessory Motions

Joint mobilization techniques. Determine which of the articulations of the distal RU, wrist, hand, or digits are restricted because of decreased joint play, and apply grade III sustained or grade IV oscillation techniques to stretch the capsules. See Figures 5.33 through 5.43 for mobilizing restricted joints of the distal forearm, wrist, hand, and digits.

PRECAUTIONS: For patients with RA, modify the intensity of joint mobilization and stretching techniques that are used to counter any restrictions. This is necessary because the disease process and steroid therapy weaken the tensile quality of the connective tissue, and consequently the tissue is more easily torn.

Unlock a subluxated ulnomeniscal-triquetral joint. The mechanism of the dysfunction is not clear, but some patients describe locking in the wrist and an inability to supinate the forearm. The meniscus may be displaced and be the cause of the blocked motion. The following techniques may free up the motion.

- Apply a volar glide to the ulna on a stabilized triquetrum (similar to Fig. 5.38).
- *Self-mobilization*. Have the patient grasp the distal ulna with the fingers of the opposite hand, place the thumb on the palmar surface of the triquetrum just medial to the pisiform, and then press with the thumb, causing a dorsal glide of the triquetrum on the radioulnar disk and ulna (Fig. 19.7).

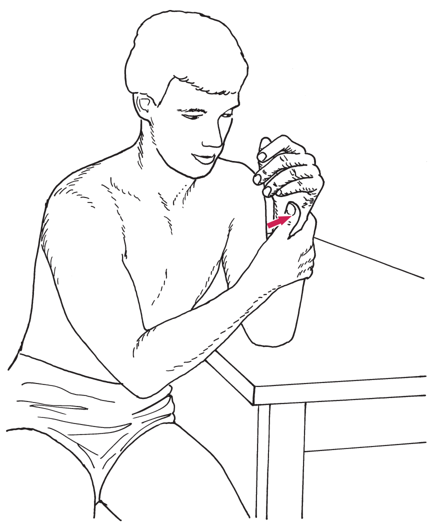

FIGURE 19.7 Self-mobilization of the ulnomeniscal-triquetral (UMI) joint.

Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques may be applied to increase ROM and/or decrease the pain associated with movement.[81] (The principles of MWM are described in Chapter 5.)

MWM of the wrist. Have the patient seated with the elbow flexed and forearm supinated (patient's palm facing toward his or her face); stabilize the distal radius with your hand placed around the lateral aspect of the forearm.

- Apply a pain-free lateral glide to the proximal row of carpals, utilizing the web space of your other hand. Have the patient then perform active wrist extension or flexion to the end of the available range, and with his or her free hand, apply a passive stretch at the end of the range (Fig. 19.8).

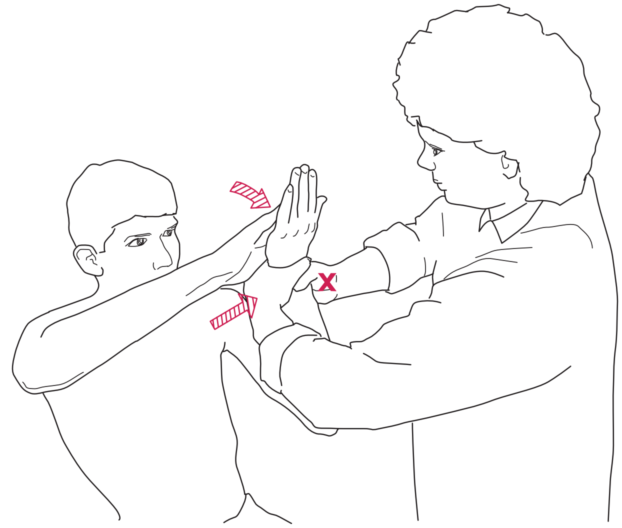

FIGURE 19.8 Mobilization with movement (MWM) to increase wrist flexion or extension. Apply a lateral glide while the patient actively flexes or extends the wrist and then applies a passive stretch force with his other hand at the end of the range.

- An internal or external rotation of the carpals relative to the radius may need to be combined with the glide to achieve pain-free, end-range loading.
- The intercarpal joint may require specific anterior-posterior gliding of one proximal row of carpals relative to its distal row neighbor combined with active physiologic motion to the end of the range. The mobilization and movement are pain-free. While holding the mobilization force, ask the patient to do repetitive gripping activities or resisted wrist motions.

MWM of the MCP and IP joints of the digits. Medially or laterally glide the involved phalanx in a painless direction, then have the patient actively flex or extend the finger and apply a pain-free, end-range stretch. Internal or external rotation of the more distal phalanx may be required in conjunction with the medial or lateral glide to achieve painless end-range overpressure.[81]

Improve Mobility, Strength, and Function

Carefully examine the multijoint and intrinsic muscles for restricted motion due to contractures or adhesions and poor movement patterns due to weakness or imbalances in strength. Stretching, tendon gliding, and strengthening exercises are described in the exercise sections of this chapter. Utilize techniques that specifically address the impairments the patient has. Once range is gained, it is critical that the patient uses the new range with active ROM and functional activities.

CLINICAL TIP

Strong muscles help protect the joints, but in the hand, imbalanced muscle forces lead to deformities. Teach isometric exercises in pain-free positions by showing the patient how

to use one hand to resist the other in carefully controlled positions and directions. These exercises can be done throughout the day whenever the patient feels discomfort in his or her joints.

Neuromuscular control and strength. Progress exercises with controlled and nondestructive force to increase strength and muscle balance between antagonists and to progress endurance training. With pathological joints, use caution when applying weights so as not to stress the joints beyond the capability of the stabilizing tissues.

Functional activities. Develop exercises that prepare the patient for functional activities. Consider prehension patterns that are required for the patient's job, recreational, and daily activities. Include exercises that require coordination and fine finger dexterity.

Conditioning exercises. Initiate physical conditioning exercises using activities that do not provoke joint symptoms, such as aquatic exercises or cycling.

Joint protection. Reinforce use of joint protection techniques as summarized in Box 19.2.

FOCUS ON EVIDENCE

In a systematic literature review of randomized, controlled trials of adult patients with RA, the reviewers concluded that there is evidence to support the idea that low-intensity therapeutic exercise is beneficial for reducing pain and improving functional status (including hand grip strength) in patients with RA, whereas high-intensity exercise programs may exacerbate symptoms.[91]

Joint Surgery and Postoperative Management

Long-standing RA, OA, or posttraumatic arthritis affecting the joints and soft tissues of the wrist and hand can lead to chronic pain, instability and deformity of joints, restricted ROM, loss of strength in the hand, and impaired function of the upper extremity. When nonoperative management is not sufficient, surgical intervention coupled with individually designed and carefully supervised postoperative rehabilitation is indicated to improve and restore function.

Some of the more common surgical options for management of arthritis of the wrist and hand are listed in Box 19.3. Refer to Table 19.2 to see the groupings of impairments typically associated with each of these surgeries.

BOX 19.3 Surgical Intervention for RA or DJD of the Wrist and Hand

Soft Tissue Procedures

- Synovectomy
- Tenosynovectomy
- Tendon repair, graft, or transfer/realignment
- Nerve decompression
- Capsuloligamentous reconstruction
- Contracture release
  - Capsulectomy/capsulotomy
  - Tendon release
- Soft tissue arthroplasty

Joint and Boney Procedures

- Excision/resection arthroplasty
  - Styloidectomy
  - Proximal row carpectomy
- Tendon interposition/trapezial resection arthroplasty
- Interposition, flexible implant arthroplasty
- Surface replacement/total joint arthroplasty
- Arthrodesis

Soft tissue procedures, such as synovectomy, tenosynovectomy for chronic tenosynovitis of the extensor and flexor tendons of the wrist, repair of ruptured tendons, capsulotomy or release of other soft tissues for correcting a deformity, or muscle balancing of the wrist or finger joints, are employed independently or concomitantly when articular surfaces of the involved joints remain reasonably intact.[16,20,39,52,140,141] If joint deterioration is significant, resection arthroplasty, such as resection of the distal ulna (Darrach procedure) or proximal row carpectomy; arthrodesis; or implant arthroplasty, performed in conjunction with soft tissue repair or reconstruction, is a surgical option for advanced joint deterioration.[12,16,20]

Some procedures are selected to relieve pain and others to minimize or delay further deformity. For example, if medical management of RA of the wrist does not adequately control synovitis, tenosynovectomy is performed to remove proliferated synovium from tendon sheaths and to prevent erosion or rupture of tendons before significant deformity and loss of active control of the wrist and fingers occur.[140] If rupture occurs, tendon repair or transfer can improve function of the hand and delay or prevent subluxation and dislocation of joints or fixed deformities.[52,54]

Partial or complete arthrodesis of the wrist and arthrodesis of an individual joint of a digit, such as the CMC joint of the thumb, yield predictable and durable results. Fusion corrects deformity and gives the patient stability and relief of pain with only some compromise of function despite the loss of joint motion.[51,52,83] If fusion is inappropriate and pain-free functional mobility is necessary, implant arthroplasty—either interposition arthroplasty or total joint replacement—is an option. In many instances, a combination of joint and soft tissue procedures is indicated.[11,16,31] For the most part, however, arthroplasty is reserved for the patient who requires only low-demand use of the hand.

General goals. The goals of surgery and postoperative management of advanced arthritis and associated deformities

of the wrist and hand include:[11,16,60,124] (1) relief of pain, (2) restoration of normal or sufficient function of the wrist and hand, (3) correction of instability or deformity; (4) restoration of ROM, and (5) improved strength of the wrist and fingers for functional grips and pinch.

A discussion of several types of arthroplasty and general guidelines for postoperative management follow. Information on surgical management and postoperative rehabilitation of tendon repairs and transfers associated with RA is then outlined. Given the complexity of hand rehabilitation, suggested phase-specific guidelines for exercise, founded on principles of tissue healing, must be individualized for each patient and determined by the patient's level of participation in the rehabilitation process and response to exercise.

Successful outcomes are contingent upon close communication among the surgeon, therapist, and patient or patient's family. An effective postoperative rehabilitation program combines early, supervised therapy with patient education and progresses to long-term self-management by the patient. Although rehabilitation is deemed essential after each of the surgical interventions covered in this section, postoperative protocols vary and have not been compared for each type of procedure, making it difficult to suggest that there is one best approach to postoperative management.

Wrist Arthroplasty

Although arthrodesis of the wrist continues to be the most common surgical intervention for late-stage arthritis of the wrist, arthroplasty has become an acceptable alternative, particularly for patients with arthritis and impaired mobility of other joints of the extremities. Although wrist arthrodesis has not been shown to limit upper extremity function in daily living activities in patients with posttraumatic arthritis of the wrist only, it is thought that loss of wrist motion may adversely affect functions, such as personal care, in patients with RA who also have impaired mobility of other upper extremity joints.[137] For these patients, wrist arthroplasty—total joint replacement or flexible implant (interposition) arthroplasty—is an option that provides relief of symptoms while retaining some wrist mobility.

Indications for Surgery

The following are common indications for arthroplasty of the wrist.[1,11,12,16]

- Severe pain in the wrist region as the result of deterioration of the articular surfaces of the distal radius, carpals, and distal ulna from chronic arthritis (usually RA, but also OA and posttraumatic arthritis) that compromises hand and upper extremity function
- Deformity and marked limitation of wrist motion that cause muscle-tendon imbalances of the digits
- Subluxation or dislocation of the RC joint
- Appropriate procedure for *low-demand* upper extremity functional needs
- Appropriate procedure for patients with bilateral wrist involvement in which arthrodesis of both wrists would limit rather than improve overall function
- Also appropriate procedure for patients with significant stiffness of the ipsilateral shoulder, elbow, or finger joints in whom unilateral wrist arthrodesis would further limit, rather than improve, functional use of the upper extremity

CONTRAINDICATIONS Box 19.4 identifies some absolute and relative contraindications to wrist arthroplasty and arthroplasty of the joints of the fingers and thumb.[1,11,12,16]

Procedures

Implant Design, Materials, and Fixation

Because partial or total arthrodesis of the wrist is often considered the procedure of choice (not just a salvage procedure) for patients with severe pain and instability of the wrist[51,83] and because resection arthroplasty of the distal radius and proximal row carpectomy[39] are also suitable options that relieve pain but retain some mobility of the wrist, the use of joint replacement surgery for patients with late-stage arthritis of the wrist has been somewhat limited.[20] Nevertheless, designs of implants and operative techniques for arthroplasty of the wrist have gradually evolved.

During the late 1960s, Swanson first used a one-piece, uncemented, double-stemmed, flexible ("hinged") implant made of silicone for the radiocarpal joint, primarily for use in patients with RA.[125] The prosthesis, which is inserted between the distal radius, through the capitate, and into the intramedullary canal of the third metacarpal (after a proximal row carpectomy), is designed to act as a *dynamic spacer* to maintain joint alignment during healing. Over time, the implant becomes encapsulated, forming a new fibrous capsule.[12,125] Although the procedure provides pain relief and some degree of stability and ROM (approximately a 60° arc of flexion/extension and a total of 10° of radial and ulnar

BOX 19.4 Contraindications to Arthroplasty of the Wrist or Digits

Absolute
- Active infection
- Expected high-demand use of the hand (e.g., manual labor) or high-impact sport activities (e.g., tennis and volleyball)
- Inadequate motor control of the wrist or hand as the result of neurological damage
- Rupture of the radial wrist extensors
- Limited ROM without pain

Relative
- Severe and irreparable deformity of the wrist or digits
- Rupture of multiple extensor tendons of the digits
- Inadequate, poor quality bone stock
- Need for ambulation aids (e.g., crutches or a walker) that place significant forces across the wrist and hand
- Compromised immune system

deviation), its use has been associated with a high rate of failure as the result of excessive wear of the prosthesis or cystic changes in bone and eventual breakage or loosening of the prosthesis.[1,11,12,16] It also has been suggested that, as a silicone implant gradually wears (abrades), it may give rise to *particulate synovitis* (silicone synovitis).[61] Design changes have been made to reinforce the silicone implant with bone-shielding devices (titanium grommets) to improve the long-term durability of the prosthesis.[11,12] Despite improvements, with the increased use of rigid implants for wrist arthroplasty, flexible interposition implant arthroplasty now plays a limited role, with its use reserved for the low-demand, older (> 60 years) patient with RA.[16]

Numerous designs of total wrist replacement arthroplasty (Fig. 19.9) have been developed and consistently refined over the past few decades, making arthroplasty available not only to patients with late-stage joint disease but also those with severe deformity and collapse of the wrist joint.[11,77] Total wrist arthroplasty typically involves inserting a two-piece system with elliptical (convex-concave) surfaces that are loosely constrained or nonconstrained. Components are made of rigid materials (cobalt-chrome or titanium and high-density polyethylene). The implants are sometimes porous-coated along the stems for bio-ingrowth,[100] and a combination of cement and screws is employed for additional fixation.[11,12,16] Most total wrist systems are designed to allow a combined 90° arc of flexion and extension.

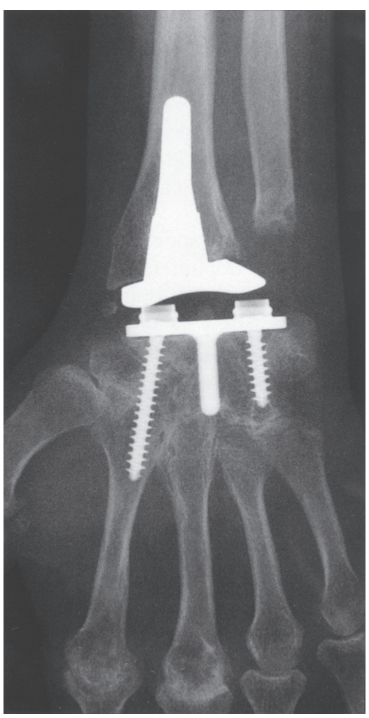

FIGURE 19.9 Total wrist arthroplasty. *(From Wadsworth, C, Steyers, C, and Adams, B: Postoperative Management of the Wrist and Hand. Independent Study Course 15.2. Postoperative Management of Orthopedic Surgeries. La Crosse, WI: Orthopedic Section, APTA, 2005:25, with permission.)*

Operative Overview

Total wrist arthroplasty requires a longitudinal incision along the dorsal aspect of the wrist in line with the third metacarpal.[11,12,16,72] Concomitant *dorsal clearance* (synovectomy of the wrist and tenosynovectomy of the extensor tendons) is often necessary. The retinaculum is incised and reflected, and the digital extensor tendons are retracted for access to the joint capsule.

The distal portions of the radius and ulna, some of the carpals, and a small portion of the proximal aspect of the third and often the second and fourth metacarpals are resected. The rigid, stemmed prosthetic components are then tightly fit into the reamed intramedullary canals of the necessary metacarpals and the distal radius.[11,52] With instability and subluxation of the radiocarpal joint, capsule and ligament reconstruction typically is performed to improve wrist stability. Soft tissue balancing is critical for satisfactory results.

After closure of the dorsal incision, the hand is placed in a long-arm or short-arm bulky compression dressing and elevated several days postoperatively to control edema.

Postoperative Management

Immobilization

After total wrist arthroplasty, the wrist is continuously immobilized in a neutral position for several days to 2 weeks. After the bulky, postoperative dressing is removed, the wrist and forearm are placed in a short-arm volar wrist splint with the wrist positioned in about 10° to 15° extension. The splint allows full finger ROM and opposition of the thumb. The time frame for removal of the splint for exercise varies from 1 to 4 weeks, depending on the extent of soft tissue reconstruction and bone stock qualtiy.[16,72,100]

If a concomitant repair of the extensor tendons was performed, the immobilizer is fitted with outriggers that have elastic slings to hold the fingers in extension. Even after wrist exercises are initiated, the immobilizer is worn for protection between exercise sessions. A static resting splint is worn at night for 6 to 8 weeks postoperatively.[54]

With a duration as short as 3 to 4 weeks or as long as 6 to 8 weeks, flexible implant arthroplasty generally requires a longer period of immobilization than total wrist replacement to allow time for encapsulation of the prosthetic spacer to occur.[122,138]

Exercise Progression

As with arthroplasty of other large or small joints, the goals and progression of exercise during each successive phase of rehabilitation after wrist arthroplasty (both total wrist or interposition arthroplasties) are based on the stages of soft tissue healing. If concomitant extensor tendon repairs were also done, the guidelines and timeframe for exercise are adjusted and special precautions are taken, as discussed in a later section of the chapter on repair of extensor tendon ruptures in RA.

CLINICAL TIP

When implementing a postoperative exercise program after any type of wrist arthroplasty, stability of the wrist always takes precedence over restoration of wrist mobility. As a point of interest with regard to wrist ROM, the results of biomechanical studies of normal individuals performing a variety of functional activities have revealed that no more than 35° of wrist flexion or extension is used during most activities.[92,102]

For protection of the wrist after arthroplasty, precautions, identified in Box 19.5, must be incorporated into postoperative exercises and functional activities during and after rehabilitation.[72,121]

Exercise: Maximum and Moderate Protection Phases

The focus of rehabilitation during the maximum protection phase is to control pain and peripheral edema, protect the wrist, and prevent stiffness of the rest of the upper extremity. When the immobilizer can be removed for wrist exercises, protection of the wrist is still essential.

The emphasis during the moderate protection (controlled motion) phase, which typically begins about 4 to 8 weeks postoperatively, is to gradually restore active control and mobility of the digits, wrist, and forearm motion without jeopardizing wrist stability

Goals and interventions. The following goals and interventions should be considered before and after the wrist immobilizer can be removed for exercise.[60,72,122,138]

- ***Maintain and later improve mobility of unoperated joints.***
  - Begin active ROM exercises of the digits, elbow, and shoulder while the wrist is immobilized and the use of the hand is restricted.
  - If there is limitation of finger mobility preoperatively, around 6 weeks postoperatively, selectively use low-load, dynamic finger splint(s) during the day or gentle passive stretching *initially with the wrist maintained in a neutral position* to increase mobility for a sufficient level of hand function.
  - Grade II and possibly grade III joint mobilization techniques are appropriate if the joints of the digits are not inflamed.
- ***Restore control and mobility of the wrist.***
  - Include active ROM, emphasizing wrist extension more than flexion, and tendon-gliding exercises with the wrist in neutral (see Fig. 19.17 A through E).

PRECAUTIONS: Postpone radial and ulnar deviation if wrist stability is questionable.[60] When performing radial and ulnar deviation, avoid wrist flexion with ulnar deviation (the position of wrist deformity).

- ***Regain use of wrist, finger, and thumb musculature.***
  - Start with gentle setting exercises and progress to low-intensity, isometric resistance exercises of the wrist and finger musculature.
  - After total wrist arthroplasty, begin to use the hand for light (minimum-load) functional activities around 6 to 8 weeks.[100]
  - After flexible implant arthroplasty, such use of the hand may be delayed until about 12 weeks postoperatively.[122]

Exercise: Minimum Protection/Return to Function Phase

During the final phase of rehabilitation, which usually does not begin until 8 to 12 weeks postoperatively, regaining sufficient strength and muscular endurance of the entire upper extremity for appropriate functional activities is the priority.[72] In the wrist, emphasize strengthening the wrist extensors rather than the wrist flexors. Patient education focuses on incorporating joint protection during functional activities (refer to Box 19.2). Use of a cock-up resting splint is advisable at night, particularly if a wrist flexion contracture persists. Although 15° of wrist extension is preferable for a strong functional grasp, the use of manual stretching procedures to increase wrist extension is not consistently advocated, as they may compromise wrist stability.[122]

Goals and interventions. The following goals and interventions can be progressed as the extent of protection decreases.

- ***Regain functional strength of the hand and wrist.***
  - Transition to low-intensity, dynamic resistance (about 1 lb) exercises of the hand and wrist.[72]
  - Emphasize simulated functional movement patterns, such as various types of grasping activities, being certain to reinforce principles of joint protection.[95] If not previously initiated, begin to use the hand for light functional activities.
  - Twelve weeks after total wrist arthroplasty or flexible implant arthroplasty, the patient may use the hand for most low-load functional activities.[100,138]
- ***Increase ROM of the wrist to a functional level.***
  - Continue active ROM and gentle stretching exercises as dictated by the stability of the wrist.

BOX 19.5 Precautions After Wrist Arthroplasty

- Avoid weight bearing on the operated hand during transfers, ambulation with assistive devices, or other daily living activities.
- If ambulation aids are required because of lower extremity joint involvement, use forearm-support crutches or walker.
- Avoid functional activities that place more than 5- to 10-lb loads on the wrist.
- Wear a wrist splint for additional protection during functional activities.
- Permanently refrain from high-impact vocational or recreational activities, such as heavy labor or racquet sports.

- Use low-load dynamic splinting of the wrist, emphasizing wrist extension to at least 15°.
- In patients who exhibit significant postoperative stiffness of the wrist soon after surgery, stretching activities may be initiated earlier than during the minimum protection phase, possibly at 6 weeks postoperatively.[138]

Outcomes

A successful outcome after wrist arthroplasty gives the patient a stable, pain-free wrist with functional ROM. Postoperative outcomes typically measured are pain relief, use of the hand for functional activities, wrist and forearm ROM, and grip strength. Instruments, such as the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire and the Patient-Rated Wrist Evaluation, are used to assess pain, function, and satisfaction.

For the patient with late-stage arthritis in multiple joints, the sequencing of joint surgeries is critical for successful outcomes. For example, a hip or knee replacement should be done before wrist arthroplasty to avoid the need to place weight on the wrist replacement when using an assistive device for ambulation.[1]

Pain relief. Barring complications, short- and long-term relief of pain after flexible implant arthroplasty[64,122] and total wrist arthroplasty[11,16] is a consistent finding. For example, in a retrospective study that followed 14 patients with arthritis of the wrist (12 with RA), who underwent 17 primary semi-constrained total wrist replacements, preoperatively 88% of wrists (15 of 17) were ranked as moderately to severely painful. Postoperatively, all wrists were less painful, with 15 ranked as pain-free and 2 as mildly painful.[100] Another resource indicated that about 75% of patients experience complete pain relief after total wrist arthroplasty.[16]

In a long-term study, patients with RA who underwent Swanson silicone wrist arthroplasty were followed for a minimum of 10 years (mean follow-up 15 years) and reported "good" or "very good" outcomes, primarily due to adequate pain relief.[64]

Wrist and forearm ROM, strength, and function. Improvement in ROM is less predictable than pain relief. ROM of the wrist achieved postoperatively is usually about 15° to 30° each of wrist flexion and extension, 5° to 10° each of radial and ulnar deviation, and at least a 100° arc of pronation and supination.[122] A functional level of active wrist ROM appears to be retained over an extended number of years. For example, 10 or more years after implantation of the Swanson silicone prosthesis, a group of patients (all with RA) in a follow-up study had 28° flexion and 15° extension (i.e., a total flexion/extension arc of 43°).[64]

In studies comparing pre- and postoperative results of newer designs of total wrist arthroplasty, the postoperative ROM reported was greater for most motions than ROM achieved after flexible implant arthroplasty. However, actual *improvements* in ROM after arthroplasty have[42] and have not[100] been statistically significant.

Grip strength[100] and use of the operated hand for functional activities[42] routinely improve after wrist arthroplasty. Relief of pain has an obvious impact on hand function. Concomitant soft tissue repair, such as repair of ruptured tendons, also contributes to improved function. Furthermore, arthroplasty provides some additional length to the wrist, which in turn improves the length-tension relationship of the muscle-tendon units that cross the wrist.[11]

Complications. Complication rates have always been higher for wrist arthroplasty, particularly the early designs, than replacement arthroplasty of larger joints, such as the shoulder, hip, and knee.[12] Potential complications, any of which can compromise outcomes following wrist arthroplasty, fall into two broad categories: intraoperative and postoperative.[1]

During surgery, there is a risk of fracture of the radius or carpal bone during component implantation, particularly if there is weakening of the cortical bone from long-standing synovitis. This complication requires use of a bone graft and an extended period of immobilization, which can result in postoperative tendon adhesions and stiffness of the wrist. There is also risk of intraoperative damage to an extensor tendon when exposing the joint, requiring repair of the tendon and modification of postoperative exercises so as not to place excessive stress on the repaired tendon.

Postoperative complications include wound infection, dislocation or component loosening, and component wear and eventual breakage. One resource has suggested that one in five wrist arthroplasties requires revision within 5 years.[11] After flexible implant arthroplasty, prosthetic breakage rates have been reported at 20%[52] and 22%[113] 5 to 10 years postoperatively. Loosening of the distal component and dislocation are frequently reported complications associated with total wrist arthroplasty,[1,11,16] particularly the early designs.[77] Early results of recent modifications to implant designs appear to decrease the rate of loosening.[16,42,100]

Complications may require an alternative procedure or revision arthroplasty. If a silicone implant arthroplasty fails, total wrist replacement is still possible; if a total wrist arthroplasty fails because of mechanical loosening or component failure, revision arthroplasty and wrist arthrodesis are still viable alternatives.[1,11,12,51,83]

Metacarpophalangeal Implant Arthroplasty

Arthroplasty of the MCP joints of fingers (digits 2 to 5), combined with necessary reconstruction of soft tissues, is the most common surgical procedure performed to manage impaired function and progressive deformity as the result of late-stage RA of the hand.[31] In patients with RA, hand function has been shown to improve over a 1-year period following MCP arthroplasty when combined with ongoing medical management. In contrast, the level of hand function does not deteriorate but does not improve over the same time period with ongoing medical management alone.[29]

Arthroplasty is also an option for patients with idiopathic OA and posttraumatic arthritis of the MCP joints.[31,98,116]

For MCP arthroplasty to be successful, a patient must have intact extensor digitorum communis tendons, or repair of these tendons must be performed. The two procedures may be staged, one prior to the other, or performed simultaneously as determined by the surgeon. Other procedures to balance soft tissues must also accompany MCP arthroplasty for improved hand function postoperatively.[31,75,116]

If joints other than the MCP joints are involved, which is often the case in RA, surgeries are carefully sequenced. For example, if the wrist is involved, a radiolunate or total wrist arthrodesis for pain-free wrist stability in a functional position may be necessary prior to MCP arthroplasty. In contrast, a swan-neck deformity of a finger is managed with PIP fusion in 30° to 40° of flexion, but typically it is done after—not before—MCP arthroplasty.[31,121]

Similar to wrist arthroplasty, the overall goals of this surgery and postoperative management are to relieve pain, correct alignment of the fingers, improve active hand opening and grasp, and improve the cosmetic appearance of the hand.[75,121]

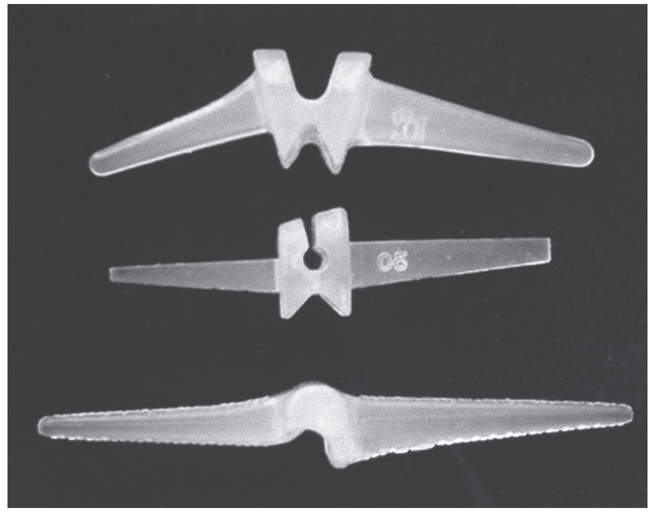

FIGURE 19.10 Lateral view of the three most common silicone-based implants: Neuflex (*top*), Avanta (*middle*), Swanson (*bottom*). Note that the Avanta and Swanson implants are of a 0° bend type. *(From Manuel, JLM, and Weiss, APC: Silicone metacarpophalangeal joint arthroplasty. In: Strickland, JW, Graham, TJ [eds]: Master Techniques in Orthopedic Surgery—The Hand, ed. 2. Philadelphia: Lippincott Williams & Wilkins, 2005, p. 393, with permission.)*

Indications for Surgery

The following are common indications for arthroplasty of the MCP joint(s).[12,31,75,116]

- Pain at the MCP joint(s) of the hand and diminished hand function as the result of deterioration of the articular surfaces, usually because of RA but sometimes as the result of OA or posttraumatic arthritis
- Instability, often coupled with volar subluxation, and deformity (flexion and ulnar drift) of the MCP joint(s) that cannot be corrected with soft tissue releases and reconstruction alone
- Stiffness and decreased active ROM of the MCP joints, often associated with a deficient extensor mechanism, causing inability to open the hand to grasp large objects
- Poor appearance of the hand as the result of deformity

Procedures

Implant Design, Materials, and Fixation

MCP joint arthroplasty is designed to provide a balance of stability and mobility to the MCP joints for patients with late-stage arthritis. Several designs using different materials and methods of fixation have been developed over the past few decades. Swanson developed a one-piece, flexible, double-stemmed prosthesis made of silicone (Fig. 19.10) that is uncemented; it serves as a dynamic spacer and an internal joint mold, as it becomes encapsulated during the healing process.[12,15,55,75,84] The implant maintains internal alignment of the joint during healing and allows early postoperative joint motion. As with radiocarpal flexible implants, the MCP silicone implant sometimes is reinforced with circumferential titanium grommets to minimize long-term component wear or fracture and the possibility of silicone synovitis.[124]

Although the original Swanson implant has undergone some minor design changes, it has been a highly reliable design and remains the most widely used MCP implant for patients with RA.[31,124] The Swanson implant also has been used successfully in patients with OA[98] and posttraumatic arthritis.[31]

Other silicone implants have been developed as alternatives to the Swanson implant. One such design is the Neuflex® implant (see Fig. 19.10), which is preformed in 30° of flexion to replicate the position of the MCP joints when the hand is at rest. The design is intended to improve ROM.[41,75]

As an alternative to flexible implant arthroplasty, two-component, convex-concave, surface replacements made of either metal and high-density polyethylene or pyrolytic carbon (pyrocarbon) with highly polished, articular surfaces also have been developed.[31,44] The metal-plastic surface replacements typically use cement fixation, but the pyrocarbon implants rely exclusively on press-fit, noncemented fixation because of the nature of the material.[30,31]

Unlike the one-piece flexible implants, the two-component NCP joint replacements have little to no inherent stability and therefore must rely on intact or repairable collateral ligaments for joint stability. Consequently, the two-component designs are used infrequently for patients with RA who typically have poor quality soft tissues as the result of long-standing inflammation and deformity, making it difficult to repair the collateral ligaments. Rather, these designs are reserved for patients with OA or posttraumatic arthritis whose collateral ligaments are either intact or can be repaired.[44] One resource suggests that a silicone implant is indicated if there is an extensor lag (lack of active extension) of the MCP joints > 60° and ulnar deviation > 45°.[31]

Operative Overview

MCP arthroplasty and related soft tissue balancing involve the following procedures.[31,75,98] The involved MCP joints are approached by either a single, transverse incision over the dorsal aspect of the metacarpal heads or by double, longitudinal incisions made between the index and middle fingers and the ring and little fingers. The joint capsule is exposed by carefully separating the extensor tendons, which are often ulnarly displaced, from the underlying capsule and longitudinally incising the extensor hood. The tendons are retracted; the ulnar and possibly the radial collateral ligaments, if intact, are reflected from the head of each metacarpal; and the dorsal aspect of the capsule is incised (capsulotomy). Every effort is made to preserve the radial collateral ligaments. A synovectomy is performed if necessary. If a significant flexion contracture exists, the volar aspect of each capsule may also be incised to allow greater extension of the MCP joints.

The heads (distal aspect) of the metacarpals and proximal aspect of the first phalanges of the involved joints are excised, and the intramedullary canals of the metacarpals and proximal phalanges are widened to accept the prosthetic implants. After insertion of the implants, the ROM of the replaced joints is checked. The joint capsule, radial collateral ligament (if preserved), and extensor mechanism of each digit are repaired. The wound is then closed, and a bulky compression dressing and volar hand and forearm splint are placed on the hand. The hand is elevated to control edema.

Postoperative Management

As with arthroplasty of the wrist or other joints of the digits, the postoperative rehabilitation program is founded on the principles of soft tissue healing and includes phase-specific goals and interventions, including the use of dynamic and/or static splinting and a supervised home exercise program.

General postoperative guidelines from a number of resources for a progression of exercises combined with the use of splints to maintain alignment and protect soft tissues as they heal are summarized in this section.[14,21,31,124,130,138] These guidelines must be individualized, based on the type of arthroplasty and soft tissue procedures performed and each patient's response. Ongoing patient education and close communication with the surgeon are essential for effective outcomes. Postoperative rehabilitation continues for 3 to 6 months.

Immobilization

Initially, the wrist and hand are continuously immobilized in the bulky compression dressing and volar splint applied at the end of surgery, with the wrist positioned in neutral, the MCP joints in full extension and either neutral or slight radial deviation (opposite the position of deformity), and the distal joints (PIP and DIP) in slight flexion.[31,72,124] In some instances, the splint extends only to the level of the PIP joints.[98] The bulky dressing is later replaced with a light compression dressing.

Continuous immobilization is not lengthy but varies with the type of arthroplasty, the type and quality of the soft tissue repairs, and the stability of the reconstructed joints. If only an MCP implant was performed, the hand remains immobilized for only a few days. If, in addition to the MCP arthroplasty, ruptured extensor tendons also were repaired or transferred, the hand remains immobilized longer to protect the tendons.[54]

Dynamic splinting. When the compression dressing is removed, the hand is placed in a dynamic MCP extension splint with an outrigger (Fig. 19.11). The splint is worn to protect healing structures, maintain alignment (to prevent recurrent flexion and ulnar drift deformities at the MCP joints), and control and guide the range and plane of motion during exercises as soft tissues heal.[14,29,124,130,135]

FIGURE 19.11 A dynamic extension splint with rubber bands attached to a dorsal outrigger used after MCP arthroplasty, permits active MCP flexion, and at rest, maintains the MCP joints in extension and sometimes slight radial deviation. *(Courtesy of Janet Bailey, OTR/L, CHT.)*

The dynamic splint holds the wrist in about 10° to 15° of extension and the MCP joints in full extension and slight radial deviation as well as supination of the index finger, but it does not control motion in the IP joints. Slings under the proximal phalanx of each finger with rubber bands attached to the outrigger of the splint hold the MCP joints in extension when the hand is at rest but still allow active flexion of the MCP joints within a functional range. The patient wears the dynamic splint throughout the day, including exercise sessions for about 6 weeks.[29]

In some instances, a dynamic MCP flexion splint may be indicated at 2 to 3 weeks and worn intermittently or alternately during the day with the dynamic extension splint if sufficient MCP flexion has not yet been attained, particularly in digits 3, 4, and 5.[12,14,72,124,130,135,138] By 6 weeks—but sometimes as late as 12 weeks postoperatively—dynamic splinting is gradually discontinued unless an active extensor lag or a flexion or extension contracture of the MCP joints persists.[14,29,31,72,124,130,135]

Static splinting. If a dynamic splint is worn during the day, the patient wears a volar static (resting splint), which holds the wrist in 15° of extension and the fingers in full or almost full extension, at night. A block along the ulnar border of the

splint prevents ulnar deviation of the fingers. If a flexion contracture or active extensor lag of the MCP joints is present, night splinting is often continued for 3 to 4 months or as long as a year.[14,72,130,135]

Although dynamic splinting is widely used after MCP arthroplasty, another option is the alternating use of two static splints, one that holds all of the finger joints in extension and another that holds the MCP joints in flexion and the PIP and DIP joints in almost full extension.[21] Each splint is worn for 24 hours at a time. During the day, the splint is removed frequently for gentle assisted ROM exercises. Some clinicians suggest that static splints are as effective as dynamic splints; easier and less expensive to fabricate, modify, and self apply; and less cumbersome to wear, because there is no need for the high-profile outrigger and rubber band suspension slings used in a dynamic splint.[21]

FOCUS ON EVIDENCE

In a prospective study by Burr and colleagues[21] designed to investigate the effectiveness of an alternating static splinting regimen combined with postoperative exercises as an alternative to dynamic splinting, 15 patients with RA who underwent 51 MCP silicone implant arthroplasties were followed for 19 months. The results indicated there was a significant improvement in the mean total arc of active flexion/extension when the preoperative ROM of all MCP joints (27.6°) was compared to the postoperative ROM (47.2°) at 19 months. In addition, there was a significant improvement in the total arc of active MCP flexion/extension for each of the four fingers. The mean active MCP extension deficit also improved significantly from 50° before surgery to 18° postoperatively. The degree of ulnar deviation also improved, decreasing from 30.4° to 9.7°.

Although this study did not include a dynamic splint comparison group, the investigators compared their findings to the results of other studies over a similar period of follow-up in which dynamic splinting had been used and found that the two approaches to splinting yielded similar results.

Exercise Progression

Protected motion in a dynamic splint or out of a static splint is initiated as early as 3 to 5 days or as late as 10 to 14 days postoperatively when the bulky compression dressing is removed and splints have been fabricated.[14,21,31,72,124,130] Time frames vary with the type of procedures performed, the underlying pathology, and the stability of the joint. Even after the bulky dressing is removed, exercise may be delayed for several weeks for a patient with poor quality soft tissue repairs and potential joint instability or delayed wound healing.

With OA or posttraumatic arthritis, the involved MCP joints usually are stable postoperatively. Therefore, MCP exercises typically are begun earlier and progressed more rapidly in these patients than is permissible for patients with RA, whose joints tend to be less stable as the result of long-standing tissue inflammation and deformities.[98]

Swanson and associates[124] proposed that a goal of exercise for the patient with RA is to achieve full or almost full active extension and about 45° and 60° of flexion of the MCP joints of the index and middle fingers respectively and 70° in the ring and little fingers. Greater ROM may be possible for the patient with OA, particularly in the index and middle fingers. In addition to improving the overall excursion of each reconstructed joint, another goal of exercise is to *elevate* the arc of active MCP motion to a more functional range—that is, to decrease or eliminate the active extension deficit (extensor lag) while increasing flexion to improve hand opening and grasp.[21,55]

CLINICAL TIP

During the course of rehabilitation, active MCP flexion usually plateaus before active MCP extension, with flexion leveling off at about 3 to 4 months but extension often continuing to improve for up to a year.[40]

Exercise: Maximum Protection Phase

For the first 4 to 6 weeks, the patient performs only assisted or active exercises and is not allowed to use the hand for functional activities. The focus of management is to protect healing structures while applying safe levels of stress to soft tissues to influence organized scar tissue formation and prevent adhesions through protected motion within limited ranges. Early motion also assists in controlling or reducing postoperative peripheral edema.

CLINICAL TIP

Every effort should be made to obtain the desired degree of flexion—particularly in the ring and little fingers—by the end of the third week postoperatively. At this time, the reconstructed joint capsules become very tight, and gaining additional joint ROM becomes difficult.[124,130]

Goals and interventions. The following goals and exercises are emphasized during the maximum protection phase.[14,21,72,130,135,138]

- ***Maintain mobility of the shoulder, elbow, and forearm.***
  - Perform active shoulder, elbow, and forearm ROM. This is particularly important for patients whose RA is affecting multiple joints of the body.
- ***Improve functional ROM of the fingers and maintain gliding of tendons within their sheaths.***
  - Initiate active PIP and DIP flexion and extension, with the MCP joints held in extension by the dynamic splint. If static splinting is used, remove the splint and

teach the patient to manually stabilize the MCP joints in extension.

- Perform active, pain-free MCP flexion initially with the IP joints in extension followed by extension of the MCP joints assisted manually or by the dynamic splint. The dynamic splint usually allows no more than 60° to 70° of MCP flexion.[72,130] Manually stabilize the IP joints in extension or temporarily splint them in extension with tape and tongue depressors during exercise sessions, so the lumbricals act to flex the MCP joints. If multiple MCP joints have been replaced, which is usually the case in patients with RA, have the patient exercise one MCP joint at a time to be certain that flexion and extension increase in each of the MCP joints. If the patient is having difficulty actively flexing the MCP joint of the little finger, the fourth and fifth digits can be taped together some of the time to allow the ring finger to assist flexion of the little finger.[14,21,72,130]
- If it is permissible to remove the splint for exercise, teach the patient to perform active radial deviation of the MCP joints by placing the open hand palm-down on a table, stabilizing the dorsum of the hand with the opposite hand, and sliding ("walking") the fingers toward the thumb.
- Include active composite finger flexion and opposition of the thumb to each digit, emphasizing pad-to-pad pinch rather than lateral pinch.

PRECAUTIONS: During exercise, avoid lateral pressure of the thumb against the digits, which could contribute to recurrence of an ulnar deviation deformity of the fingers. Carefully observe the incision during MCP flexion, being certain to avoid excessive tension on the skin and delay wound closure.

- ***Prevent adhesions along the healed incision.***
  - Perform gentle mobilization of the scar when sutures have been removed.

Exercise: Moderate and Minimum Protection Phases

The emphasis of the *moderate protection phase*, which begins at about 3 to 4 weeks or as late as 6 weeks postoperatively, is to achieve full *active* extension of the MCP joints (no extensor lag) and continue to increase active MCP flexion as early as possible during this phase of rehabilitation for functional use of the hand.[14,124,130,135]

At the beginning of this phase or by 6 weeks, removal of the dynamic extension splint for exercise may be permissible if the MCP joints are stable. Very low-intensity strengthening exercises and light use of the hand for ADL also are initiated around 4 to 6 weeks. If the joints are stable and well aligned and there is sufficient MCP flexion and no active extension deficit, daytime splinting during general activity is gradually discontinued starting around 6 weeks or as late as 12 weeks if joint stability is in question.[14,21,72]

During the *minimum protection phase*, which begins around 8 to 12 weeks postoperatively, progressive strengthening of the wrist and hand musculature and increasing use of the hand for functional activities while reinforcing principles of joint protection are emphasized. In most instances, a patient is allowed full use of the hand for light to moderate functional tasks by 12 weeks postoperatively.

Goals and interventions. During the moderate and minimum protection phases, goals include the following.[14,21,31,72,124,130,135]

- ***Continue to increase ROM and active control of the MCP joints.***
  - Have the patient continue active flexion exercises in the dynamic splint or with the static splint removed and even after daytime splinting is discontinued. Add gentle passive stretching, one finger at a time, to increase flexion.
  - Emphasize active MCP extension with the wrist in neutral and the IP joints flexed (the intrinsic minus/hook fist position of the hand) to reinforce the action of the extensor digitorum communis (EDC) muscle and minimize influence of the intrinsic finger extensors. This movement also promotes gliding of the extrinsic extensors in the tendon sheaths.
  - Reinforce end-range MCP extension by maintaining the extended position briefly with each repetition.
- ***Restore ROM of the wrist.***
  - When the dynamic splint can be removed during exercise, initiate active ROM of the wrist, emphasizing wrist extension. Be sure the fingers are relaxed during wrist motions.
- ***Improve functional strength of the hand and wrist.***
  - Have the patient begin isometric flexion and extension against submaximal manual resistance or a solid object at 6 to 8 weeks postoperatively. Then transition to resisted dynamic finger flexion and extension using a variety of exercise devices, such as a small spring-loaded hand exerciser or exercise putty.
  - Include resisted radial deviation of the digits. For example, have the patient place the hand on a table palm-down and stabilize the dorsum of the involved hand with the opposite hand. Abduct the index finger against the resistance of a rubber band or push against a coffee cup and slide it across the table.[14]
- ***Regain use of the hand for functional activities while protecting the operated joints to prevent recurrence of deformity.***
  - Reinforce principles of joint protection and energy conservation through patient education (see Box 19.2). Emphasize avoidance of stresses on the fingers in an ulnar direction.
  - Perform simulated functional grasping activities, beginning with light prehension activities. Use the hand for light to moderate functional activities by 8 to 12 weeks postoperatively.
  - Modify activities of daily living that could contribute to deforming stresses on the MCP or other involved joints.[72,94,95] Consider use of a commercially fabricated, hand-based, digital alignment splint made of neoprene during heavier, more stressful activities.[14]

Outcomes

A successful outcome provides the patient with pain-free, stable, properly aligned MCP joints combined with improved active extension of the digits while retaining or improving MCP flexion sufficient for functional grasp. Of these outcomes, pain relief is the primary value of MCP arthroplasty.

Pain relief and patient satisfaction. Pain relief is excellent or good for most patients, and correction of a flexion/ulnar drift deformity is consistently sufficient after silicone implant arthroplasty and resurfacing arthroplasty. Both of these outcomes contribute to patient satisfaction, because they improve hand function and the cosmetic appearance of the hand.[29,31]

ROM and hand function. As noted previously, approximately 70° of active flexion of the MCP joints of the ring and little fingers and 45° to 60° of flexion of the index and middle fingers, full active extension, and correction of ulnar drift of the fingers and pronation of the index finger are considered an ideal overall result.[124]

This degree of mobility enables a patient to open the hand far enough to grasp large objects, touch the fingertips of the ulnar digits to the palm (which is necessary for grasping small objects), and touch the tips of the index finger and thumb for pinch. Less MCP flexion in the index and middle fingers is acceptable because limited motion of the MCP joints enhances stability and allows dexterity and pinch without compromising functional grasp.[12,124] In an early follow-up study[15] of 28 patients with RA after 115 Swanson implant arthroplasties followed by a dynamic splinting program, the mean arc of active motion for all operated joints at 54 months was 43° (56° of flexion with a 13° active extension deficit). In a review of a number of short- and long-term studies of patients with various types of arthritis undergoing MCP arthroplasty, the postoperative range of MCP flexion/extension varied considerably from study to study, with the mean arc of active motion for all fingers reported to be 45° and a mean extensor lag of 15°.[31] In another review of studies in which only the Swanson silicone implant arthroplasty was used in patients with RA, the reviewers found that the mean postoperative arc of active motion was 50° with a range of flexion from 39° to 67° and an active extension deficit from 7° to 28°.[40] In the early study and in both reviews, the ROM outcomes are less than the potential ranges suggested by Swanson and associates.[124] However, postoperative ROM was not reported for individual fingers in any of these studies.

When comparing pre- and postoperative mobility, the total range of flexion/extension may increase only to a small or moderate extent, but the arc of active motion postoperatively often is elevated and becomes more functional. For example, in an 8-year follow-up study of 901 Swanson silicone MCP implants in 294 patients with RA, the mean total active ROM was 40° preoperatively and 50° postoperatively, an increase of only 10°. However, active MCP extension deficit was 40° preoperatively but only 10° postoperatively, creating a more functional range of active MCP movement (an arc from 10° to 60° of flexion) for hand closing and opening.[55] Similar findings were reported in a follow-up study of two-piece, nonconstrained, pyrocarbon implants.[30] In this study, the prosthetic joints were stable and pain-free, and the mean range of flexion/extension improved by just 13°, but the arc of motion was elevated by 16°.

Few studies have directly compared one type of prosthetic implant to another. However, a recent prospective, double-blind study of patients with RA, which followed patients for 2 years postoperatively, compared the results of two types of silicone implant, the Swanson and the Neuflex® designs (see Fig. 19.10). The findings indicated there was a significantly greater improvement in MCP flexion in patients who received the Neuflex® design than in patients who received the Swanson implant, but there was no significant difference in active MCP extension, ulnar deviation, or grip strength between the two groups.[41] Of interest in this study is that the Neuflex® implant, which is preformed in 30° of flexion, did not adversely affect active MCP extension, which had been a concern of the investigators.

Although satisfactory improvement of MCP mobility and a significant correction of deformity (decreased ulnar drift of the fingers) are predictable outcomes after joint arthroplasty, grip and pinch strength do not seem to increase significantly or consistently, or they improve only modestly.[31] For example, results of a study by Chung and associates[29] demonstrated that grip and pinch strength had decreased at 6 months after surgery (compared to preoperative measurements) and then gradually increased to preoperative levels by 1 year.

Complications. As the result of a number of complications, approximately 70% of MCP silicone implants survive 10 years before revision is necessary.[31] However, some postoperative complications affect outcomes but do not necessitate additional surgery. Delayed wound healing is a short-term complication that may have an adverse effect on re-establishing adequate MCP flexion for functional grasp.[121]

As with the wrist, the most common long-term complication after silicone implant arthroplasty is breakage of the prosthesis,[12,44,124] whereas subluxation or dislocation, mechanical loosening, and periprosthetic fracture are common reasons for failure of the two-component metal-plastic and pyrocarbon designs.[30,31,44] It is believed that these long-term complications can be minimized if the patient adheres to joint protection principles by consistently avoiding heavy loads, high-impact activities, and deforming forces on the reconstructed joints.

Proximal Interphalangeal Implant Arthroplasty

There are a number of joint and soft tissue procedures for managing arthritis and associated deformities of the PIP joints. They include soft tissue release and reconstruction for swan-neck and boutonnière deformities[121] and implant arthroplasty or arthrodesis when there is significant destruction of the articular surfaces.[1,69,123,127] PIP arthroplasty is used more frequently for late-stage OA or posttraumatic arthritis

than for RA, but may or may not be preferable to arthrodesis to improve functional use of the hand.

In the ulnar digits, where mobility of the PIP joints is particularly important for functional grasp, arthroplasty may be the procedure of choice.[52] However, in the index finger, where stability of the PIP joint is a necessity for many functional tasks, arthrodesis is often preferable.[2,12,124] If the MCP and PIP joints are involved, as is often the case in patients with RA, the MCP joint is usually replaced, but the PIP joint deformity (usually a swan-neck deformity) is corrected by soft tissue reconstruction[124] or fusion.[2]

Indications for Surgery

In general, PIP implant arthroplasty is indicated for patients with isolated PIP involvement, particularly those who are free of MCP joint disease. Implant arthroplasty of contiguous joints (both the MCP and PIP joints) is not recommended.[12,123,124] The following are commonly accepted indications for PIP joint arthroplasty.[2,12,52,53,72,123]

- PIP joint pain and destruction of the articular surfaces (with or without joint subluxation) secondary to OA or posttraumatic arthritis (less frequently indicated for RA) when nonoperative management has been unsuccessful
- Loss of hand function as the result of joint stiffness, deformity, and decreased ROM that cannot be corrected with soft tissue reconstruction and/or nonoperative treatment
- Only occasionally for isolated boutonnière deformity or swan-neck deformity if fusion is not a viable option

NOTE: Necessary prerequisites for PIP arthroplasty include adequate bone stock, intact neurovascular system, and functioning flexor/extensor mechanisms.[12,53,72,123]

Procedure

Implant Design, Materials, and Fixation

The type of arthroplasty of the PIP joint selected by the surgeon depends on the underlying pathology, the extent of associated impairments and deformities, and the experience of the surgeon. As with MCP arthroplasty, there are two categories of implant arthroplasty for the PIP joints: a one-piece, flexible silicone joint spacer[12,123,127] or a two-component (nonarticulated), minimally constrained, surface (total joint) replacement system made of metal and plastic or pyrolytic carbon.[2,69,121,127,139] The components of a metal-plastic surface replacement are secured by cement fixation. In contrast, the pyrolytic carbon designs involve noncemented, press-fit fixation.

The silicone implant, designed by Swanson during the 1960s, remains in use today.[123,124] Two-piece, surface replacement systems, first developed during the late 1970s, have undergone many design changes and improvements.[2,12,127] A surface replacement design affords greater joint mobility than the one-piece silicone design but provides no inherent stability. Therefore, when PIP arthroplasty is deemed appropriate for patients with RA, who typically have compromised joint stability as the result of damage to periarticular soft tissues secondary to chronic synovitis, a one-piece silicone implant tends to be used to provide some stability to the joint. In contrast, surface replacement arthroplasty is used almost exclusively in patients with OA or posttraumatic arthritis, because the collateral ligaments usually are intact or repairable.

Operative Overview

A curved, longitudinal incision is made usually along the dorsal aspect of the PIP joint. Occasionally, a volar (palmar) or lateral approach is used. With a dorsal approach, either a *central slip-sparing technique* (which leaves the central tendon intact) or a *central slip-splinting technique* (where the central tendon is incised longitudinally) is used. The latter approach is selected when there is significant joint deformity. Table 19.3 provides an overview of which soft tissues are released, repaired, and require protection during the postoperative program and which structures remain intact during the operative procedure.[2,10,53,69]

CLINICAL TIP

Although published resources provide descriptions of the various surgical approaches, it is important to review the operative report in a patient's medical record to learn what type of surgical approach was used and which soft tissue structures were incised or released, repaired prior to closure, and will require protection during rehabilitation.

TABLE 19.3 Comparison of Surgical Approaches for PIP Joint Arthroplasty

Type of Approach	Structures Released, Repaired, and Protected Postoperatively	Structures Left Intact
Dorsal approach—central slip-sparing technique	Collateral ligaments incised/repaired; Volar plate disrupted	Central tendon/extensor mechanism intact; allows AROM immediately after surgery
Dorsal approach—central slip-splitting technique	Central tendon incised longitudinally and detached; delays AROM after surgery Volar plate may or may not be disrupted	Collateral ligaments intact; provides joint stability

Portions of the head of the proximal phalanx and the base of the middle phalanx are resected. The intramedullary canals of the proximal and middle phalanges are reamed and prepared for the prosthetic implant(s), which is then inserted.

If necessary, the volar plate is released for a flexion contracture, and the extensor tendon mechanism (if split during the approach) is repaired. Then the joint capsule is repaired; the wound closed; and a bulky compression dressing placed on the hand. The hand is supported in a volar splint, which includes the forearm, and elevated in a sling above the level of the shoulder to minimize edema.

Postoperative Management

Immobilization

When the surgical dressing is removed, a custom volar resting splint and possibly a dynamic extension splint with an outrigger are fabricated. These are hand-based splints that leave the wrist free but maintain the MCP joints in flexion.[2,12,53,124,131] An extension stop also may be incorporated into the splint to limit PIP hyperextension.[139] The position of PIP joint immobilization varies with the type of preoperative deformity that existed and the type of soft tissue reconstruction performed. Recommended positions of the immobilization are summarized in Table 19.4.[2,12,124,131]

The duration of immobilization varies with the type of arthroplasty, whether extensor tendon or collateral ligament reconstruction of the fingers was part of the procedure, and the surgeon's philosophy.[2,12,52,53,72,124,131] Protective splinting with frequent sessions of assisted or active exercises continues during the day for at least 6 to 8 weeks postoperatively and is gradually eliminated by 12 weeks. Night splinting may continue for 3 to 6 months or up to a year to protect the repaired joint(s).

Exercise Progression

The sequence of exercises after PIP arthroplasty emphasizes early but protected motion of the operated and adjacent joints. The time frame for initiating PIP exercises in the dynamic splint or out of the static splint varies from a few days[2,52,53,72,139] to 10 to 14 days[131] postoperatively based on the type and extent of impairments of the fingers preoperatively and the type of prosthetic implant and reconstructive procedures used. For example, after a *central slip-sparing approach* (extensor mechanism remains intact), ROM exercises are initiated as soon as the bulky dressing has been removed (1 to 3 days postoperatively). After a *central slip-splitting approach* in a joint with no associated swan-neck or boutonnière deformity, ROM exercises are begun several days to a week to 10 days later.

The goals of exercise during each of the following phases of rehabilitation after PIP arthroplasty are similar to those already detailed in this chapter for rehabilitation after MCP arthroplasty. Only guidelines and precautions unique to PIP arthroplasty or procedures for associated correction of specific soft tissue deformities of the PIP joints are addressed in this section.

TABLE 19.4 Position of Immobilization After PIP Arthroplasty

Preoperative Deformity	Postoperative Positioning in Splint
PIP flexion contracture	PIP extension
Boutonnière deformity	PIP extension and slight DIP flexion
Swan-neck deformity	–10° to 30° PIP flexion and full DIP extension

Exercise: Maximum and Moderate Protection Phases

The primary goals of the maximum and moderate protection phases of rehabilitation after PIP arthroplasty are to control peripheral edema and restore functional mobility of the operated joint(s) without compromising the repair or reconstruction of soft tissues.

In most instances, the emphasis is to regain full or nearly full active PIP extension while gradually increasing PIP flexion by 10° to 15° per week.[2] It is desirable to achieve approximately 70° of PIP flexion in the ring and little fingers, 60° in the middle finger, and at least 45° in the index finger with full or almost full PIP extension by the end of the moderate protection phase (by 6 to 8 weeks postoperatively).[17] Dynamic flexion splinting may be instituted if adequate flexion is not achieved with exercise alone.

CLINICAL TIP

A balance of ROM exercises to regain flexion and extension must occur. Regaining PIP flexion should not be at the expense of attaining full or nearly full active PIP extension, so there is little to no extensor lag.[53]

Goals and interventions. The following goals and interventions are recommended as general guidelines during the first 6 to 8 weeks after surgery. Detailed protocols describing use of splints and progression of exercises following different types of PIP arthroplasty are described in several resources.[2,12,52,53,72,124,131,139]

- ***Maintain mobility of the wrist, MCP and DIP joints.***
  - Immediately after surgery, initiate active ROM of all joints not restricted by the bulky dressing.
- ***Restore ROM of the operated joints.***
  - Begin active PIP flexion in the dynamic splint or with the static splint removed and assisted flexion and extension of each PIP joint. Stabilize the MCP and DIP joints in neutral to direct motion to the PIP joint (promotes joint mobility and tendon gliding).
  - If a *boutonnière deformity* was corrected (which requires reconstruction of the extensor mechanism), follow the guidelines and precautions described in Box 19.6.[121,131]

BOX 19.6 Postoperative Guidelines and Precautions after Correction of a Boutonnière Deformity

Exercise
- Maintain as much extension as possible of the PIP joint through splinting and exercise for 3 to 6 weeks postoperatively. Remove the splint only for exercise and wound care.
- Initiate early DIP flexion exercises with the PIP joint stabilized in extension to maintain the length of the oblique retinacular ligament.
- Begin active or assisted PIP flexion/extension exercises by 10 to 14 days or sooner postoperatively. Stabilize the MCP joint in neutral (on a book or at the edge of a table) during PIP movements.
- Emphasize PIP extension and DIP flexion during exercise.

Precautions
- Avoid hyperextension of the DIP joint.
- Because correction of a boutonnière deformity requires a central slip splitting approach and repair of the extensor mechanism, avoid resisted exercises and stretching of the extensor mechanism of the PIP joint for 6 to 8 weeks or as long as 12 weeks postoperatively.

- If a *swan-neck deformity* was corrected, follow the guidelines and precautions noted in Box 19.7.[52,121,131] A central, slip-splitting approach is necessary for correcting a swan-neck deformity to allow the tension on the extensor mechanism to be adjusted and greater excursion of the PIP joint into flexion.

BOX 19.7 Postoperative Guidelines and Precautions after Correction of a Swan-Neck Deformity

Exercise
- Maintain the PIP joint(s) in 10° to 20°[131] or 20° to 30°[52] of flexion and the DIP joint(s) in full extension with static digital splinting.
- Initiate active ROM exercises at the PIP and DIP joints several days[52] to 10 to 14 days[131] postoperatively.
- Perform DIP extension exercises with the PIP joint stabilized in slight flexion.
- Stabilize the DIP joint in neutral during PIP ROM exercises.
- Emphasize PIP flexion and DIP extension.

Precautions
- Limit PIP extension to 10° of flexion during exercise to avoid excessive stretch to the volar aspect of the capsule.
- Avoid extreme flexion of the DIP joint.

PRECAUTION: During ROM exercises, it is essential to avoid lateral and rotational stresses to the operated joints that could compromise the integrity of the collateral ligaments and joint stability.

Exercise: Minimum Protection/Return to Function Phase

The primary goal of the minimum protection phase shifts from restoration of functional ROM to improving strength in the hand and wrist and gradually incorporating safe but progressive use of the hand into functional activities of daily living. This transition occurs around 6 to 8 weeks—or as late as 12 weeks—postoperatively. The status of the soft tissue repairs, particularly the extensor tendons, determines how early resisted exercises are initiated. For optimal results, rehabilitation may need to continue (through adherence to a home program) for 6 months or longer postoperatively.

As with MCP arthroplasty, low-intensity strengthening exercises can be performed with equipment specifically designed for hand rehabilitation, such as exercise putty, or through graded functional activities that involve resisted movements. Principles of joint protection (see Box 19.2) are integrated into daily living through patient education, with attention to continued avoidance of lateral stresses to the PIP joints.

Outcomes

After PIP joint arthroplasty, an optimal result provides the patient with a pain-free, mobile but stable and well-aligned joint for functional use of the hand.[2,10,12,123,124] Pain relief is the most consistent outcome after PIP arthroplasty.[2] Although patients typically report improvement in use of the hand for functional activities, improvements in ROM and grip strength tend to be marginal at best.[44,139]

Successful outcomes are dependent on proper balancing and repair of the collateral ligaments, adequate soft tissue coverage, and lack of infection following surgery. Outcomes usually are better in patients with OA than in those with posttraumatic arthritis or RA and in fingers without preoperative deformity,[2] but there is no conclusive evidence that one surgical approach or type of current-day arthroplasty is superior to another.[44]

Optimal ROM for functional use of the hand after arthroplasty of the PIP joint is 45° to 70° of active flexion (depending on the finger) and full or almost full active extension (no extensor lag). However, postoperative ROM reported in most studies is substantially less than optimal.[2] For example, results of a large follow-up series of patients who had undergone flexible implant arthroplasty showed that approximately two-thirds of the replaced PIP joints had greater than 40° of motion.[123] In a follow-up study after surface replacement arthroplasty primarily for OA, the average arc of motion was 47° (average 16° extensor lag and 63° of PIP flexion).[69]

If the extensor tendon mechanism is intact and a central slip-sparing approach is used, which allows early initiation of mobility exercises, approximately 10° more PIP flexion can

be expected than if a central slip-splitting approach is used or repair of extensor tendons is required.[124] If a swan-neck deformity was corrected, a slight (up to 10°) flexion contracture at the PIP joint is acceptable to protect the volar aspect of the joint capsule and possibly avoid recurrence of the deformity.

Complications. The potential complications that can arise following PIP arthroplasty are similar to those associated with MCP arthroplasty. Sclerosis around the implant and eventual implant loosening or breakage are long-term complications seen with one-piece silicone implant arthroplasty; however, silicone synovitis is rare.[44] Joint instability, subluxation, and dislocation are complications seen with the two-component metal-plastic or pyrocarbon surface replacements, because these designs have no inherent stability. Loosening is a long-term complication that may occur regardless of whether cemented or noncemented fixation was used. A unique complication reported only in pyrocarbon designs is an audible squeaking of the implant during joint motion.[44]

Patients must continue to avoid forceful grasping and high-impact activities and must practice principles of joint protection for a lifetime to prevent common long-term complications, such as fracture of the implant.[2,131]

Carpometacarpal Arthroplasty of the Thumb

Arthritis of the CMC joint, also called the trapeziometacarpal joint, of the thumb, leads to pain and stiffness and occurs with advancing age in women more often than men.[87] When this joint is involved, a patient has difficulty with forceful grasp and pinch and wringing motions. If a patient remains symptomatic after a period of conservative management, including anti-inflammatory medications, splinting, activity modification, and exercise, arthrodesis or one of several types of arthroplasty may be appropriate for relief of symptoms and improved function.[32]

Indications for Surgery

The following are common indications for CMC arthroplasty of the thumb.[12,23,32,116,129]

- Disabling pain at the base of the thumb, specifically the CMC joint, as the result of OA, posttraumatic arthritis, or RA. However, most CMC arthroplasties are performed for degenerative joint diseases and less often for synovium-based diseases.
- Dorsal-radial instability (subluxation or dislocation) of the first metacarpal on the trapezium, leading to a hyperextension deformity at the MCP joint of the thumb.
- Stiffness and limited ROM (often an adduction contracture) of the thumb.
- Decreased pinch and grip strength because of CMC pain or subluxation.
- Arthrodesis of the CMC joint is inappropriate.

Procedures

Background and Surgical Options

The type of procedure selected depends on the degree of ligament laxity, the extent of destruction of the articular surfaces, the underlying pathology, and the expected demands that will be placed on the hands postoperatively.[32,116] Arthrodesis, rather than arthroplasty, is an option for patients who use the hand for high-demand occupational activities. However, for the patient whose activities place less stress on the hand, there are several soft tissue and boney procedures that relieve pain and restore joint stability, but preserve functional mobility at the base of the thumb.[32,87] Retaining some CMC joint mobility is particularly important for the patient with RA, who typically has loss of mobility of other joints of the hand and wrist.[129]

Procedures for CMC arthroplasty fall into three broad categories: (1) ligament reconstruction; (2) trapezial resection/tendon interposition or suspension arthroplasty (usually with ligament reconstruction); and (3) surface replacement arthroplasty (resurfacing or total joint surface replacement) of the CMC joint with prosthetic components that are cemented in place.[32,134] Among these procedures, ligament reconstruction alone is used when there is pain and instability but little to no loss of articular cartilage.[32] One of the many variations of trapezial resection/tendon interposition arthroplasty is by far the most widely used approach to treatment when there is joint subluxation and loss of the joint space due to deterioration of articular cartilage.[10,12,23,32,52,67,116,129] Trapezial resection, combined with ligament reconstruction but without tendon interposition, also has been shown to be an effective surgical approach to treatment.[68]

Surface replacement arthroplasty is an alternative to trapezial resection/tendon interposition arthroplasty for a select few patients with CMC OA, who require improved pinch but do not need to use the hand for high-load, high-impact activities.[12,32,52] Surface replacement arthroplasty involves either resurfacing one articular surface or replacing the surfaces of the trapezium and metacarpal (also known as a total joint surface replacement) with a two-component, saddle-shaped rigid implant that is cemented in place.[32,134] A patient must have good quality bone stock to be a candidate for surface replacement arthroplasty. If bone stock is poor, as often occurs in RA, cement fixation of the prosthetic components usually is unsuccessful. Although considered a viable option in the past,[34] silicone implant arthroplasty now is used infrequently because of the problems of joint dislocation and silicone wear.[10,32]

Because instability (hyperextension) and arthritis of the MCP joint are frequently associated with CMC arthritis, concomitant stabilization with a temporary K-wire or arthrodesis of the MCP joint is performed in addition to reconstruction of the CMC joint.[32,129]

Operative Overview

Tendon interposition arthroplasty. For a tendon interposition arthroplasty, a dorsal incision is made at the base of the thumb, with careful attention paid to protecting the branches

of the superficial radial nerve. The capsule is approached through the extensor tendons and incised longitudinally. All or a portion of the trapezium is resected (trapeziectomy), as is a small portion of the base of the first metacarpal. A tendon graft is harvested from a portion of the flexor carpi radialis, abductor pollicis longus, or palmaris longus and inserted into the trapezial space to act as a soft tissue spacer.[10,12,23,32,52,67,116,129] The anterior oblique ligament may also be reconstructed with a portion of the tendon graft; if not used for the tendon graft, the abductor pollicis longus may be imbricated or advanced to enhance joint stability and function of the abductor postoperatively.[52] The capsule and adjacent soft tissues are then repaired, and the wound is closed.

Surface replacement arthroplasty. For a surface replacement arthroplasty, a dorsal approach is also used to reach the capsule through a longitudinal incision between the abductor pollicis longus and the extensor pollicis brevis. For a total joint surface replacement, a volar approach may be used.[32] With a two-component design, after the capsule has been split longitudinally, the distal portion of the trapezium and the base of the first metacarpal are resected. The trapezium and the intramedullary canal of the metacarpal are prepared, and the prosthetic components are inserted and cemented in place. The capsule is repaired, and as with soft tissue interposition arthroplasty, the abductor pollicis longus may be advanced to enhance joint stability. Joint stability and ROM are assessed prior to closure and application of a bulky compression dressing.

Postoperative Management

The overall goal of rehabilitation following CMC arthroplasty is to attain sufficient pain-free mobility of the thumb for functional activities while maintaining joint stability for strong pinch and grasp. It may take up to a year after surgery for a patient to achieve optimal results.

Immobilization

With all procedures, the thumb and hand are immobilized postoperatively in a bulky compression dressing and elevated for several days to a week to control edema.

After the postoperative dressing is removed, the hand is placed in a static, forearm-based thumb spica cast, which is later replaced with a removable splint, with the CMC joint immobilized in abduction (40° to 60°), the MCP joint in slight flexion, and the wrist in neutral to slight extension.[12,32,52,87,104,134] The IP joint of the thumb and the fingers are left free.

The length of time the CMC joint is *continuously* immobilized depends on the surgery. The time frame varies from just 1 to 2 weeks after total surface replacement arthroplasty[32,134] to 3 to 5 weeks after ligament reconstruction/tendon interposition arthroplasty or resurfacing arthroplasty with prosthetic implants.[12,32,52,87,104,129,138]

When ROM exercises are permitted after surgery, the splint is removed during the day for frequent exercise sessions. From 8 to 12 weeks, as the patient uses the hand for functional activities, daytime splinting is gradually discontinued. Use of a night splint to stabilize the thumb continues for 8 to 12 weeks or until the joint is stable and essentially pain-free.[32,104,129]

Exercise Progression

Progression of exercises varies with the type of arthroplasty. Guidelines presented in this section are for *ligament reconstruction/tendon interposition arthroplasty*, still the most common form of CMC arthroplasty. Management guidelines unique to total surface replacement arthroplasty also are noted. Precautions after CMC arthroplasty are summarized in Box 19.8.[32,87,104]

Exercise: Maximum Protection Phase

The focus of the first 6 weeks of rehabilitation is to control pain and edema, maintain ROM in nonimmobilized joints, and initiate protected motion of the CMC joint when it is permissible to remove the thumb spica splint for exercise.[32,87,104,129]

Goals and interventions. The following are suggested goals and exercise interventions for the first 6 weeks after surgery.

- ***Maintain mobility of the fingers and IP joint of the thumb.***
  - During the period of continuous immobilization of the wrist and CMC and MCP joints of the thumb, have the patient perform active ROM of the fingers and the IP joint of the thumb.
- ***Initiate protected mobility of the thumb and wrist.***
  - When permissible, begin active, controlled ROM of the thumb within protected ranges and the wrist.
  - After *tendon interposition arthroplasty*, protected ROM is not initiated until about 3 to 6 weeks after surgery to allow time for the reconstructed soft tissues to heal adequately.[32,87,104,129,138]

BOX 19.8 Precautions after CMC Arthroplasty of the Thumb

- Initially refrain from full CMC flexion with adduction (sliding the thumb across the palm to the base of the fifth finger) as this motion places excessive stress on the dorsal aspect of the capsule and ligament reconstruction. Be certain it is possible to oppose the thumb to each fingertip before attempting to touch the base of the fifth finger.
- When stretching to increase CMC abduction or extension, apply the stretch force to the metacarpal, not the first phalanx, to avoid hyperextension or compromising stability of the MCP joint. Follow the same precaution during light resistance exercises.
- Avoid forceful pinch and grasp for at least 3 months after surgery.
- Modify activities of daily living to limit heavy lifting. If occasionally heavy lifting is necessary, advise the patient to wear a protective splint.

- After *total surface replacement arthroplasty*, ROM may be initiated at about 1 week postoperatively because of the inherent stability of the cemented implants prosthesis.[32] When it is permissible to remove the splint for exercise, begin active wrist ROM in all directions and CMC ROM with active abduction and extension; then add opposition and circumduction. Also include active MCP flexion and extension, being certain to stabilize the CMC joint.

Exercise: Moderate and Minimum Protection Phases

While continuing to regain ROM, the focus of rehabilitation during the intermediate and final phases of rehabilitation gradually shifts to developing grip and pinch strength for functional tasks.

Goals and interventions. Consider the following goals and interventions.

- ***Re-establish functional mobility of the hand and wrist.***
  - Continue active ROM exercises using gradually increasing ranges.
  - At about 8 weeks, begin gentle self-stretching exercises or dynamic splinting if limitations in functional ROM persist.
- ***Regain strength and functional use of the hand and wrist.***
  - At about 8 weeks postoperatively, initiate isometric exercises against light resistance, emphasizing abduction and extension.
  - If the CMC joint is stable and pain-free, progress to dynamic resistance exercises to regain pinch and grasp strength.
  - Between 8 and 12 weeks, remove the splint when using the hand for light ADL, such as buttoning and unbuttoning.[87,129,138]
  - Incorporate principles of joint protection during strengthening exercises and ADL.
  - Continue to increase use of the hand for light to moderate ADL over the next 4 to 6 weeks. A patient typically can return to light-duty work by 3 to 4 months and can resume most functional activities by 4 to 6 months.

Outcomes

Most of the studies reported in the literature have investigated outcomes of trapezial resection/tendon interposition arthroplasty with limited evidence reported on the results of surface replacement arthroplasty. Based on data from a variety of instruments that measure pain, ROM, hand function, patient satisfaction, and quality of life, pain-free range of motion of the basal joint of the thumb and improved hand function, measured by patient's dexterity, pinch, and grasp, are considered successful overall outcomes following CMC arthroplasty.[12,23,32,116,129] The time required to achieve maximum benefit from the surgery is typically 6 to 12 months.[12,104]

Among the procedures available, trapezial resection/tendon interposition arthroplasty with or without ligament reconstruction yields the most predictable and successful outcomes.[32] In a review of tendon interposition arthroplasty, outcomes appear better when the procedure includes reconstruction of ligaments, possibly because the CMC joint is more stable with reconstruction.[32]

Pain relief and patient satisfaction. Regardless of the type of CMC arthroplasty, the most consistent and predictable benefit of these procedures is relief of pain.[12,23,32,34,52,67,68,134] For example, in a review of outcomes of a number of studies for patients with OA who had undergone tendon interposition arthroplasty with or without ligament reconstruction, 94% of patients reported long-term relief of pain.[116] Although tendon interposition is designed to resurface the deteriorated joint to make motion more comfortable, in a prospective, randomized study of patients with OA, investigators compared the results of trapezial resection and ligament reconstruction with and without the use of tendon interposition. They found that at a mean of 48 months after surgery, both groups had equally satisfactory pain relief.[68]

A patient's quality of life also improves after CMC arthroplasty. In a follow-up study of 103 patients with OA, who had primary tendon interposition arthroplasty, participants completed several standardized self-assessment questionnaires at a mean of 6.2 years after surgery.[5] In an overall rating, 79 of 103 reported their quality of life had improved greatly, and an additional 15 reported slight improvement.

ROM and hand function. Active ROM of the thumb, particularly opposition, and dexterity usually improve after CMC arthroplasty. Increased abduction and extension widen the web space, making it easier to open the hand to grasp large objects. However, the results of some studies of ligament reconstruction/tendon interposition arthroplasty indicate that preoperative and postoperative ROM essentially is unchanged. Although evidence is limited, surface replacement arthroplasty is thought to produce greater improvement in ROM compared with soft tissue procedures.[32] However, results of a recent study of total surface replacement arthroplasty (two-component, metal-plastic design) demonstrated that, although significant pain relief and improvement of bilateral hand function occurred in some tests, there was no significant improvement in range of opposition or grip and pinch strength at a mean follow-up of 3 years after surgery.[134]

In contrast, other studies that follow patients for several years after surgery indicate that measurements of pinch and grasp strength as well as performance of functional tasks improve significantly.[23,32] The most successful long-term functional outcomes have been reported for patients who use the hand primarily for low-demand activities.[34]

Complications. Complications vary with the type of CMC arthroplasty. Overall, the rate of complications is low, with inadequate pain relief and recurrence of joint instability the most common complications that necessitate revision arthroplasty. In a retrospective study of 606 primary tendon interposition-ligament reconstruction arthroplasties performed

over a 16-year period, only 3.8% were known to have required a revision procedure for mechanically based pain.[33] Neuropathic pain also can develop after CMC arthroplasty. The pain may be caused by damage to or impingement of the radial nerve (radial sensory neuritis), carpal tunnel syndrome, or complex regional pain syndrome.[23,33]

For arthroplasties that include implantation of prosthetic components, loosening and dislocation are the most common complications. Overall, implant loosening is more likely to occur with uncemented fixation, but has been reported to occur in cemented procedures as well.[134]

Tendon Rupture Associated with RA: Surgical and Postoperative Management

Background and Indications for Surgery

Ruptures of tendons of the hand are common in patients with chronic tenosynovitis associated with RA. The site of the rupture may be in the wrist or the hand. When a tendon ruptures, there is a sudden loss of active control of one or more of the digits. Rupture of a single or multiple tendons is usually painless and occurs during unremarkable use of the hand.[10,52,54] Such ruptures are evidence of severely diseased tendons.

The extensor tendons are affected far more frequently than the flexor tendons. In order of frequency, extensor tendons that most often rupture are the common extensor tendons to the small and ring fingers and the extensor pollicis longus (EPL). The most common flexor tendon to rupture is the flexor pollicis longus (FPL).[52,54,140]

The causes of rupture include infiltration of proliferative synovium in the tendon sheaths and into tendons, which subsequently weakens the affected tendon; abrasion and fraying of a tendon as it moves over a boney prominence roughened or eroded by synovitis; periodic use of local steroid injections over time; or ischemic necrosis caused by direct pressure from hypertrophic synovium, particularly at the dorsal retinaculum, that compromises blood supply to a tendon. Common sites of abrasion that affect the extensors are the distal ulna, Lister's tubercle, and the volar aspect of the scaphoid where it contacts the flexor tendons.[10,52,54,140]

The indication for surgery is loss of function of the hand. Rupture of a single tendon, such as the extensor digiti minimi, may not impair a patient's function, whereas rupture of multiple tendons simultaneously or over a period of time may cause significant limitations of function and disability.

Procedures

The surgical procedures available for treatment of tendon ruptures in RA vary depending on which tendon(s) has ruptured, the number of ruptured tendons, the location of the rupture, the condition of the tendon at the site of rupture, and the quality of the remaining intact tendons of the hand. Options include[10,52,54,140]:

- ***Tendon transfer.*** A tendon is removed from its normal distal attachment and attached at another site. For example, the extensor indicis proprius (EIP) can be transferred if the EPL has ruptured. A flexor tendon can also be transferred to the dorsal surface of the hand to act as an extensor if multiple extensor tendons have ruptured.
- ***Tendon graft reconstruction.*** A portion of another tendon that acts as a "bridge" is inserted between and sutured to the two ends of the ruptured tendon. The palmaris longus tendon is often selected as the donor tendon. A wrist extensor tendon may be selected if a wrist arthrodesis is performed at the time of the tendon reconstruction.
- ***Tendon anastomosis (side-to-side tenorrhaphy).*** The ruptured tendon is sutured to an adjacent intact tendon. This is a common option at the wrist for the finger extensor tendons.[140]
- ***Direct end-to-end repair.*** The two ends of the ruptured tendon are re-opposed and sutured together. This option is used only occasionally, because the ends of the ruptured tendons in patients with RA usually are frayed. Therefore, a considerable portion of the frayed tendon(s) must be resected, which shortens the tendon, making it difficult to suture end-to-end.

Concomitant procedures in the rheumatoid hand include tenosynovectomy, removal of osteophytes from boney prominences, and ligament reconstruction or arthrodesis for instability. If late-stage MCP joint disease also is present and passive extension of the MCP joints is significantly limited, arthroplasty of the involved joints may be indicated as well, either simultaneously with the tendon procedure or during two separate operations as determined by the surgeon. Without adequate joint mobility, the transferred or reconstructed extensor tendons become adherent, resulting in a poor outcome.

Postoperative Management

The guidelines described in this section apply only to management of tendon transfer, reconstruction, or repair of extensor tendons in the rheumatoid hand. As mentioned previously, rupture of extensor tendons occurs far more frequently than flexor tendon rupture. As with postoperative management for other surgeries described in this chapter, pain and edema control and exercises for the nonoperated extremities are always essential components of rehabilitation.

Tendon transfers and reconstruction are delicate procedures requiring ongoing communication between the therapist and surgeon and active involvement of the patient in the postoperative program. Therefore, patient education is woven into every phase of rehabilitation.

Immobilization

A bulky compression dressing is applied to the hand and wrist at the close of extensor tendon surgery to control edema. The surgical compression dressing is removed after several days, and the wrist and hand are then immobilized in a volar splint. A forearm-based, resting splint holds the wrist and digits in a position that minimizes stress to the transferred or reconstructed tendon(s).

For example, after side-to-side finger extensor transfer or extensor tendon reconstruction, the wrist and all fingers are

immobilized in extension in the splint, but the thumb is free to move. After reconstruction of a ruptured EPL tendon or transfer of the EIP tendon to restore thumb extension, the wrist is immobilized in extension and the thumb in adduction, but the fingers are free to move.

Continuous immobilization of the wrist and digits is maintained for approximately 3 to 4 weeks to protect the healing tendons.[73,140] Daytime splinting is discontinued at about 12 weeks, but night splinting typically continues for 6 months or longer.

CLINICAL TIP

Use of dynamic splinting and early mobilization (a few days after surgery) typically is not recommended for tendon reconstruction or transfers in the rheumatoid hand. Tissue healing is slower and the risk of re-rupture higher postoperatively for patients with long-standing, systemic disease (who likely have been treated periodically with corticosteroids) than in otherwise healthy patients who have sustained an acute laceration or rupture of a tendon in the hand.[46]

Exercise Progression

During each phase of postoperative rehabilitation after extensor tendon transfer or reconstruction, exercises are progressed very gradually. Precautions during exercise and functional use of the hand are summarized in Box 19.9.

Exercise: Maximum Protection Phase

During the first 6 weeks after surgery, the priorities of rehabilitation are edema control and protection of the transferred or reconstructed tendon(s), followed by carefully controlled mobility of the operated areas to prevent adherence of healing tissues. It is usually permissible to remove the protective splint for exercise at around 3 to 4 weeks. If tendon quality is poor and the security of the sutured tissues is in question, exercise may be delayed until about 6 weeks postoperatively.

Goals and interventions. The goals and intervention during the first phase of rehabilitation include the following.[54,73,140]

- ***Maintain mobility of the elbow and forearm, unsplinted digits, and other involved joints.***
  - While the operated hand is immobilized, perform active ROM of all necessary joints.
- ***Re-establish mobility and control of the repaired or transferred extensor muscle-tendon units.***
  - When the splint may be removed for exercise, initiate active wrist motions with the fingers relaxed.
  - Begin assisted MCP extension of each of the fingers or thumb with the wrist and IP joints of each digit stabilized in neutral.
  - Perform *place and hold* exercises by passively positioning the operated MCP joint first in a neutral and later in a slightly extended position. Have the patient briefly hold the position. This emphasizes end-range extension to prevent an extensor lag.
  - Progress to dynamic MCP extension with the wrist in neutral, initially from slight MCP flexion with the palm of the hand on a table and the fingers relaxed over the edge.

CLINICAL TIP

To help a patient learn the new action of a transferred tendon, initially have the patient focus on the original action (function) of the muscle-tendon unit. For example, if the EIP was transferred to replace the action of the EPL of the thumb, have the patient think about extending the index finger when trying to actively extend the thumb. Use biofeedback or functional electrical stimulation (FES) to assist with the motor learning.[73]

- ***Regain active flexion of the digits.***
  - Initiate MCP flexion of the fingers by having the patient relax the EDC after active extension rather than actively flexing the fingers.
  - Progress to active MCP flexion within a protected range with the wrist and PIP joints stabilized in neutral. With the wrist and MCP joints stabilized in extension, actively flex (hook fist/intrinsic minus position) and extend (straight hand position) the PIP joints. PIP flexion while in wrist and MCP extension prevents stiffness of the IP joints without placing a stretch on the repaired EDC tendon(s).[48]

Exercise: Moderate and Minimum Protection Phases

By 6 to 8 weeks postoperatively, the transferred or reconstructed tendon can withstand greater imposed stresses. Use of the hand for light functional activities usually begins at

BOX 19.9 Precautions after Extensor Tendon Transfers or Reconstruction in the Rheumatoid Hand

- During the early phase of rehabilitation, do not initiate MCP extension from full, available MCP flexion to avoid excessive stretch on the operated tendon(s).
- Postpone stretching to increase MCP flexion if there is a deficit in active extension.
- Avoid activities or hand postures that combine finger flexion or thumb flexion and adduction with wrist flexion, as this places extreme stress on the reconstructed or transferred extensor tendons. If a patient must use the hands for transfer activities, avoid weight bearing on the dorsum of the hand.
- Avoid vigorous gripping activities that could potentially overstretch or rupture the reconstructed or transferred extensor tendon(s).

this time. At about 8 weeks, daytime splinting is gradually decreased and typically discontinued by 12 weeks postoperatively. If there is an extensor lag, splint use during the day continues over a longer period of time.

Goals and interventions. Consider the following goals and interventions to progress the rehabilitation program.

- ***Continue to increase active mobility of the operated digits.***
  - Add gentle passive stretching to increase MCP extension or flexion if one or both motions are restricted.
  - Continue active MCP extension exercises to prevent an extensor lag, or consider dynamic extension splinting if an extensor lag has developed and persists. If MCP extension to neutral is possible (no extensor lag), perform active MCP extension with the palm of the hand on a flat surface, and extend each finger beyond neutral.
  - With the wrist in neutral or slight extension, gradually increase MCP flexion by touching each fingertip to the palm of the hand (first straight and then full-fist positions) or the thumb to each fingertip and gradually to the base of the fifth finger. At 8 to 12 weeks, institute dynamic flexion splinting intermittently during the day if grasp is significantly limited.
- ***Regain strength, control, and functional use of the hand.***
  - Incorporate active movements of the digits into manual dexterity and coordination activities that simulate functional activities. Remove the splint for functional activities that involve light grasp, such as picking up or holding light objects or folding clothing.
  - Around 8 to 12 weeks add isometric and dynamic, *submaximal* resistance exercises to improve functional strength and endurance of the hand.
  - Through ongoing patient education, reinforce principles of joint protection during functional use of the hand.

Outcomes

The results of surgical intervention and postoperative management of ruptured tendons in the rheumatoid hand are highly dependent on the extent of involvement in the joints and soft tissues of the hand and wrist preoperatively. It is often difficult to differentiate postoperative functional improvement strictly as the result of a tendon transfer or reconstruction from procedures performed concurrently, such as joint arthroplasty or arthrodesis.

Barring complications, the most common of which is tendon re-rupture, a few generalizations can be made.[52,54,140] Patients with a recent rupture of a single tendon, who have full passive ROM of the affected joint, realize an optimal postoperative outcome: full functional grasp and no extensor lag in the involved digit. The greater the number of tendon ruptures or associated impairments, such as joint contractures, fixed deformities, or joint instabilities, the poorer the results.

Repetitive Trauma Syndromes/Overuse Syndromes

Disorders from cumulative or repetitive trauma in the wrist and hand lead to significant loss of hand function and lost work time.[9] The causes are related to repeated movements over an extended period of time. The resulting inflammation can affect muscles, tendons, synovial sheaths, and nerves. Diagnoses include carpal tunnel syndrome, trigger finger, de Quervain's disease, and tendinopathy (tendonitis/tenosynovitis). Management of impairments related to carpal tunnel syndrome and nerve compression in the tunnel of Guyon is described in Chapter 13.

Tendinopathy

Etiology of Symptoms

Pathological breakdown of the tendon structure results from continued or repetitive use of the involved muscle beyond its ability to adapt, the effects of RA, a stress overload to the contracting muscle (such as strongly gripping the steering wheel during a motor vehicle accident), or roughening of the surface of the tendon or its sheath.[38,99]

Common Structural and Functional Impairments

- Pain whenever the related muscle contracts or whenever there is movement that causes gliding of the tendon through the sheath.
- Warmth and tenderness with palpation in the region of inflammation.
- In RA, synovial proliferation and swelling in affected tendon sheaths, such as over the dorsum of the wrist or in the flexor tendons in the carpal tunnel.
- Frequently, an imbalance in muscle length and strength or poor endurance in the stabilizing muscles. The fault may be more proximal in the elbow or shoulder girdle, causing excessive load and substitute motions at the distal end of the chain.

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

A common limitation of tendinopathy is the inability to perform repetitive or sustained work, recreational, or leisure gripping activities or hand motions that require contraction of the involved musculotendinous unit due to pain that worsens with the provoking activity.

Management: Protection Phase

Follow the guidelines for acute lesions described in Chapter 10, with special emphasis on education, relieving the stress in the involved musculotendinous unit, and maintaining

a healthy environment for healing with nondestructive forces.

- ***Patient education.*** Inform the patient how the mechanism of injury and repetitive activity is provoking the symptoms and explain the necessity to modify the activity to allow healing. Engage the patient in the rehabilitation program.
- ***Rest the part.*** Splint the related joints to rest the involved tendon.
- ***Tendon mobility.*** If the tendon is in a sheath, apply cross-fiber massage while the tendon is in an elongated position, so mobility develops between the tendon and sheath.
  - Teach the patient tendon-gliding exercises to prevent adhesions. (These are described in the exercise section of this chapter.)
- ***Muscle integrity.*** Teach the patient how to perform multi-angle muscle setting in pain-free positions followed by pain-free ROM.

Management: Controlled Motion and Return to Function Phases

- ***Exercise progression.*** Progress to dynamic exercises, adding resistance within the tolerance of the healing musculotendinous structure. Eccentric exercises that load the tissue should be carefully monitored in order not to provoke recurrence of the symptoms.
- ***Biomechanical assessment.*** Assess the biomechanics of the functional activity provoking the symptoms and design a program to regain a balance in the length, strength, and endurance of the muscles. Frequently, problems arise in the wrist and hand because of poor stabilization or endurance in the shoulder or elbow.
- ***Prevention.*** Continue to emphasize the importance of self-monitoring the symptoms, maintaining a safe exercise program, and unloading the wrist/hand when symptoms occur.[38]

FOCUS ON EVIDENCE

Backstrom[7] reported a case study of a patient diagnosed with de Quervain's disease of 2 months' duration in which mobilization with movement (MWM) was used in addition to physical agents, exercise, and transverse friction massage. Pain was markedly reduced from 6/10 to 3/10 (50%) by the third intervention, and by the completion of 12 sessions it was 0 to 1/10. The author proposed that the subtle malalignments in the wrist joints associated with the overuse syndrome perpetuated the symptoms and that the MWM helped restore normal arthrokinematics. The MWM techniques used included active movements of the thumb and wrist while a passive radial glide of the proximal row of carpals was applied (similar to Fig. 19.8). The principles of MWM are described in Chapter 5.

Traumatic Lesions of the Wrist and Hand

Simple Sprain: Nonoperative Management

After trauma from a blow or a fall, an excessive stretch force may strain the supporting ligamentous tissue. There may be a related fracture, subluxation, or dislocation.

Common Structural and Functional Impairments

- Pain at the involved site whenever a stretch force is placed on the ligament
- Possible hypermobility or instability in the related joint if supporting ligaments are torn

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

- With a simple sprain, pain may interfere with functional use of the hand for a couple of weeks whenever the joint is stressed. There is no limitation of function if a splint or tape can be worn to protect the ligament, and the splint does not interfere with the task.
- With significant tears, there is instability, and the joint may subluxate or dislocate with provoking activities, requiring surgical intervention.

Management

Follow the guidelines in Chapter 10 for treating acute lesions with emphasis on maintaining mobility while minimizing stress to the healing tissue. If immobilization is necessary to protect the part, only the involved joint should be immobilized. Joints above and below should be free to move. This maintains mobility of the long tendons in their sheaths that cross the involved joint. Avoid positions of stress and activities that provoke the symptoms while healing. Cross-fiber massage to the site of the lesion may help prevent the developing scar from adhering and restricting motion.

Lacerated Flexor Tendons of the Hand: Surgical and Postoperative Management

Background and Indications for Surgery

Lacerations of the flexor tendons of the hand, which can occur in various areas (zones) along the volar surface of the fingers, palm, wrist, and distal forearm, are common and cause an immediate loss of hand function, consistent with the tendons severed. The musculotendinous structures damaged depend on the location and depth of the wound. Damage to one or more tendons may be accompanied by vascular, nerve, and skeletal injuries, which can cause additional loss of function and complicate management. An acute rupture of a

flexor tendon may also occur as the result of a closed traumatic injury to the hand.[36,119]

The volar surfaces of the forearm, wrist, palm, and fingers are divided into five zones; the thumb is divided into three zones. These zones are illustrated in Figure 19.12. The anatomical landmarks for each of the zones are described in Box 19.10.[36,56,76,109,119,120] Use of this system of classifying lacerations improves consistency of communication and can provide a basis for predicting outcomes.[82]

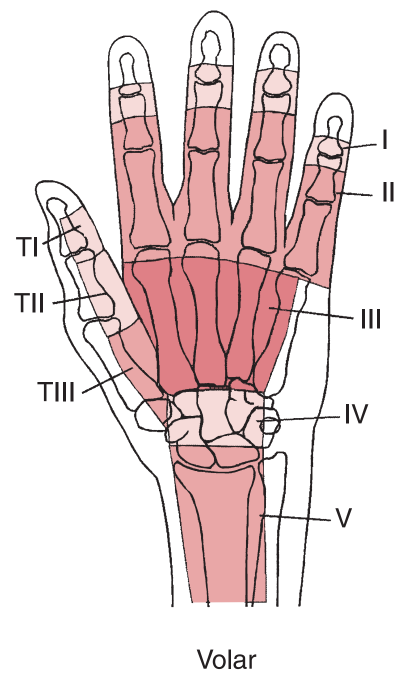

FIGURE 19.12 Flexor tendon zones; volar aspect of the hand and wrist.

Knowledge of the complex anatomy and kinesiology of the hand is essential to understand the impairments and functional implications caused by damage to the flexor tendons in each of these zones. Box 19.11 identifies common impairments associated with damage in each of the zones.[36,76]

When severed or ruptured, flexor tendons readily retract, thus requiring surgical intervention in most instances to restore function to the hand and prevent deformity. Repair and rehabilitation of lacerations in zone II, traditionally referred to as "no-man's land," pose a particular challenge to hand surgeons and therapists.[78] Because of the confined space in which the extrinsic flexors of the fingers lie and the limited vascular supply to the tendons in zone II, healing tissues in this area are prone to excursion-restricting adhesions. Scar tissue formation during the healing process can interrupt tendon-gliding in the synovial sheath and subsequently restrict ROM of the involved fingers.

In zone IV (the carpal tunnel), the extrinsic flexor tendons of the digits (FDS, FDP, FPL) lie in close proximity to each other. An injury in this zone may lead to adherence of adjacent tendons to each other in the carpal tunnel and impairment of differential gliding between the tendons.

BOX 19.10 Flexor Tendon Zones: Anatomical Landmarks

Zones of the Fingers, Palm, Wrist, and Forearm
- I—from the insertion of the FDP on the distal phalanx to just distal of the FDS insertion on the middle phalanx
- II—from the distal insertion of the FDS tendon to the level of the distal palmar crease (just proximal to the neck of the metacarpals)
- III—from the neck of the metacarpals, proximally along the metacarpals to the distal border of the carpal tunnel
- IV—the carpal tunnel (area under the transverse carpal ligament)
- V—area just proximal to the wrist (proximal edge of the carpal ligament) to the musculotendinous junction of the extrinsic flexors in the distal forearm

Zones of the Thumb
- T-I—from the distal insertion of the FPL on the distal phalanx of the thumb to the neck of the proximal phalanx.
- T-II—from the proximal phalanx, across the MCP joint to the neck of the first metacarpal.
- T-III—from the first metacarpal to the proximal margin of the carpal ligament.

Procedures

Types and Timing of Operative Procedures

Many factors influence the type of surgical repair selected to manage a flexor tendon injury.[36,56,76,109,118,119,120] Injury-related factors include the mechanism of injury; the type and location (zone) of the laceration; the extent of associated skin, vascular, nerve, and skeletal damage; the degree of wound contamination; and the time elapsed since the injury. Surgery-related factors include timing of the repair, the need for staging surgeries, and the hand surgeon's background and experience. Patient-related influences are the patient's age, health, and lifestyle (especially nutrition and smoking). These factors also have a significant impact on postoperative rehabilitation and outcomes of a tendon repair.[78]

Types of repair or reconstruction. Surgical options for repair of lacerations or a closed rupture of flexor tendons can be classified by the *type* of procedure.[36,76,79,109,119]

- ***Direct repair.*** An end-to-end repair in which the tendon ends are re-opposed and sutured together.
- ***Tendon graft.*** An autogenous donor tendon (autograft), such as the palmaris longus, is sutured in place to replace the damaged tendon. This is necessary when the ends of the severed tendon(s) cannot be brought together without undue tension. Tendon grafts are performed in one or more stages depending on the severity, type, and location of injury.

BOX 19.11 Consequences of Injury to the Volar Surface of the Hand, Wrist, and Forearm

- *Zone I.* Only one tendon, the FDP, can be severed as can the A-4 and A-5 retinacular pulleys, which are important for maintaining the mechanical advantage of the FDP for complete finger flexion (full fist).
- *Zone II.* FDS and FDP tendons, a double-layered synovial sheath and multiple annular pulleys (including A-1) of the flexor retinaculum (the fibrous sheath that approximates the tendons to the underlying bones and maintains them relatively close to the joints for full tendon excursion) can all be damaged. Inability to flex the PIP and DIP joints occurs if both tendons are severed. Potential damage to the vincula, the vascular structures that provide blood, and supplement nutrition derived from synovial diffusion can compromise tendon healing.
- *Zone III.* In addition to loss of the FDP and FDS, damage to lumbricals can disrupt MCP flexion.
- *Zone IV.* Damage in this zone (in the carpel tunnel) can affect all three extrinsic flexors of the digits—FDP, FDS, FPL—which disrupts finger and thumb flexion. Synovial sheath also sustains damage. Nerve injury frequently accompanies laceration in this zone.
- *Zone V.* Laceration in the forearm can cause major damage to flexor tendons of the digits and wrist, resulting in loss of wrist and digital flexion. The median and ulnar nerves and the radial and ulnar arteries also lie superficial in this zone.
- *Zones T-I and T-II.* Damage to the retinacular pulley system of the thumb, synovial sheath in addition to the FPL, and possibly the distal insertion of the FPB can occur; IP and MCP flexion are disrupted.
- *Zone T-III.* Potential damage to the thenar muscles.

A straight laceration usually lends itself well to a direct (end-to-end) repair, whereas a jagged laceration that frays the tendon may require a tendon graft.

Timing of a repair. Another method of classifying and describing tendon repairs is the *timing* of the repair, as related to the elapsed time since the injury. The timing of a repair after an acute tendon injury is critical, because the severed ends of the tendon begin to soften and deteriorate quickly, and the proximal portion of the tendon retracts. These factors make it difficult to reattach the tendon with a strong repair at its normal length. However, only a tendon laceration associated with major damage to the vascular system is considered an emergency situation.[36,76,119] Although better outcomes are thought to occur if the repair is done within the first few days, a delay of up to 10 days yields results equal to those of an immediate repair. Delays beyond 2 weeks are associated with poorer outcomes.[36,119] If a repair must be delayed for more than 3 to 4 weeks, a direct repair is no longer possible, which necessitates a tendon graft.[36]

Categories of surgeries based on elapsed time include:[36,58,76,109,119,120]

- ***Immediate primary repair:*** A repair done within the first 24 hours after injury.
- ***Delayed primary repair:*** A repair performed up to 10 days after injury.
- ***Secondary repair*:** A repair done 10 days to 3 weeks after injury.
- ***Late reconstruction:*** Surgery performed well beyond 3 to 4 weeks, sometimes months after the injury.
- ***Staged reconstruction:*** Multiple separate surgeries performed over a period of weeks or months.[58,79] A staged reconstruction enables a surgeon to prepare an extensively damaged or scarred tendon bed months prior to a tendon graft, so adhesions are less likely to develop.

A simple, clean, acute laceration of a tendon without associated injuries of the hand is most often managed with a *direct primary repair*, either immediate or delayed a few days.[36,119,120] However, if the wound is not clean, a *delayed primary repair* allows time for medical intervention to reduce the risk of infection. Lengthy delays that necessitate a *secondary repair* or *late reconstruction* are often associated with multiple injuries, such as extensive skin loss, fractures that cannot be stabilized immediately, or long-standing scarring and contractures. If there is damage to one or more of the tendon pulleys, these must be repaired before the lacerated tendon can be repaired effectively.

Of the multiple-stage reconstructions for extensive and complex flexor tendon injuries of the hand, the *Hunter two-stage reconstruction passive or active implant* is most widely known. During the first stage of this procedure, the scarred and adherent portions of the damaged flexor tendon are resected. An implant (rod) made of silicone is then secured in place to act as a *tendon spacer* around which a new sheath develops over a period of 3 months. In addition, a damaged retinacular pulley system is reconstructed, and any contractures are released during the first surgery. During the second phase, the implant is removed, and a donor tendon (graft) is drawn through the new sheath and sutured in place.[58,79]

Operative Overview

Some general aspects of the many variations of operative procedures for primary flexor tendon injuries are described in this section.[36,76,79,82,118,119,120] However, careful review of a patient's operative report and close communication with the hand surgeon are necessary sources of specific details of each patient's surgery.

Surgical approach. For example, for repair of lacerated finger tendons in zone II, a volar, zigzag approach, designed to avoid the lines of stress or a lateral incision, may be elected by the surgeon, the volar zigzag approach is the more common. When approaching the lacerated tendon, the incision is made between the annular pulleys to ensure optimal excursion. This approach preserves the function of these fibrous sheaths, which encircle the finger flexors and keep the tendons close to the joints, preventing bowstringing of the tendon.

Suturing technique. For a direct repair after the tendon ends are located, prepared, and re-opposed, there are a number of delicate techniques for suturing the tendons.[36,76,107,111,118,119,120] Core sutures and epitendinous sutures are used to hold the tendon ends together. A larger number of suture strands across the repair site (e.g., four or six strands instead of two) produces a proportionally stronger repair. Running, locked epitendinous sutures used in addition to core sutures appear to further increase the initial strength of the repair.[107,111]

CLINICAL TIP

Suturing technique and the number of suture strands influence the initial strength of the repair and consequently the type and timing of motion allowable postoperatively.

Suturing technique must also address the vascular supply to the repaired tendon. Nonreactive sutures are placed in the nonvascular volar aspect of the tendon so as not to disturb the vincula, which lies in the dorsal aspect of the tendon and provides a blood supply to the tendon.[36,77,109,118,119,120] When present, as in zones II and IV, the synovial sheath is also repaired to re-establish circulation of synovial fluid, an important source of nutrition to the healing tendons.[118]

Closure. After all repairs have been completed, the incision(s) is closed, and the hand and wrist are immobilized in a bulky compression dressing and elevated to control edema. The compression dressing remains in place for 1 to 3 days. When the bulky surgical dressing is removed, it is replaced with a light compressive dressing and splint.

Postoperative Management

General considerations. After surgical intervention for a flexor tendon injury, a strong, well-healed tendon that glides freely is the cornerstone for restoring functional mobility and strength in the hand.[50,93,118,119,120] Every effort is made to prevent excursion-restricting adhesions from forming while simultaneously protecting the repaired tendon as it heals. Box 19.12 summarizes the factors that contribute to adhesion formation after tendon repair.[36,50,57,82,93,119]

Many of the same patient and injury-related factors—already noted—that a surgeon weighs when determining the most appropriate approach to surgical management for a patient's hand injury also influence the complex components and progression of postoperative rehabilitation. In addition, surgery-related factors, including the type and timing of the repair, suturing technique, strength of the tendon repair, and the need for concomitant operative procedures affect rehabilitation and eventual outcomes. Furthermore, therapy-related factors—in particular the time at which therapy is initiated, the use of early or delayed mobilization procedures, the quality of splinting, the expertise of the therapist, and ultimately the quality and consistency of the patient's involvement in the rehabilitation process—influence outcomes.

BOX 19.12 Factors that Contribute to Adhesion Formation After Tendon Injury and Repair

- Location of the injury and repair: higher risk in zones II and IV; tendons glide in a closely confined area
- Extent of trauma: higher risk with extensive trauma and damage to associated structures
- Reduced blood supply, subsequent ischemia, and reduced nutrition to healing tendons
- Excessive handling of damaged tissues during surgery
- Ineffective suturing technique
- Damage or resection of components of the tendon sheath
- Prolonged immobilization after injury or repair, which prevents tendon-gliding
- Gapping of the repaired tendon ends associated with *excessive* stress to the healing tendon

Extensive research has been done on the process of tendon healing, the tensile strength of tendon repairs, adhesion formation, and tendon excursion and imposed stresses (loading) on a repaired tendon during digital motion. A number of sources provide an in-depth analysis and summary of basic and clinical studies, typically animal and cadaveric but some *in vivo* human studies, as they apply to rehabilitation.[25,36,50,57,58,93,118,119,120]

The purpose of this section is to examine and summarize current concepts and approaches to immobilization and exercise used in rehabilitation after flexor tendon injury and repair, rather than to put forth or ascribe to any one particular approach or protocol. Therapists treating patients after tendon repair must be familiar with the various postoperative protocols or guidelines used by referring hand surgeons and those described in the literature.

A therapist's knowledge of the underlying concepts in any protocol is essential for effective communication with the surgeon. A therapist's skill in applying and teaching exercise procedures is equally necessary for effective patient education and helping a patient achieve optimal functional outcomes. This knowledge enables a therapist to make sound clinical judgments to determine when the progression of activities in a protocol preferred by a referring surgeon is safe or when activities must be adjusted based on each patient's responses. Remember, a regimented protocol is only safe and effective when there are no postoperative variables, a situation that certainly does not occur in the clinical setting.

Approaches to postoperative management. There are two basic approaches to management after flexor tendon repair characterized by the timing and type of exercises in the program. They are categorized as *early controlled motion*, either passive or active, and *delayed motion*.

Numerous published protocols with considerable variability fall within these categories. Most current-day programs emphasize early controlled (protected) motion after surgery

and include both passive and active exercises of the operated digit(s). Advances in surgical management (in particular, improved suturing techniques) that establish a relatively strong initial tendon repair allow the use of early motion.

FOCUS ON EVIDENCE

Tottenham and colleagues[132] studied 22 patients who underwent primary zone II flexor tendon repairs. Half of the patients began passive motion exercises of the operated fingers by the first 7 days after surgery, whereas the other half began passive motion 7 to 21 days postoperatively. The results of the study, based on several assessment measures of motion and function, indicated there was a significant difference between groups, with all of the early motion group—but only 75% of the delayed motion group—achieving "excellent or good" results (i.e., 25% of the delayed motion group had only "fair or poor" results). The investigators noted that nonrandomization and the small size of the groups were limitations of their study.

Box 19.13 summarizes the rationale for early, but carefully graded, motion as soon as a day or two after tendon repair based on four decades of evidence derived from scientific studies.* However, there are instances when a traditional, delayed motion approach must be used. Indications for prolonged (3 to 4 weeks) immobilization after tendon repair (and therefore delayed motion) are noted in Box 19.14.[17,90,93,109,118,119]

Key elements of early passive and active motion approaches and the delayed motion approach with regard to immobilization and selection and progression of exercises are presented in the following sections. More detailed descriptions of these approaches, as well as specific protocols advocated by various practitioners and researchers, are available in many sources.*

*25,27,36,50,57,93,107,111,118,119,120

BOX 19.13 Rationale for Early Controlled Motion After Tendon Repair

- Decreases postoperative edema.
- Maintains tendon-gliding and decreases the formation of adhesions that can limit tendon excursion and that consequently limit functional ROM. Gliding deteriorates by 10 days after repair when a tendon is immobilized.
- Increases synovial fluid diffusion for tissue nutrition, which increases the rate of tendon healing.
- Increases wound maturation and the tensile strength of the repaired tendon more rapidly than continuous immobilization by means of *appropriate-level* stresses achieved with early tendon motion. The repair site loses strength during the first 2 weeks after surgery.
- Decreases gap formation at the repair site, which in turn increases the tensile strength of the repair.

BOX 19.14 Indications for Use of Prolonged Immobilization and Delayed Motion After Flexor Tendon Repair

- Patients who are unable to comprehend and actively participate in an early controlled motion exercise program. This includes:
  - Children less than 7 to 10 years of age.
  - Patients with diminished cognitive capacity associated with head injury, developmental disability, or psychological impairment.
- Patients who have the cognitive ability to understand and follow an early controlled motion program but who are unlikely to adhere to the program
  - The unmotivated patient
  - The overzealous, impatient individual with a history of a previously failed repair
- Patients in whom repair of other hand injuries or surgeries necessitates extended immobilization of the hand

With all approaches, the postoperative goals and interventions for pain reduction, edema control, and maintenance of function in uninvolved regions (e.g., the elbow and shoulder) are consistent with management following other operative procedures previously discussed in this chapter. Patient education is of the utmost importance for effective outcomes after hand surgery.

NOTE: Unless otherwise noted, the guidelines described in this section for immobilization and exercise are for injury and primary repair or one-stage tendon grafts of the FDS and/or FDP muscle-tendon units in zones I, II, and III. The guidelines are similar but not addressed for zones T-I and T-II of the thumb. Postoperative guidelines for multistage or late reconstructions are progressed in a similar but more cautious manner. Refer to other resources for this information.[58,93,109]

Immobilization

The duration, type, and position of immobilization must be considered.

Duration of immobilization. With some exceptions previously noted (see Box 19.14), when prolonged immobilization (3 to 4 weeks) is necessary, the repaired tendon is continuously immobilized after surgery for up to 5 days while the bulky compression dressing is kept in place. This allows some time for postoperative edema to decrease.

Type or method of immobilization. This usually depends on the preference of the hand surgeon and therapist, the approach to postoperative exercise, and the stage of tissue

*17,25,27,36,49,50,82,93,107,110,111,115,117,118,119,120,133,135,138

healing. If motion of the operated digit is to be delayed for 3 to 4 weeks, a cast or static splint provides the immobilization. Early controlled motion approaches require the fabrication of different types of customized splints.

There are three general types of splint used after flexor tendon repair: a static dorsal blocking splint;[27,45,50,93,115,119] a dorsal blocking splint with dynamic traction, originally proposed by Kleinert and colleagues[66,70] and subsequently modified and improved by clinicians and researchers;[50,93,111,115] and a dorsal tenodesis splint with a wrist hinge.[24,25,118,119,120] Descriptions of these static and dynamic splinting techniques for immobilization and/or exercise are noted in Box 19.15. Figure 19.13 shows an example of a dorsal blocking splint with dynamic traction. The splint allows active extension of the involved finger, and the elastic band passively returns the finger to a flexed position. (See Figure 19.14 A for a depiction of a dorsal tenodesis splint.)

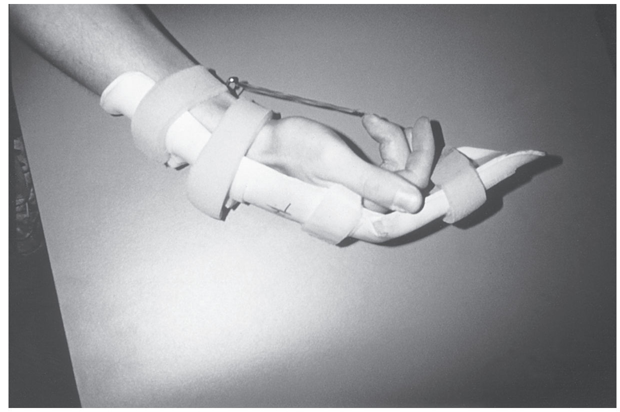

FIGURE 19.13 A dorsal-blocking splint with dynamic traction for early controlled motion after flexor tendon repair.

Position of immobilization. The typical position of immobilization for repairs of flexor tendons in zones I, II, and III is wrist and MCP flexion coupled with PIP and DIP extension. This position prevents full lengthening and undue stress on the repaired FDS and/or FDP tendons while minimizing the risk of IP flexion contractures. The recommended degrees of wrist and MCP flexion differ somewhat from one source to another. Recommended positions range from 10° to 45° of wrist flexion and from 40° to 70° of MCP flexion with the IP joints in full but comfortable extension.[24,25,27,36,45,50,93,115,118,119,120] The wrist typically is positioned in less flexion than the MCP joints. The trend over the years has been to fabricate splints that allow less wrist and MCP flexion than early protocols recommended to increase patient comfort and reduce the risk of carpal tunnel syndrome.[50,93]

The wrist is typically positioned at neutral with 70° MCP flexion following a zone IV repair.[93]

Exercise: Early Controlled Motion Approaches

There are two basic approaches to the application of early, controlled motion to maintain tendon-gliding and prevent tendon adhesions after flexor tendon repair: early passive motion and early active motion. The way in which passive or active motion of the repaired tendon is achieved, however, varies among protocols.

Early controlled passive motion. Historically, the use of early passive motion is based on the work of Duran and Houser[45] and of Kleinert and associates.[66,70] Both proposed early passive flexion of the IP joints within a protected range postoperatively, but used different approaches to splinting and exercise. Duran

BOX 19.15 Static and Dynamic Dorsal Blocking Splints: Position and Use

Static Dorsal Blocking Splint

- Covers the dorsal surface of the entire hand and the distal forearm (the thumb is free).
- Positioned in wrist and MCP flexion and IP extension to avoid excessive tension on the repaired flexor tendon. The degrees of flexion vary with the philosophy of the surgeon or therapist and the approach (protocol) implemented.
- Fabricated with straps placed across the volar aspect of the hand and forearm to hold the wrist and fingers in the correct position.
- Restricts wrist and MCP extension.
- Worn during early phases of rehabilitation. Splint is loosened or removed for early exercises.
- Also worn as a protective night splint.

Dorsal Blocking Splint with Dynamic Traction

- Allows early motion of the operated joint while the hand is in the splint.
- Fabricated with an elastic band (or nylon line with a rubber band), which is attached to the nail of the operated finger (or all four fingers), and passes under a palmar bar that acts as a pulley, and then is attached proximally at the wrist.
- At rest, the elastic band provides dynamic traction that holds the operated finger in flexion.
- Allows *active extension* of the IP joints to the surface of the dorsal splint.
- When PIP and DIP extensors relax, tension from the elastic band pulls on the finger, causing *passive flexion.*

Dorsal Tenodesis Splint with Wrist Hinge

- Worn *exclusively* for exercise sessions
- No dynamic traction with elastic bands.
- Allows full wrist flexion and limited (approximately 30°) wrist extension but maintains the MCP joints in at least 60° of flexion and the IP joints in full extension when the straps are secured.
- Loosening of straps across the fingers allows active wrist extension during initial passive IP flexion and later when finger flexion is maintained for several seconds by a static contraction of the IP flexors.

advocated use of a static dorsal blocking splint and early removal of the splint or loosening of the stabilization straps for passive ROM exercise of the IP joints of the operated finger(s). Kleinert and colleagues advanced use of a dorsal splint with dynamic traction for early exercise (see Fig. 19.13). Within the confines of the splint, the patient performs *active extension* of the operated finger. The elastic band returns the finger to a flexed position with each repetition after the finger extensors relax, causing excursion of the repaired tendon without active tension in the finger flexors. A manual push into maximum DIP flexion may be added to increase passive flexion.

NOTE: When a dynamic traction splint is used during the day, a static splint is worn at night. The splint holds the IP joints in neutral and the wrist and MCP joints in flexion to prevent IP flexion contractures.

These original passive motion protocols have been modified over the past three decades. Today, some surgeons and therapists use selected elements (splinting and/or exercise) of these passive motion approaches.[25,27,50,93,133,135] However, use of early *active* motion that imposes controlled stresses on the repaired tendon is gradually replacing passive motion approaches.[118]

Early controlled active motion. The primary feature that distinguishes an early active motion from an early passive motion approach is the use of *minimum-tension, active contractions* of the repaired muscle-tendon units initiated during the acute stage of tissue healing, often by the first 24 to 72 hours but no later than 5 days postoperatively.[25,49,50,107,110,111,118,119,120,133] Some passive exercises also are incorporated into active regimens.

Based primarily on experimental studies using animal models, it is hypothesized that gentle stresses placed on a repaired tendon by means of a very low-intensity static or dynamic muscle contraction, which "pulls" the repaired tendon through its sheath, is a more effective method of creating tendon excursion (gliding) than "pushing" the tendon with passive motion.[49,50,57,109,111,118,119] Early active motion has become more widely accepted, because stronger suturing techniques produce a repair that can withstand early, controlled stresses.

PRECAUTION: Proponents of early, active tendon mobilization caution that this approach is recommended only for primary tendon repairs, using the stronger four- and six-strand core and epitendinous suture techniques (in contrast to two-strand suturing) in carefully selected patients who have access to rehabilitation with an experienced hand therapist and are most likely to adhere to the prescribed exercise and splinting regimen.[24,25,49,50,57,93,119,120]

There are two ways in which early active motion can be implemented. Both methods are founded on an analysis and application of evidence in the scientific literature on tendon repair and healing, tendon excursion, and imposed loading on repaired tendons.[107,110,111,118,119,120]

- ***Place-and-hold approach.*** One approach uses "place-and-hold" exercises by means of *static* muscle contractions to generate active tension of the finger flexors and impose controlled stress on the repaired tendon. (Place-and-hold exercises are described in the phase-specific exercises that follow.) This approach to early active motion is used in the Indiana protocol.[24,25,82,118,119,120]
- ***Dynamic approach.*** The other approach to early active motion, developed by Evans[49,50] and others,[107,110,111] uses *dynamic*, short-arc, minimum muscle tension exercises to impose initially low-intensity stresses on the healing tendon.
- ***Combined approach.*** Proposed by Groth,[57] a recently developed conceptual model for the use of early active motion and application of progressive forces to the healing tendon after flexor tendon repair combines elements of both the place-and-hold and dynamic approaches. In addition, in the rationale for this model, Groth discusses the effects of each level of exercise on internal tendon loads and tendon excursion supported by key evidence from the literature when available.
    - A unique feature of Groth's model is that it is criterion-based rather than time-based. By providing criteria for progressing exercises based on optimal tendon loading, this program provides a mechanism for an individualized sequence of exercises adjusted for each patient rather than using predetermined timelines for progression.
    - The model contains eight progressive levels of active exercises, from the least to the greatest levels of loading on the tendon. The sequence is preceded by warm-up exercises (slow, repetitive passive finger motions in protected ranges). As with other early active motion approaches, exercises are begun during the first few days after surgery and are progressed until conclusion of postoperative rehabilitation. Box 19.16 describes the eight-level sequence of exercises in Groth's conceptual model.[57]

A number of retrospective studies and prospective, nonrandomized case series have been published describing the effectiveness of early active motion or early passive motion approaches to postoperative rehabilitation following flexor tendon repair. The following prospective, randomized study,[133] which was recently published, directly compared these two approaches to therapy and therefore is an important addition to the body of evidence.

FOCUS ON EVIDENCE

Trumble and associates[133] conducted a multicenter study in which patients who had undergone zone II flexor tendon repair of one or more digits were randomly assigned to participate in therapist-supervised rehabilitation using either an early passive motion or early active motion (place-and-hold) protocol. All patients began therapy within 72 hours after surgery. ROM was measured at 6 and 12 weeks postoperatively and again at 6 and 12 months. Dexterity tests were performed and functional outcomes and patient satisfaction questionnaires were completed at one year.

BOX 19.16 A Sequence of Exercises for Early Active Motion with Progressive Tendon Loading after Flexor Tendon Repair[57]

Warm-up

Warm-up exercises (passive finger motions within protected ranges precedes each exercise session.

Progressive Levels of Exercise*

- Level 1—place-and-hold finger flexion
- Level 2—active composite finger flexion
- Level 3—hook and straight fist finger flexion
- Level 4—isolated finger joint motion
- Level 5—continuation of levels 1–4 of exercise and discontinuation of protective splinting with introduction of gradually increasing use of the hand for functional activities
- Level 6—resisted composite finger flexion
- Level 7—resisted hook and straight fist exercises
- Level 8—resisted isolated joint motion.

**Note:* Exercise sequence is from least to greatest tendon loading. Repetitions are highest at the lowest level of loading and least at the highest level of loading. Progression to next level occurs when specific criteria are met.

Results of the study demonstrated that total active IP ROM of the repaired digits was significantly greater and flexion contractures significantly smaller in the active motion group than the passive motion group at each of the four postoperative assessment points. In the group treated with active motion, 94% (51 of 54 digits), compared with 62% (32 of 52 digits) of the passive motion group, had "good" or "excellent" results (> 125° of combined active PIP and DIP motion) at one year. Patient satisfaction at one year also was greater in the active motion group. However, there were no significant differences in dexterity and functional outcomes between groups at one year. Tendon ruptures occurred in two digits (4%) in both groups with 3 of the 4 ruptures occurring in the little finger. Of interest is that smokers, regardless of group assignment, had poorer outcomes than nonsmokers.

Exercise: Maximum Protection Phase

NOTE: The guidelines for exercises described in this section focus on the application of early active motion after *zone I, II, or III primary flexor tendon repairs* and are drawn from several resources.

The maximum protection phase of rehabilitation begins within the first few days after surgery and continues for 3 to 5 weeks. This is the period of time when the tendon repair is weakest. The goals of this phase of rehabilitation are pain and edema control and protection of the newly repaired tendon while imposing very low-level, controlled stresses on the tendon to maintain adequate tendon gliding and prevent adhesions that can restrict tendon excursion. Interventions in this phase include elevating the hand, splint use and care, wound management and skin care, and passive and active exercises.

During the first phase of rehabilitation, most exercises are performed in a static dorsal blocking splint or in a wrist tenodesis splint (Fig. 19.14 A) specifically designed for exercise. With both methods of splinting, the stabilization straps are loosened to allow finger flexion. The following exercises are performed frequently during the day and continue for about the first 4 weeks.

- ***Passive ROM exercises.*** On an hourly basis perform passive MCP, PIP, and DIP flexion and extension of each individual

C

FIGURE 19.14 Splinting and exercise for early active motion post-flexor tendon repair. **(A)** Following removal of the surgical compression dressing and fabrication of a static dorsal-blocking splint, a tenodesis splint with a wrist hinge is fabricated. **(B)** The tenodesis splint allows full wrist flexion but limits wrist extension to 30°. During early movement of the fingers, the MCP joints are maintained in at least 60° of flexion, as the IP joints are passively moved and placed in composite flexion. **(C)** Then the patient actively extends the wrist while maintaining the flexed finger position with a static muscle contraction and the least amount of tension possible in the finger flexors. *(From Strickland, JW: Flexor tendon injuries. In Strickland, JW, and Graham, TJ [eds]: Master Techniques in Orthopedic Surgery—The Hand, ed. 2. Philadelphia: Lippincott Williams & Wilkins, 2005, p. 262, with permission.)*

joint to the extent the dorsal splint allows, followed by composite passive flexion in the confines of the splint. Composite flexion can include passive movements into full fist and straight fist positions.

- ***Independent motions of the PIP and DIP joints for differential gliding of the FDP and FDS tendons.*** For example, the DIP joint must be flexed and extended separately while each PIP joint is stabilized in flexion. In this way, as the DIP joint is passively extended, the FDP repair site glides distally, away from the FDS repair.[93,117]

PRECAUTION: It is essential to maintain the MCP joints in flexion during passive ROM of the IP joints to avoid excessive stretch of the repair site, which could cause gapping of the re-opposed tendon ends during IP extension.

- ***Place-and-hold exercises.*** Many programs initiate place-and-hold exercises of the repaired digit with the patient wearing either a dorsal blocking splint[49,50,111] or a tenodesis splint.[24,25,57,118,119,120] With the MCP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors. If the patient is wearing a tenodesis splint, combine place-and-hold finger flexion with active wrist extension (Fig. 19.14 B and C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend. Initially, have the patient practice this with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production in the FDP and FDS.

FOCUS ON EVIDENCE

Research has shown that it is preferable to perform place-and-hold exercises with the wrist extended and the MCP joints placed in flexion, because wrist extension is the position in which the IP joints can be moved by contraction of the FDS and FDP with the *least* amount of contraction force and, therefore, a very low-level load on the repaired tendon.[106]

- ***Minimum-tension, short-arc motion.*** Some programs begin active, dynamic finger flexion during the first few days after surgery if the suturing technique and strength of the repair allow.[49,50] Active contractions that generate minimum tension—just enough tension to overcome the resistance of the extensors and cause flexor tendon excursion—are performed with the wrist in slight extension and the MCP joints flexed.

Exercise: Moderate Protection Phase

The moderate protection phase begins at about 4 weeks and continues until 8 weeks postoperatively. The focus during this phase is on safely increasing stresses on the repaired tendon and achieving full active flexion and extension of the wrist and digits and differential gliding of the tendons. If a tenodesis splint was worn for early active exercises, it is discontinued at the beginning of this phase. However, use of the static dorsal blocking splint continues during the day except for exercise until at least 6 to 8 weeks. Use of a night splint continues for protection or to decrease or prevent a flexion contracture. Exercises include:

- ***Place-and-hold exercises.*** Continuation of place-and-hold exercises but with gradually increasing tension.
- ***Active ROM.*** Continuation or initiation of active composite flexion and extension of the IP joints with the MCP joints flexed, MCP flexion/extension with the IP joints relaxed, and active wrist flexion and extension with the fingers relaxed.
- ***Tendon-gliding and blocking exercises.*** These exercises are initiated at about 5 to 6 weeks (see Fig. 19.17 A through E, Fig. 19.18 A through C, and descriptions in the final section of this chapter).

PRECAUTION: Avoid finger extension combined with wrist extension for about 6 to 8 weeks, as this position places extreme tension on the repaired flexor tendon.

Exercise: Minimum Protection/Return to Function Phase

The minimum protection/return to function phase begins at approximately 8 weeks postoperatively and is characterized by gradually progressed use resistance exercises to improve strength and endurance, dexterity exercises, and use of the hand for light (1 to 2 lb) functional activities. (Refer to the final section of this chapter for suggested exercises and activities.)

Protective splinting is discontinued, but intermittent splinting may be necessary if the patient has a persistent extensor lag or flexion contracture. After primary flexor tendon repairs, most patients return to full activity by 12 weeks after surgery.

Exercise: Delayed Motion Approach

In instances where continuous immobilization of a repaired flexor tendon extends for 3 to 4 weeks (see Box 19.14 for indications), some degree of tendon healing and adhesion formation already has occurred by the time exercises can be initiated.

PRECAUTION: Despite the extended period of immobilization, at 3 to 4 weeks, the tendon repair must still be protected in a dorsal blocking splint, and exercises must be performed in protected positions and progressed gradually.

Exercises such as passive ROM, tendon-blocking and tendon-gliding, and active ROM can be initiated when the cast is removed. Exercises used in early motion approaches are appropriate. The reader also is referred to additional resources that provide detailed exercise programs when delayed mobilization is necessary.[17,93,115]

Outcomes

Functional outcomes. There is a substantial body of evidence on flexor tendon repairs, some of which is based on longitudinal clinical outcome studies.[36,58,109,118,119] One review of the literature[118] indicated that with the advances

made in flexor tendon surgery and rehabilitation techniques over the past few decades, recovery of good or excellent function can be expected in 80% or more of patients after flexor tendon injury and repair. Two factors that have contributed considerably to a high rate of favorable outcomes are the use of improved suturing techniques that produce a strong repair site and implementation of early motion in rehabilitation programs.

There are several quantitative assessment tools used in outcome studies of tendon repair.[93] It is helpful to become familiar with the more frequently used assessments in order to understand the findings of studies. With some of these tools, results are reported as excellent, good, fair, and poor. For the most part, these terms are not simply subjective descriptors, but rather, are associated with objective measurement tools. For example, in the Strickland system,[46,93] the terms refer to a percentage of "normal" total active motion (total active flexion minus deficits in active extension) of the PIP and DIP joints achieved after zone I, II, or III repairs and rehabilitation.

Some generalizations can be made about outcomes after flexor tendon repair. Findings in the literature indicate that immediate primary and delayed primary repairs (up to 10 days after injury) yield equally positive outcomes.[109] However, late reconstructions and multistage reconstructions, not surprisingly, result in poorer outcomes (less active and passive ROM, greater functional limitations) than primary repairs.[79,109] This is consistent with the findings that the greater the severity and number of associated injuries, the less favorable the outcomes.[119]

Studies dating back to the 1980s have documented that the use of 4 weeks of uninterrupted immobilization leads to a slower return of tensile strength in the repaired tendon and greater adhesion formation than the use of early mobilization.[36] Although extended immobilization continues to be the treatment of choice for children less than 7 to 10 years of age, one study indicated that the incidence of chronic contractures or diminished hand function is minimal in this age group.[90]

Studies of various approaches to early motion, passive or active, after flexor tendon repair demonstrate superior outcomes when compared with outcomes after extended immobilization.[27,108,132] Although the use of early motion in rehabilitation after flexor tendon repair has been well documented in the literature and is now the "norm" for treatment, only a limited number of studies directly comparing early active motion with early passive motion approaches have been published.

In one such study, carried out retrospectively, a "passive flexion-active extension" program of exercises in a dynamic traction splint was compared with a "controlled active motion" program that included therapist-supervised, active contractions of the repaired FDS and FDP muscle-tendon units.[8] The investigators reported that although there were no significant differences in outcomes (total active flexion and active extension deficit) 16 weeks after surgery between groups in patients with zone I repairs, there were substantial differences between groups in patients with zone II repairs. In the "passive flexion-active extension" group, 50% of patients had good or excellent results, whereas 94% of patients in the "controlled active motion" group had good or excellent results. In addition, 39.7% of the passive flexion group had an active extension deficit > 15°, but only 10.5% of the active flexion group had an extensor lag 4 months after repair.

A comparable percentage of excellent and good outcomes for total active motion was reported in a 9-year, prospective follow-up study of 130 patients with zone I and II repairs who began supervised active exercises, including minimal-tension IP flexion and extension (detailed in the study), the day after surgery. Patients also performed active extension exercises in a dynamic traction splint regularly during the day. At the conclusion of the study, 92% of the patients had excellent and good results.[65] The prospective randomized study by Trumble and co-investigators[133] highlighted previously in this section lends further support for the use of early active motion for the management of repaired flexor tendons.

Complications. The most frequent early complication after surgery is rupture of the repaired tendon, and the most frequent late complication is flexion contracture or a deficit in active extension of the repaired DIP and/or PIP joints, typically as the result of tendon adhesions.[36,120] Overall, the rate of postoperative complications is higher in zone II repairs than in other zones.[78] Most ruptures usually occur around 10 days postoperatively when the repaired tendon is in its most weakened state.[78] A rupture may occur during strong gripping activities or as the result of encountering an unexpected high load, but it also may occur while the patient is asleep if the hand is unprotected during the first few months after surgery.

Although there is general agreement that early motion after tendon repair reduces adhesion formation, there have been concerns that initiating early active contractions (static or dynamic) of the PIP or DIP flexors, which place active tension on the newly repaired tendon, may increase the risk of tendon rupture. Overall, however, rupture rates are low and appear to be relatively equal to those seen with early passive flexion/active extension programs.[118,133] In studies that have used passive flexion/active extension exercise in a dynamic traction splint, rupture rates have ranged from 3.0%[8,70] to 6.8%.[27] Similarly, in patients using dynamic traction splinting, who also have participated in a variety of early active exercises, including active flexion, rupture rates have been reported at 3.6%,[111] 5.0%,[8] and 5.7%.[65] Equal rupture rates (4%) have occurred in zone II tendon repairs when early passive motion and early active motion (place-and-hold) approaches to therapy were implemented.[133]

Lacerated Extensor Tendons of the Hand: Surgical and Postoperative Management

Background and Indications for Surgery

Laceration and traumatic rupture of the extensor tendons of the fingers, thumb, or wrist are more common than in the flexor tendons.[43] Their superficial location makes the extensor

tendons vulnerable to damage when trauma occurs to the dorsum of the hand. Furthermore, extensor tendons in the digits are substantially thinner than flexor tendons, making them more prone to traumatic rupture.[43,88,101]

As with the flexor surface, the extensor surface of the hand, wrist, and forearm is divided into zones (Fig. 19.15). The dorsal surface of the fingers and wrist are divided into seven zones, and the thumb into four zones. Each of these zones is identified by specific anatomical landmarks, as noted in Box 19.17.[43,46,56,88,101] The odd-number zones correspond to the location of the DIP, PIP, MCP, and wrist joint regions. Although not depicted in Figure 19.15, the dorsal surface of the distal and middle forearm is often identified as zones VIII and IX, respectively. The area at the CMC joint of the thumb is often identified as zone T-V.[88]

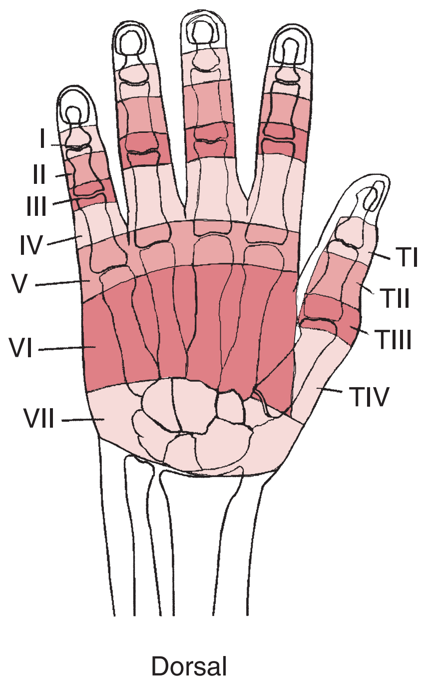

FIGURE 19.15 Extensor tendon zones; dorsal aspect of the hand and wrist.

The extensor mechanism of the hand and wrist is complex. The structural characteristics of these mechanisms vary in each zone. Damage in one zone produces compensatory imbalances in adjacent zones. Knowledge of the anatomy and kinesiology of the extensor mechanism is basic to an understanding of how a patient's physical impairments and functional limitations occur according to the structures damaged in each zone. Box 19.18 identifies key structures and characteristic impairments associated with tendon rupture or laceration by zone.[43,46,88,101] Of all the extensor zones, injuries in zones III and VII pose the greatest surgical and rehabilitative challenges.

Depending on the type and location of injury to the extensor mechanism and the extent of associated skeletal, joint, vascular, or nerve damage, surgery may or may not be indicated.

BOX 19.17 Extensor Tendon Zones: Anatomic Landmarks

Zones of the Dorsal Surfaces of the Fingers, Hand, Wrist, and Forearm

- I—DIP joint region
- II—middle phalanx
- III—PIP joint region
- IV—proximal phalanx
- V—apex of the MCP joint region
- VI—dorsum of the hand
- VII—wrist region/dorsal retinaculum
- VIII and IX—distal and middle forearm

Zones of the Thumb

- T-I—IP joint region
- T-II—proximal phalanx
- T-III—MCP joint region
- T-IV—metacarpal
- T-V—carpometacarpal joint region

The tendons of the extensor system distal to the dorsum of the hand have many soft tissue attachments along various structures, making extensor tendons far less likely to retract when lacerated or ruptured than flexor tendons.[44,88,101] Consequently, with a rupture (closed injury) or a simple laceration in a peripheral zone, the tendon is re-opposed and managed by uninterrupted immobilization in a splint or cast for 6 weeks as it heals.[44,101] For example, this is a common course of treatment for a *mallet finger* (or thumb) deformity, which is a closed rupture of the terminal extensor tendon in zone I, usually from forceful hyperflexion.[88]

Nevertheless, surgical intervention, even for a simple distal tendon injury, usually is necessary to restore active ROM, muscular balance, strength, and function to the hand and prevent contractures and deformity. Although the extensor muscles of the digits are substantially weaker than the flexors, an intact extensor mechanism is essential for functional grasp and release.

Procedures

Types of Repairs and Reconstruction

Surgical options for extensor tendon repair include a direct (end-to-end) repair or a reconstruction. As with flexor tendon repair or reconstruction, surgeries are classified as primary (immediate repair or delayed up to 10 days), secondary repair, and late or staged reconstruction.[22,43,88,101] Reconstruction usually involves use of a graft. These terms already have been defined in the previous section of this chapter on flexor tendon repair and rehabilitation. Operative procedures, such as tendon transfers, for ruptured, diseased extensor tendons associated with RA also were described earlier in the chapter.

Operative Overview

Although similar definitions exist for extensor and flexor tendon procedures, there are substantial differences in operative

BOX 19.18 Consequences of Injury to the Dorsal Structures of the Hand and Wrist

- ***Zones I and II.*** Damage to the terminal extensor leads to inability to actively extend the DIP joint (extensor lag) and eventual DIP flexion contracture and deformity (mallet finger). A swan-neck deformity secondary to an unopposed central slip and migration of the extensor mechanisms proximally may also develop. Damage in those zones is usually the result of a closed rupture rather than a laceration.
- ***Zones III and IV.*** Damage to the central slip tendon and possibly the lateral bands results in an inability to actively extend the PIP joint from a 90° flexed position. Flexion contracture of the PIP joint and eventually a boutonnière deformity develops as the lateral bands slip volarward and cause hyperextension of the DIP joint.
- ***Zone V.*** Damage to the common extensor tendons (EDC), extensor indicis proprius (EIP), extensor digiti minimi (EDM), and sagittal bands that surround the MCP joints causes inability to actively extend the MCP joints, eventually resulting in MCP flexion contractures.
- ***Zones VI and VII.*** The juncturae tendium along the dorsum of the hand (VI) and the dorsal retinaculum (VII) under which multiple extensor tendons of the wrist and digits pass in close proximity can be damaged. A bowstring effect occurs in the extensor tendons if the retinaculum, which acts as a pulley, is lacerated. The synovial sheath through which the tendons glide in zone VII can also be damaged, subsequently compromising synovial diffusion and nutrition to the tendons. Injuries in zones VI and VII can result in loss of extension of the digits and wrist.
- ***T-I and T-II.*** Damage to the EPL and possibly the EPB (if laceration is in the proximal region of the proximal phalanx) leads to loss of hyperextension of the IP joint (mallet thumb deformity) and weakened MCP extension.
- ***T-III and T-IV.*** Damage to EPB leads to weakened MCP extension and transfers extension forces to IP joint, leading to a flexion deformity of the MCP joint and a hyperextension deformity of the IP joint if the EPL is intact.

techniques used to repair extensor versus flexor tendons. These differences are based largely on the fact that extensor tendons are morphologically thinner than flexor tendons. This fact led to the belief that extensor tendon repairs are more prone to gapping, have less tensile strength, and are more likely to rupture than flexor tendons after repair. However, stronger suturing techniques, specifically designed for extensor tendon repair and reconstruction, are used more frequently today, allowing early postoperative mobilization of the repaired tendon while lessening concerns of gapping and rupture.[43,46,114]

Zone III/IV primary repair. Operative procedures for repair of lacerated or ruptured extensor tendons vary significantly in the distal versus the proximal zones. In this overview only repair of a zone III/IV laceration (the most common cause of injury in these zones) is described, simply as an example. Detailed descriptions of operative techniques for primary repair and late reconstruction of extensor tendons in all zones of the hand, wrist, and forearm can be found in several sources.[10,22,43,56,88,101]

With an acute laceration of the PIP joint and middle phalanx, the wound often enters the joint space. Therefore, the area must be débrided, cleansed, and treated with antibiotics. The central slip, which refers to the extensor mechanism in zones III and IV, then can be managed with a direct repair.[43,56,88] The severed tendon is repaired and then sutured into the fibrocartilaginous dorsal plate of the middle phalanx, which is thicker and holds sutures better than the central slip, thereby producing a stronger repair.[43]

NOTE: The suturing and repair technique in zones III and IV may decrease the overall length of the tendon by 2 to 3 mm, causing a loss of 2° to 5° of PIP flexion.[88]

If damaged, the lateral bands are repaired. If a boutonnière deformity is evident or likely to develop, a K-wire may be inserted to immobilize the PIP joint in extension for about 3 weeks and then removed. After closure of the area, a bulky compression dressing immobilizes the repaired tissues and controls edema.

Postoperative Management

General considerations. The overall goal of postoperative rehabilitation after extensor tendon injury and repair is the same as after flexor tendon repair—that is, to restore mobility and strength to the hand and wrist for functional activities. Adhesion formation is a concern in the extensor tendons after repair, just as it is after repair of the flexor tendons. As noted previously, extensor tendons of the fingers are less likely to retract after laceration or rupture because of the extensor mechanism's multiple soft tissue linkages to surrounding structures. However, these attachments make extensor tendons prone to adhesion formation and loss of excursion during the healing process. At the dorsum of the hand, the extensor tendons are relatively mobile, but also are surrounded by synovial sheaths to which they may adhere if immobilized over a period of time.[43,88,101] As with management after flexor tendon repair, emphasis after extensor tendon repair is placed on preventing adhesions that restrict tendon gliding and limit joint ROM and functional use of the hand. (Refer to Box 19.12 to review factors that contribute to adhesion formation.)

The components and progression of postoperative rehabilitation and eventual outcomes after extensor tendon repair are influenced by many of the same factors that influence rehabilitation and outcomes of flexor tendon repair, including the location (level) and severity of the injury; the specifics of the surgical procedure(s), particularly the type of suturing technique and strength of the repair; and

the timing of and the patient's access and commitment to a supervised rehabilitation program with an experienced hand therapist.[26,46,114,117,135]

Approaches to postoperative management. Two general approaches to rehabilitation after surgical repair of extensor tendon injuries are described in the literature: prolonged, uninterrupted immobilization with motion of the injured region(s) delayed for 3 to 6 weeks or, in carefully selected patients, early controlled passive or active motion initiated during the first few postoperative days. The latter is based on the same rationale as for early mobilization of flexor tendon repairs (see Box 19.13).

Historically, prolonged immobilization has been used more widely than early motion after extensor tendon repair, perhaps because of concerns that inadvertent but forceful or rapid movements could cause gapping or rupture of the repair if the splint or cast is removed early in the healing process[10] or simply that alternative forms of immobilization, such as dynamic splinting, are cumbersome and more costly for the patient.[96] Given these issues, the use of early motion after extensor tendon repair has evolved more slowly than it has for use after flexor tendon repair.

There are situations when an extended immobilization/delayed motion approach is the only appropriate method of management (see Box 19.14). Some studies continue to show that in many instances this traditional approach yields acceptable reults.[96] However, during the past two to three decades, some studies have shown that extensor tendon repairs, managed with prolonged immobilization, are more likely to develop adhesions, resulting in only marginal outcomes (increased incidence of extensor lag, joint contracture, boutonnière deformity).[28,89] In addition, these and other studies have demonstrated that early motion programs after *primary* repair of acute extensor tendon injuries in zones III and VII are effective and safe[18,19,35,47,48,59,63,103,128] and produce superior outcomes compared with prolonged immobilization/delayed motion programs.[28,35,47,89,103] Consequently, early motion approaches have become more widely used in recent years.

It should be noted, however, that prolonged immobilization continues to be the most frequently selected method of treating zone I and II extensor tendon injuries.[44,88,101] Late reconstruction, which is more complex and usually involves tendon grafts, also is managed in most cases with continuous, extended immobilization and delayed motion.[22]

The first early motion programs for extensor tendons involved passive mobilization, with dynamic extension splinting, which allows active flexion followed by passive extension (see Fig. 19.11).[28,48,89,103] In these programs, although active flexion is initiated just a few days after surgery, active digital extension—at least at the level of the repair—typically is delayed for 4 to 5 weeks.[18,19,28,35,59,103] For an explanation of dynamic extension splinting after extensor tendon repair, refer to the earlier section of this chapter on repair of tendon ruptures associated with RA.

Although dynamic extension splinting for early mobility of the extensor tendons continues to be used, there is a growing trend to incorporate controlled active extension into early mobilization programs.[26,46,47,63,128] Following a brief overview of immobilization procedures, key elements of early active motion and delayed motion approaches to rehabilitation after extensor tendon repair are presented.

Immobilization

Immobilization typically is maintained with a volar (palmar) splint after the bulky surgical dressing is removed a few days postoperatively. The duration of immobilization, the type(s) of immobilization selected, the joints immobilized, and the position of immobilization are based on the location (zone) of the injury and repair and the structures involved.

Duration of immobilization. If a patient is a good candidate for an early motion program, the duration of uninterrupted immobilization often is just a few days. If delayed motion is a more appropriate course of action, uninterrupted immobilization ranges from 3 to 6 weeks. In early motion programs, some type of protective splinting is used during exercise for about 6 weeks after surgery.

Types of immobilization. Either static or dynamic splinting or a combination of both is used. Depending on the joints immobilized, a forearm and wrist-based or a hand-based splint is indicated to block excessive flexion at the region of the repair and prevent stretching of the repaired tendon(s). A static splint is considered a low-profile splint, whereas a dynamic splint (see Fig. 19.11) with its outrigger secured to the dorsal surface of the splint for the elastic band and sling attachments is a high-profile splint. The slings and elastic band attachments hold the digits in extension at rest but allow active flexion.

For a delayed motion program, a static volar or bivalved circumferential splint is fabricated and worn on a continuous basis (other than daily skin care). A dynamic splint, worn during the day for frequent exercise sessions, is an integral component of many early motion programs, but a static splint must be worn at night to protect the repair. Some early active motion programs use only static splints that allow active motion when the straps are loosened but otherwise prevent excessive motion of joints. Special static template splints for the repaired digits also are fabricated and used only during short-arc exercises to limit the range of allowable motion (see Fig. 19.16).

The joints are immobilized in an extended position or a position that places only minimal tension on the tendon to protect the repair from excessive stretch and potential gapping. As examples, for a zone III/IV repair, the PIP and sometimes the DIP joints are placed in extension, but for a zone V/VI repair, the wrist is held in 30° of extension and the MCP joints in 30° to 45° of flexion. Recommended positions of the joints proximal or distal to the injured zone vary considerably. Several resources provide detailed information on immobilization and splinting procedures after extensor tendon repairs.[26,46,114]

Exercise: Early Controlled Active Motion Approach

As interest in the application of early active motion after tendon repair has grown, so have the number of studies

describing details of exercise programs and outcomes. In addition to one example of an early active motion program for zone III/IV repairs presented in this section, guidelines for early mobilization of zones V, VI, and VII also have been proposed and detailed in the literature.[26,46,63,114,128]

CLINICAL TIP

The distinguishing feature common to all early active motion programs following extensor tendon repair is that low-intensity and controlled active contractions of the repaired muscle-tendon units are initiated during the first few postoperative days, albeit in the confines of some type of static volar splint.

As noted previously, extensor tendon repairs in zones III and IV are especially prone to adhesion formation because of multiple soft tissue attachments of the extensor mechanism to surrounding structures and the broad bone-tendon interface of the proximal phalanx along which the extensor mechanism must glide.[43,46,56,88,101] Evans[46,47] proposed an early motion program of splinting and exercise for repairs of the central slip that involves minimal active tension of the repaired extensors for controlled, short-arc motion of the PIP and DIP joints.

FOCUS ON EVIDENCE

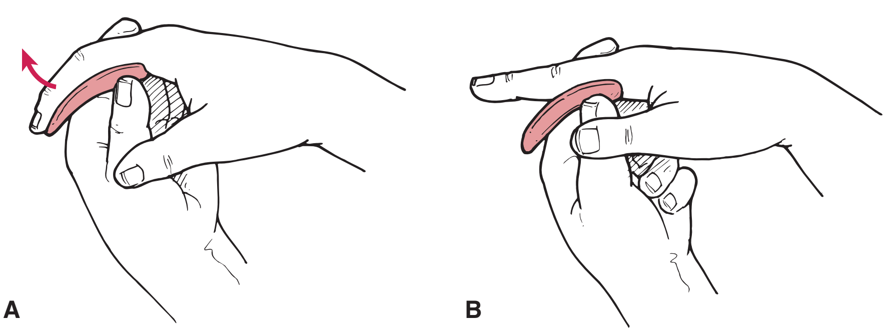
Evans[47] compared the results of a prolonged immobilization/delayed motion program and an early short-arc motion (SAM) program in 55 patients who had undergone primary repair of 64 fingers for injury of the central slip. Patients in one group (36 digits) were managed with 3 to 6 weeks (mean 32.9 days) of continuous immobilization, whereas patients in the early motion group (28 digits) began active motion in a protected range at 2 to 11 days (mean 4.59 days) after surgery. After 6 weeks of treatment, patients in the delayed motion group had significantly less PIP flexion (44°) than the early motion group (88°). At discharge, the delayed motion group continued to have significantly less PIP flexion (72° after 76 days) than the early motion group (88° at 51 days). In addition, at discharge, the delayed motion group had significantly less DIP flexion than the early motion group (37.6° and 45.0°, respectively). It also is interesting to note that at discharge the delayed motion group compared to the early motion group had significantly greater PIP extensor lag (8.1° and 2.9°, respectively). However, at the initiation of treatment, the delayed motion group had a 13° PIP extensor lag, whereas the early motion group had only a 3° lag.

Key elements of the early, short-arc, active motion program for central slip repairs include the following splinting and exercise procedures.[26,46,47]

Use of customized static volar splints. Several types of customized splints are used with this approach. A static, hand-based volar splint is fabricated and applied as soon as the surgical dressing is removed. It holds only the PIP and DIP joints in 0° extension; the wrist and MCP joints are free. This splint is removed for exercise on an hourly basis during the day but replaced between exercise sessions.

- A forearm-based resting splint is worn at night for protection for at least 6 weeks postoperatively.
- Two static, volar, finger-based, template splints are fabricated and worn only during exercise to limit joint motion, extensor tendon excursion, and the level of stress on the repaired central slip. One splint (Fig. 19.16) is molded to limit PIP flexion to 30° and DIP flexion to 20° or 25° during exercise. A second template splint is fabricated to hold the PIP joint in full extension during isolated DIP flexion limited to 30° to 35°.
- The PIP exercise splint is revised during the second week of exercise to allow 40° of flexion if no extensor lag is present. The PIP flexion allowed by the splint is increased incrementally by 10° each week thereafter.

Exercise progression. The patient is taught the concept of minimum active tension (MAT) to protect healing tissues during tendon excursion. MAT is just enough tension generated



A B

FIGURE 19.16 One of two static volar template splints used during early short-arc exercises of the PIP and DIP joints after repair of the extensor mechanism in zones III/IV. During exercise, the patient actively holds the wrist in approximately 30° of flexion and manually holds the MCP joint in neutral to slight flexion. **(A)** Using minimal active tension during combined active PIP and DIP flexion, the splint initially limits PIP and DIP flexion to 30° and 20° to 25°, respectively, to prevent excessive stretch of the repair site. **(B)** The patient actively and slowly extends the PIP and DIP joints to full extension and briefly holds the extended position.

during an active muscle contraction to overcome the elastic resistance of an antagonist.[47]

- Exercises are initiated within the first few postoperative days and performed hourly during the day. While actively holding the wrist in 30° of flexion and manually stabilizing the MCP joint in neutral to slight flexion, the patient performs active PIP and DIP flexion within the limits allowed by the PIP exercise splint (see Fig. 19.16 A), followed by full active extension held for several seconds (see Fig. 19.16 B).
- The patient also performs active, isolated DIP flexion/extension in the second volar template splint that stabilizes the PIP joint in full extension.
- Exercises continue regularly during the day for several weeks using revised exercise splints. Ideally, by the end of 4 weeks, the patient achieves 70° to 80° of active flexion and full extension of the PIP joint.
- Composite MCP, PIP, and DIP flexion (full fist) is postponed for at least 4 weeks or when the exercise splints have been discontinued.
- By 6 to 8 weeks, low-intensity resisted exercises are initiated along with gradual use of the hand for functional activities.

Exercise: Delayed Mobilization Approach

If a traditional approach to postoperative management of extensor tendon repairs is used, exercises are delayed for at least several weeks after surgery. Special considerations and precautions for exercise using a delayed motion approach are summarized by zones in Box 19.19.[17,26,46,96,114,135]

BOX 19.19 Special Considerations for Exercise After Extensor Tendon Repair and Extended Immobilization

Zones I and II

- Tendon injuries in these zones are typically managed nonoperatively.
- PIP and MCP AROM while the DIP is continuously immobilized in extension for at least 4 weeks but more often 6 to 8 weeks.
- When splint can be removed for exercise, perform active DIP extension and very gentle active flexion with the MCP and PIP joints stabilized in neutral. Briefly hold the extended position with each repetition.
- Emphasize active extension more than flexion to avoid an extensor lag.
- After initiating exercises, splint between exercise sessions an additional 2 weeks or longer if an extensor lag develops.

PRECAUTION: Increase active flexion of the DIP joint *very gradually,* initially limiting flexion to 20° to 25° during the first week of exercise. The strong FDP can easily place excessive stress on the terminal extensor tendon and cause gapping or rupture of the repair. Progress active flexion by about 10° per week. Do not attempt full DIP flexion for about 3 months.

Zones III and IV

- If the lateral bands were intact, begin DIP AROM 1 week postoperatively while the PIP joint is immobilized in extension in a volar splint or cylinder cast. Early DIP motion prevents adherence and loss of extensibility of the lateral bands and oblique retinacular ligaments and loss of mobility of the DIP joint.
- If the lateral bands were damaged and repaired, postpone DIP ROM until 4 to 6 weeks postoperatively.
- At a minimum of 3 to 4 weeks but more often at 6 weeks, the volar splint is removed for active ROM of the PIP joints with the MCP joints stabilized. Emphasize active extension more than flexion.

PRECAUTIONS: Progress PIP flexion in *very gradual* increments; limit PIP flexion to 30° the first week of PIP ROM exercises. Increase an additional 10° per week if no extensor lag.

- If the wrist and MCP joints have been immobilized postoperatively, include active ROM of the wrist with the MCP and PIP joints stabilized and active MCP ROM with the wrist and PIP joints stabilized in extension.

Zones V and VI

- When the volar splint can be removed for exercise (between 3 and 4 weeks or as late as 6 weeks postoperatively), begin active or assisted MCP extension and passive flexion with the wrist and IP joints stabilized in neutral and the forearm *pronated*. Actively hold the extended position for a few seconds with each repetition. Let the extensors relax to flex the MCP joints.
- Add carefully controlled active MCP flexion within a protected range with the wrist stabilized in extension.
- Emphasize active MCP extension more than flexion to prevent an extensor lag.

PRECAUTION: Initially limit active MCP flexion to 30° in the index and middle fingers and 35° to 40° in the ring and small fingers.

- During active IP flexion and extension exercises, stabilize the MCP joints in neutral and the wrist in slight extension. Encourage full-range DIP motion.
- Combine active MCP extension with active PIP flexion (hook fist position) and PIP extension (straight hand position).
- Incrementally progress to full fist position over several weeks if no extensor lag develops.

Zone VII

- If the wrist extensors are intact and only extrinsic finger extensors have been repaired, follow the guidelines for zone V/VI repairs.
- If the wrist extensors were repaired, begin active wrist extension from neutral to full extension in a gravity-eliminated position (forearm in mid-position) at 3 to 4 weeks.
- Incrementally increase wrist flexion beyond neutral between 5 and 8 weeks postoperatively.
- Perform radial and ulnar deviation with the wrist in neutral.

Guidelines for resistance exercises to strengthen the hand and continuation or modification of splinting for protection are not addressed in this summary. In general, splinting is continued during the day if an extensor lag persists and at night for protection for about 12 weeks. If grasp is limited because of insufficient finger flexion, passive stretching is initiated, or dynamic flexor splinting may be incorporated into the program by alternating flexion and extension splints.

Resistance to the repaired muscle-tendon unit is not initiated until 8 to 12 weeks postoperatively regardless of the site of the repair. First, emphasis is placed on gradually strengthening the extensors to prevent or minimize an extensor lag. After 10 to 12 weeks, *low-intensity* resisted grasp and pinch activities are initiated to gradually strengthen the flexors if no extensor lag is present.

Outcomes

Outcomes, including complications, after extensor tendon repair and postoperative rehabilitation are well documented in the literature. Early and late complications are similar to those occurring after flexor tendon repair, including rupture, adhesion formation, and limited motion. Outcomes typically measured and reported after extensor tendon repair are ROM of the wrist and/or digits and grip strength with only limited information reported on use of the hand for functional activities.

Digital motion often is expressed in terms of "pad-to-palm" distances or total active motion (active flexion minus extensor lag). These figures are then compared to the contralateral hand or to the "normal" population and are typically expressed as excellent, good, fair, or poor. For example, if ROM is only 75% of that found in normal individuals or if there is < 15° of extensor lag in a digit and sufficient digital flexion to touch the pad of the distal phalanx to the mid-palm, the result is described as "good." To understand the results of studies on tendon repair, it is necessary to have some understanding of the various assessment tools.

Some generalizations about outcomes can be drawn from the literature regarding the severity and location of the injury. As with flexor tendon injuries, the greater the extent of associated skeletal, joint, vascular, or nerve injuries, the poorer are the results of the repair with respect to extensor lag and digital flexion for grasp. For example, in a study of outcomes after extended immobilization following extensor tendon repair, 64% of patients with simple tendon injuries had good results, whereas only 47% of patients with associated skeletal or joint injuries had good results.[89] In the same study, investigators found that repairs of distal injuries (zones I to IV) have less favorable results than repairs of more proximal injuries (zones V to VIII).

Outcomes of the various approaches to postoperative management of extensor tendon injuries are reported in the literature on an ongoing basis. With regard to the timing of the surgical intervention, for example, primary repairs of acute injuries (rupture or laceration), whether repaired immediately or delayed for up to 10 days, yield equally good results.[43,88] As noted throughout this section on extensor tendon injury and repair, numerous studies have been published describing outcomes of the various approaches to postoperative management. Although some studies support the use and effectiveness of prolonged immobilization of extensor tendon repairs,[96] there is growing use and ongoing modification and refinement of early controlled motion approaches to help patients achieve the best possible outcomes.

For example, dynamic extension splinting, a mainstay of early passive mobilization protocols for more than 20 years, now is being re-evaluated. Although some studies[19,35] have demonstrated that high-profile, dynamic splinting continues to be used and is effective, other studies reflect a return to the use of low-profile, static splinting if coupled with early active motion.[47,63,128]

In a prospective, randomized study, Khandawala and associates[63] compared the effectiveness of two early mobilization programs for patients with zone V/VI extensor tendon repairs—a dynamic splinting program and a static splinting program combined with early active exercise. One group of 50 patients performed exercises in a volar, wrist-based dynamic extension splint that allowed free movement of IP joints and active MCP flexion to the level of the splint. The elastic bands and slings passively extended the MCP joints to a neutral position as the flexors relaxed. A second group of 50 patients wore a static volar blocking splint that positioned the wrist in 30° of extension and the MCP joints in 45° of flexion. The IP joints were free. With the stabilization straps loosened, this group performed active MCP flexion to 45° (further motion was blocked by the splint) and MCP extension to neutral. In both groups, IP motion was unrestricted. After 6 weeks of exercise, splinting was discontinued, and outcomes were measured by two assessment tools. As reflected by scores on the two assessment instruments, a high percentage of patients in both groups had good and excellent results, specifically 95% and 98% of the dynamic splinting group and 93% and 95% of the static splinting/active exercise group. These results, when analyzed, demonstrated that there were no significant differences in outcomes between the groups. With two splinting and early motion approaches yielding equally favorable results, the investigators concluded that static splinting could be considered a less cumbersome and expensive alternative to dynamic splinting for early motion programs. Additional research is needed to determine if modification of early active motion programs could provide significantly better outcomes over early passive motion programs.

Exercise Interventions for the Wrist and Hand

Techniques for Musculotendinous Mobility

Active muscle contraction and specific motions of the digits and wrist are used to maintain or develop mobility between the multijoint musculotendinous units and other connective

tissue structures in the wrist and hand. Because adhesions between the various structures can become restrictive or incapacitating, *tendon-gliding exercises* and *tendon-blocking exercises* are used whenever possible to develop or maintain mobility. This is particularly important when there has been immobilization after trauma; surgery; or fracture, and scar tissue adhesions have developed. If restrictions occur as a result of scar tissue adherence between tendons or between tendons and surrounding tissues, mobilization techniques described in this section may be necessary. General stretching techniques also may be necessary; they are described in the next section. The tendon-gliding and tendon-blocking exercises described here also may be used to develop neuromuscular control and coordinated movement.

Tendon-Gliding and Tendon-Blocking Exercises

Place-and-Hold Exercises

Place-and-hold exercises are a form of gentle muscle setting (static/isometric) exercises that are used during the early postoperative period following tendon repair before active ROM is initiated but when a minimal level of stress on the repaired tendon and passive joint movement are beneficial for maintaining joint mobility and tendon excursion.

- Following flexor tendon repair, the patient usually wears a dorsal blocking splint[49,50,111] or a tenodesis splint.[24,25,118-120] With the MCP joints in flexion, passively place the IP joints in a partially flexed position and have the patient hold the position independently for 5 seconds with a minimum static contraction of the finger flexors.
- If the patient is wearing a tenodesis splint, combine place-and-hold finger flexion with active wrist extension (see Fig. 19.14 B and C). Have the patient relax and allow the wrist to passively flex and the digits to passively extend.
- Following extensor tendon repair, when the volar blocking splint may be removed for exercise, passively position the joint in the zone of the repair first in a neutral and later in a slightly extended position. Then, have the patient hold the position. This emphasizes end-range extension to prevent an extensor lag.
- Have the patient practice the exercise with the uninjured hand or use biofeedback to learn how to hold the position with a minimum of force production.

Flexor Tendon-Gliding Exercises

Flexor tendon-gliding exercises are designed to maintain or develop free gliding between the FDP and FDS tendons and between the tendons and bones in the wrist, hand, and fingers.[105,112,136] There are five positions in which the fingers move during tendon-gliding exercises: straight hand (all the joints are extended); hook (claw) fist (MCP joints are extended, IP joints are flexed); full fist (all the joints are flexed); table-top position, also known as the intrinsic plus hand (MCP joints are flexed, IP joints are extended); and straight fist (MCP and PIP joints are flexed, IP joints are extended) (Fig. 19.17). The following progression is suggested.

- Initiate the exercises with the wrist in neutral position.
- Once full range of the finger motions is achieved, progress to doing the gliding\exercises with the wrist in flexion and in extension to establish combined finger and wrist mobility.

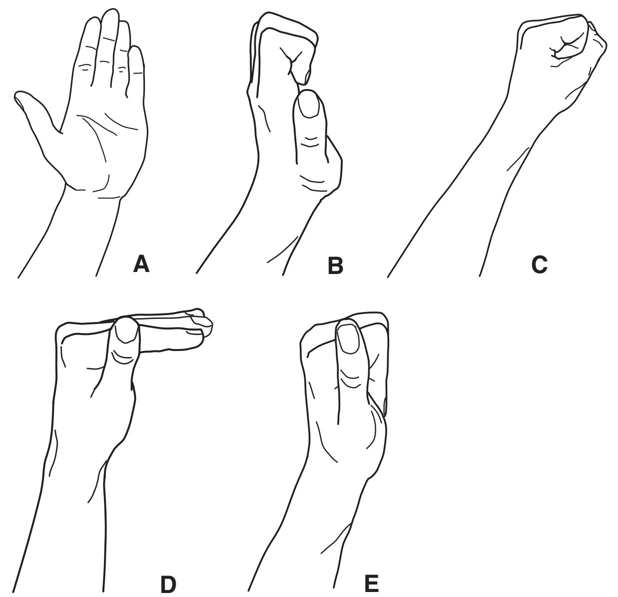


FIGURE 19.17 The five finger positions used for flexor tendon-gliding exercises: **(A)** straight hand, **(B)** hook fist (claw fist), **(C)** full fist, **(D)** table top (intrinsic plus), and **(E)** straight fist.

- Full excursion and tendon-gliding of all the extrinsic muscles are accomplished by starting with the wrist and fingers in full extension, then moving to full wrist and finger flexion, and then reversing the motion.

Hook (Claw) Fist Position

Have the patient move from the straight hand to the hook fist position by flexing the DIP and PIP joints while maintaining MCP extension (Fig. 19.17 A and B). Maximum gliding occurs between the profundus and superficialis tendons and between the profundus tendon and the bone. (There is also gliding of the extensor digitorum communis tendons; this motion is used with the extensor gliding exercises.)

Full Fist

Have the patient move to the full fist position by flexing all the MCP and IP joints simultaneously (Fig. 19.17 C). Maximum gliding of the profundus tendon with respect to the sheath and bone as well as over the superficialis tendon occurs.

Straight Fist (Sublimis Fist)

Have the patient move from the table-top position (Fig. 19.17 D) to the straight fist position by flexing the PIP joints while maintaining the DIP joints in extension

(Fig. 19.17 E). Maximum gliding of the superficialis tendon occurs with respect to the flexor sheath and bone.

Thumb Flexion

Have the patient flex the MCP and IP joints of the thumb full range. This promotes maximum gliding of the flexor pollicis longus.

Flexor Tendon-Blocking Exercises

Blocking exercises for the flexor tendons (Fig. 19.18) not only develop gliding of the tendons with respect to the sheaths and related bones, they also require neuromuscular control of individual joint motions. Therefore, they use the mobility gained by the flexor tendon-gliding exercises and are a progression of the flexor tendon-gliding exercises. Progress to manual resistance as the tissues heal and can tolerate resistance.

PRECAUTION: These exercises should not be used in the early stages of flexor tendon healing after repair because of the stress placed on the tendons.

Patient position and stabilization: Sitting with the forearm supinated and the back of the hand resting on a table. The opposite hand provides stabilization and "blocking" against unwanted movement. Each finger performs the exercise separately.

Isolated MCP Flexion (Lumbricals and Palmar Interossei)

- Have the patient flex only the MCP joint of one digit (Fig. 19.18 A).
- If necessary, stabilize the rest of the fingers in extension against the table with the other hand.
- With improved control, the hand does not have to be stabilized against the table.

PIP Flexion (Flexor Digitorum Superficialis)

- Have the patient stabilize the proximal phalanx of one digit with the opposite hand, and if possible, flex just the PIP joint of the one digit while keeping the DIP joint extended and the rest of fingers on the table (Fig. 19.18 B).
- If the patient has difficulty doing this, stabilize the other digits in extension with the opposite hand.

DIP Flexion (Flexor Digitorum Profundus)

- Have the patient attempt to flex just the distal phalanx (Fig. 19.18 C).
- Stabilize the middle phalanx of one digit with the other hand.
- Vary this exercise by increasing the range of MCP and PIP flexion to the point at which the patient just begins to lose DIP motion; stabilize in this position and have the patient attempt DIP flexion.

Full Fist

When full independent tendon-gliding is available, the patient should be able to make a full fist. Progress the exercises described by adding resistance.

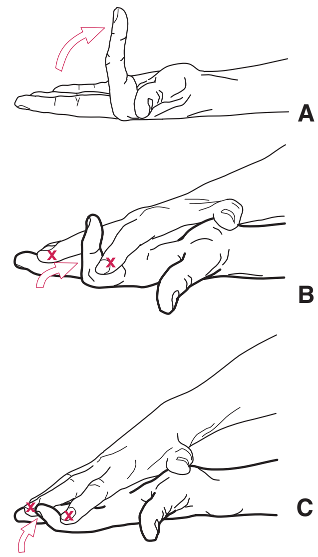

FIGURE 19.18 Flexor tendon blocking exercises: **(A)** isolated MCP flexion of one digit, **(B)** isolated PIP flexion (flexor digitorum superficialis) of one digit, and **(C)** isolated DIP flexion (flexor digitorum profundus) of one digit.

Exercises to Reduce an Extensor Lag

The extrinsic finger extensors (extensor digitorum communis, extensor digitorum indicis, and extensor digiti minimi) are more superficial than the flexor tendons and therefore more easily damaged. Their prime function is to extend the MCP joints. Extension of the IP joints requires active interaction with the intrinsic muscles of the hand via the extensor mechanism. Adhesions within their sheaths at the wrist or between tendon and bone restrict tendon-gliding both proximally (restricting active finger extension) and distally (restricting active and passive finger flexion).

When full passive range of extension is available, but the person cannot actively move the joint through the full range of extension, it is called an *extensor lag*. An extensor lag can occur as the result of weakness, but is frequently caused by adhesions that prevent gliding of the tendons when the muscles contract.

One purpose of the following exercises is to maintain mobility and thus prevent adhesions. The exercises also are used to regain control of finger extension. Mobilization of adhesions is described immediately following the differential gliding of extensor tendon exercises. Stretching techniques are described in the next section.

Isolated MCP Extension

- Have the patient move from the full fist position (see Fig. 19.17 C) to the hook fist position (see Fig. 19.17 B).
- If the patient has difficulty maintaining the IP joints in flexion, have him or her hook the fingers around a pencil while extending the MCP joints.
- Begin with the wrist in neutral and progress to positioning the wrist in flexion and extension while performing MCP extension.

Isolated PIP and DIP Extension

Extension of the interphalangeal joints requires intrinsic and extrinsic muscle (extensor digitorum communis) control.

- For strongest participation of the lumbricals, stabilize the MCP joint in flexion while the patient attempts IP extension, moving from the full fist position (see Fig. 19.17 C) to the table-top position (see Fig. 19.17 D).
- Progress to stabilizing the palm of the hand on the edge of a table (or block) with the PIP or DIP joint partially flexed over the edge.
- Have the patient extend the involved phalanx through the ROM.

Terminal-Range Extension of IP Joints

- Progress to the terminal range by stabilizing the entire hand, palm side down on a flat surface, and have the patient extend the involved phalanx into hyperextension.
- If there is not enough range available, place a pencil or block under the proximal phalanx or middle phalanx, so the PIP or DIP joint can go through a greater range (Fig. 19.19).

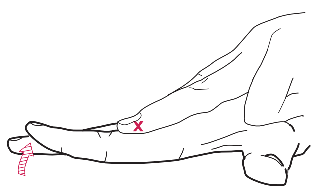

FIGURE 19.19 Terminal extension of the PIP joint. The MCP joint is stabilized in extension, and the patient lifts the middle and distal phalanges off the table.

Extensor Tendon-Gliding Exercises

Differential gliding of the extensor digitorum communis tendons to each of the fingers can be achieved by the following progression.

- Teach the patient to passively flex the MCP and IP joints of one finger with the opposite hand while actively maintaining the other fingers in extension.
- If the patient has difficulty doing this, begin with the involved hand resting on a table with the palm up. Stabilize three of the four fingers against the table while passively flexing one of the digits (Fig. 19.20). Then instruct the patient to attempt to actively keep the fingers against the table while one of the digits is passively flexed.
- Progress by having the patient actively maintain the fingers in extension with the fingers spread out and then actively flex each finger in turn while the other fingers remain extended.
- Have the patient flex the middle and ring fingers while maintaining extension of the index and little fingers (long horn sign). This promotes isolated control of the extensor indicis and extensor digiti minimi tendons and promotes their gliding on the extensor digitorum communis tendons.

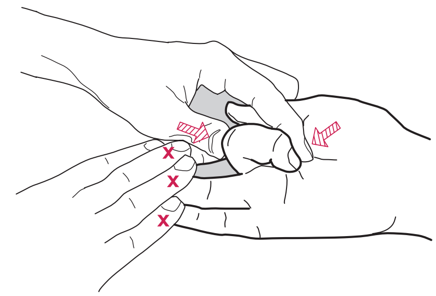

FIGURE 19.20 Differential gliding of the extensor digitorum tendons. Move each digit into flexion while stabilizing the other digits in extension.

Scar Tissue Mobilization for Tendon Adhesions

Ideally, the tendon-gliding exercises described previously in this section maintain or develop mobility between the long tendons and surrounding connective tissues or within their sheaths. However, when there has been inflammation and immobilization during the healing process following trauma or surgery, scar tissue adhesions may form and prevent gliding of the tendons. Contraction of the muscle does not result in movement of the joint or joints distal to the site of the immobile scar.

Techniques to mobilize the adhesive scar tissue include the application of friction massage directly to the adhesion. This is superimposed on active and passive stretching techniques (described in the next section), and the tendon-gliding techniques already described. To apply friction massage, hold the tendon in its lengthened position; apply pressure with your thumb, index, or middle finger and massage perpendicular to the tendon and longitudinally in proximal and distal directions. A sustained force against the adhesion allows for creep and eventual movement of the scar. Techniques to mobilize the flexor and extensor tendons follow.

To Mobilize the Long Finger Flexor Tendons

Adhesions between the flexor tendons and their sheaths or between tendons and underlying bones restrict tendon-gliding in both a proximal and distal direction, so the joints distal to the scar do not flex when the muscle contracts. Passive movement into flexion of the joints distal to the adherent scar is possible if there are no capsular restrictions. Full range of extension of the joints distal to the scar is not possible actively or passively owing to the inability of the tendon to glide distally.

The following is a suggested progression in intensity of scar tissue mobilization.

- Begin the stretching routine by passively moving the tendon in a distal direction by extending the finger joints as far as possible and applying a sustained hold to allow for creep. Follow this with active contraction of the flexor muscle to create a stretch force against the adhesion in a proximal

direction[112] using the patterns of movement described for tendon-gliding exercises (see Fig. 19.17).

- If active and passive stretching, described in the above technique, does not release the adhesion, extend the MCP and IP joints as far as allowed, stabilize them, and apply friction massage with your thumb or finger at the site of the adhesion while the tendon is held in its stretched position.[37] Apply the massaging stretch force across the tendon and in a longitudinal direction, both proximally and distally. When applying friction massage in a proximal direction, ask the patient to simultaneously contract the flexor muscle in order to superimpose an active stretch force.
- After friction massage, have the patient repeat the flexor tendon-gliding exercises to utilize any gained mobility.

To Mobilize the Extensor Tendons and the Extensor Mechanism

If the extensor tendons or extensor mechanism has restricted mobility because of adhesions, muscle action is not transmitted through the mechanism to extend the joint or joints distal to the restriction. Without free gliding, an extensor lag may result. As defined earlier, an extensor lag is the loss of active extension when there is full passive extension. The following is a progression in intensity of scar tissue mobilization.

- Stretch the adhesion in a distal direction by passively flexing the joint distal to the site. Follow this by having the patient attempt to actively extend the joint and put tension on the scar in a proximal direction.

PRECAUTION: If the extensor lag increases (i.e., flexion increases, but there is no active extension through the increased range), the tendon distal to the adhesion, rather than the adhesion, may be stretching. Do not continue with passive stretching into flexion, but rather, emphasize friction massage applied to the scar tissue.

- Apply friction massage at the site of the adhesion with the tendon kept taut by holding the joint at the end of its range of flexion. Apply friction massage across the fibers and in a distal and proximal direction. When applying friction massage in a proximal direction, have the patient actively contract the extensors to assist with the mobilization effort.
- Follow these mobilization techniques with extensor tendon-gliding exercises, as described in the previous section.

Exercise Techniques to Increase Flexibility and Range of Motion

Stretching the muscles and connective tissue structures of the wrist and hand requires knowledge of the unique anatomical relationships of the multijoint musculotendinous units and the extensor mechanism of the digits. These are described in the first section of this chapter. The principles and techniques of stretching are presented in Chapter 4, and special note is made of the importance of stabilization when stretching the multijoint muscles of the hand and fingers. This is reemphasized here. In addition, because scarring and adhesions can restrict tendon-gliding and therefore motion of the digits, it is important to recognize these restrictions and utilize specific techniques that address the adhesions as presented in the previous section (see 'Scar Tissue Mobilization for Tendon Adhesions'). Before stretching muscle or connective tissue, there also should be normal gliding of the joint surfaces to avoid joint damage. Use joint mobilization techniques to stretch the joint capsule and restore gliding (see Chapter 5).

NOTE: Patient position for most wrist and hand exercises is sitting with the forearm supported on a treatment table unless otherwise noted.

General Stretching Techniques

When stretching to increase wrist flexion or extension, it is important that the fingers are free to move, so the extrinsic finger flexor and extensor musculotendinous units do not restrict motion at the wrist. Similarly, when stretching ligaments and other periarticular connective tissues across individual finger joints, it is important that there is no tension on the multijoint tendons. The following techniques are initially applied by the therapist and then are taught to the patient as self-stretching techniques for a home exercise program when he or she understands how to safely apply the stretch force and stabilization.

To Increase Wrist Extension

- Have the patient place the palm of the hand on a table with the fingers flexed over the edge. Use the other hand to stabilize the dorsal surface of the hand to maintain the palm against the table. Then have the patient move the forearm up over the stabilized hand (similar to Fig. 19.22 except the fingers are over the edge of the table, so they are free to flex, and the stretch occurs only at the wrist).
- Have the patient place the palms of the hands together at right angles to each other and allow the fingers to intertwine and flex. Instruct the patient to press the restricted hand in a dorsal direction with the palm of the other hand and sustain the stretch.

To Increase Wrist Flexion

- Have the patient place the dorsal surface of the hand on a table. Use the other hand to provide stabilization against the palm of the hand. Have the patient move the forearm up over the stabilized hand.
- Have the patient sit with the forearm pronated and resting on a table and the wrist at the edge of the table. Press against the dorsal surface of the hand with the opposite hand to flex the wrist.
- Have the patient place the dorsum of both hands together. Then, with the fingers relaxed, move the forearms so the wrists flex toward 90°.

To Increase Flexion or Extension of Individual Joints of the Fingers or Thumb

To increase extension at any one joint, begin by positioning the patient's forearm on a table in supination; to increase flexion, position the forearm in pronation. Place the phalanx to be stretched at the edge of the table. Show the patient how to apply the stretch force against the distal bone while stabilizing the proximal bone against the table.

Stretching Techniques for the Intrinsic and Multijoint Muscles

Self-Stretching the Lumbricals and Interossei Muscles

Have the patient actively extend the MCP joints, flex the IP joints, and apply a passive stretch force at the end of the range with the opposite hand (Fig. 19.21 A).

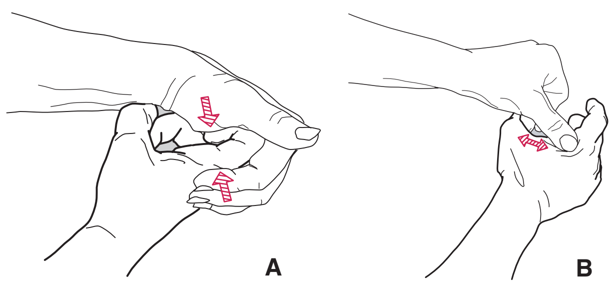

FIGURE 19.21 Self-stretching **(A)** the lumbricals with MCP extension and IP flexion and **(B)** the adductor pollicis with CMC abduction of the thumb. To increase thumb abduction, it is critical the stretch force is applied against the metacarpal head, not the proximal or distal phalanges.

Self-Stretching the Interossei Muscles

Have the patient place the hand flat on a table with the palm down and the MCP joints extended. Instruct the patient to abduct or adduct the appropriate digit and apply the stretch force to the distal end of the proximal phalanx. Holding the adjacent digit provides stabilization.

Self-Stretching the Adductor Pollicis

Have the patient rest the ulnar border of the hand on the table and abduct the thumb perpendicular to the palm of the hand. Instruct the patient to apply the stretch force with the crossed thumb and index or long finger of the other hand against the metacarpal head of the thumb and index finger and attempt to increase the web space (Fig. 19.21 B).

PRECAUTION: It is critical that the patient does not apply the stretch force against the proximal or distal phalanx. This places stress on the ulnar collateral ligament of the MCP joint of the thumb and can lead to instability at that joint and poor functional use of the thumb. Abduction occurs at the CMC joint at the articulation between the metacarpal and the trapezium.

Manual Stretching of the Extrinsic Muscles

Because they are multijoint muscles, the final step in a stretching progression is to elongate each tendon of the extrinsic muscles over all the joints simultaneously. However, do not initiate stretching procedures in this manner, because joint compression and damage can occur to the smaller or less stable joints. Begin by allowing the wrist and more proximal finger joints to relax; stretch the tendon unit over the most distal joint first. Stabilize the distal joint at the end of the range and then stretch the tendon unit over the next joint. Next, stabilize the two joints, and stretch the tendon over the next joint. Progress in this manner until the desired length is reached.

PRECAUTION: Do not let the PIP and MCP joints hyperextend as the tendons are stretched over the wrist.

Self-Stretching the Flexor Digitorum Profundus and Superficialis

Have the patient begin by resting the palm of the involved hand on a table; then extend the DIP joint, using the other hand to straighten the joint. While keeping it extended, have the patient straighten the PIP and MCP joints in succession. If the patient can actively extend the finger joints to this point, the motion should be performed unassisted. With the hand stabilized on the table, have the patient then begin to extend the wrist by bringing the arm up over the hand. The patient moves just to the point of feeling discomfort, holds the position, then progresses as the length increases (Fig. 19.22).

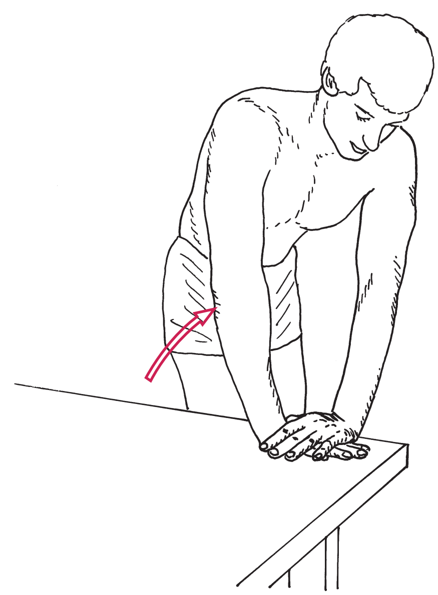

FIGURE 19.22 Self-stretching of the extrinsic finger flexor muscles, showing stabilization of the small distal joints. To isolate stretch to the wrist flexors, allow the fingers to flex over the edge of the table.

Self-Stretching the Extensor Digitorum Communis

The fingers are flexed to the maximum range, beginning with the most distal joint first and progressing until the wrist

is simultaneously flexed. The opposite hand applies the stretch force.

Exercises to Develop and Improve Muscle Performance, Neuromuscular Control, and Coordinated Movement

Exercises described in this section are for use during the controlled motion and return to function phases of rehabilitation when the tissues are in the subacute and chronic stages of healing and require only moderate or minimum protection. In addition to the conditions already described in this chapter, imbalances in the length and strength of the wrist and hand muscles may be caused by nerve injury, trauma, disuse, or immobilization.

Appropriate exercises to develop fine finger dexterity or strength and muscular endurance for strong or repetitive gripping can be selected from the following exercises or their adaptations. The flexor tendon blocking exercises and extensor tendon-gliding exercises described previously in this section also may be used to strengthen the musculature by adding resistance manually or mechanically. Exercises for shoulder, elbow, and forearm strength and muscular endurance also should be included to restore proper function in the upper extremity.

Techniques to Strengthen Muscles of the Wrist and Hand

If the musculature is weak, use progressive strengthening exercises, beginning at the level of the patient's ability. Use active-assistive, active, or manual resistance exercises as described in Chapters 3 and 6 of this text. Use mechanical resistance to progress strengthening exercises.

To Strengthen Wrist Musculature

Allow the fingers to relax. Exercise the wrist muscles in groups if their strength is similar. If one muscle is weaker, the wrist should be guided through the range desired to minimize the action of the stronger muscles. For example, with wrist flexion, if the flexor carpi radialis is stronger than the flexor carpi ulnaris, have the patient attempt to flex the wrist toward the ulnar side as you guide the wrist into flexion and ulnar deviation. If the muscle is strong enough to tolerate resistance, apply manual resistance over the fourth and fifth metacarpals.

Wrist Flexion (Flexor Carpi Ulnaris and Radialis) and Extension (Extensor Carpi Radialis Longus and Brevis and Extensor Carpi Ulnaris)

Have the patient sit with the forearm supported on a table, grasping a weight or elastic resistance that is secured on the floor. The forearm is supinated to resist flexion or pronated to resist extension (Fig. 19.23).

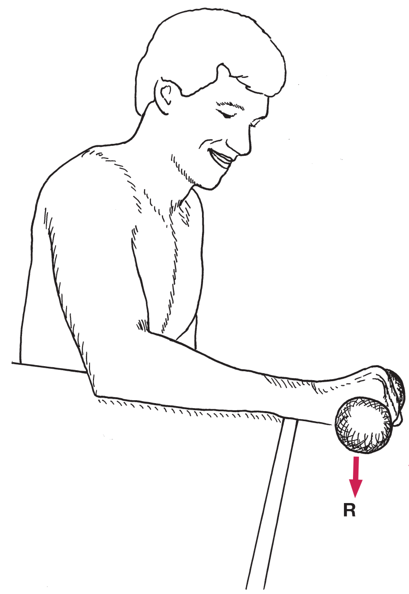

FIGURE 19.23 Mechanical resistance to strengthen wrist extension. Note that the forearm is pronated. To resist wrist flexion, the forearm is supinated.

Wrist Radial Deviation (Flexor and Extensor Carpi Radialis Muscles and Abductor Pollicis Longus) and Ulnar Deviation (Flexor and Extensor Carpi Ulnaris Muscles)

While standing, have the patient hold a bar with a weight on one end. To resist radial deviation, the weight is on the radial side of the wrist (Fig. 19.24 A); to resist ulnar deviation, the weight is on the ulnar side of the wrist (Fig. 19.24 B).

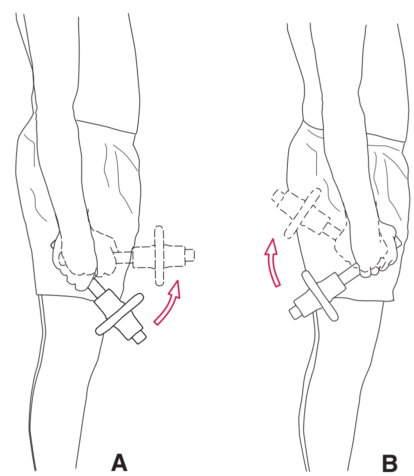

FIGURE 19.24 Mechanical resistance to strengthen **(A)** radial deviation and **(B)** ulnar deviation of the wrist using a weighted bar.

Functional Progression for the Wrist

Progress to controlled patterns of motion requiring stabilization of the wrist for functional hand activities such as repetitive gripping, picking up and releasing objects of various sizes and weights, and opening and closing the screw lid on a jar. Develop

endurance and progress to the desired functional pattern by loading the upper extremity to the tolerance of the wrist stabilizers. When the stabilizers begin to fatigue, stop the activity.

CLINICAL TIP

Functional progression of exercises for the wrist and hand should incorporate the entire upper extremity. When performing shoulder, elbow, or forearm exercises, emphasize safe wrist patterns of motion or wrist stabilization (i.e., do not let the wrist collapse into end-range flexion or extension).

To Strengthen Weak Intrinsic Musculature

NOTE: Imbalance from weak intrinsic muscles leads to a claw hand.

MCP Joint Flexion with IP Joint Extension (Lumbricals)

- Begin with the MCP joints stabilized in flexion. Have the patient actively extend the PIP joint against resistance along the middle phalanx. Increase the resistance by resisting the distal phalanx. Resistance may be applied manually or with rubber bands.
- Have the patient start with the MCP joints extended and the PIP joints flexed; then actively push the fingertips outward, performing the desired combined motion (Fig. 19.25 A and B). For resistance, have the patient push the fingers into the palm of the other hand (Fig. 19.25 C), or push the fingers into exercise putty with the desired motion.

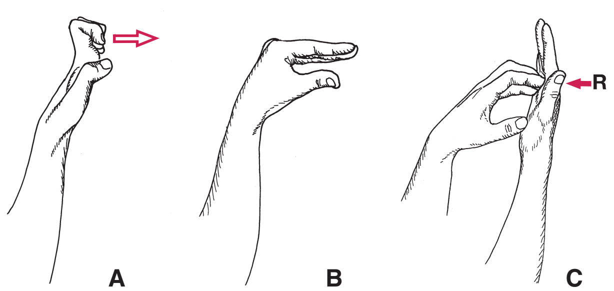

FIGURE 19.25 To strengthen intrinsic muscle function for combined MCP flexion and IP extension, the patient begins with **(A)** MCP extension and IP flexion and **(B)** pushes his fingertips outward. The same motion is resisted by **(C)** pushing the fingertips against the palm of the other hand.

- Begin with all the finger joints extended. Have the patient maintain the IP joints in extension and flex the MCP joints to the table-top position. Apply resistance against the proximal phalanx.

Isolated or Combined Abduction/Adduction of Each Finger (Dorsal and Volar Interossei)

- Have the patient rest the palm of the hand on a table. Apply resistance at the distal end of the proximal phalanx, one finger at a time, for either abduction or adduction.
- To resist adduction, have the patient interlace the fingers of both hands (or intertwine with your fingers) and squeeze the fingers together or squeeze exercise putty between two adjacent fingers.
- To resist abduction, place a rubber band around two digits and have the patient spread them apart.

Abduction of the Thumb (Abductor Pollicis Brevis and Longus)

- Have the patient rest the dorsum of the hand on a table. Apply resistance at the base of the first phalanx of the thumb as the patient lifts the thumb away from the palm of the hand.
- Place a rubber band or band of exercise putty around the thumb and base of the index finger and have the patient abduct the thumb against the resistance.

Opposition of the Thumb (Opponens Pollicis)

- Have the patient use various prehension patterns such as tip-to-tip and tip-to pad, with the thumb opposing each digit in succession, and pad-to-side, with the thumb approximating the lateral side of the index finger.
- Use elastic resistance or have the patient pinch exercise putty, a pliable ball, or a spring-loaded clothespin.

To Strengthen Weak Extrinsic Muscles of the Fingers

NOTE: The wrist must be stabilized for the action of the extrinsic hand musculature to be effective. If wrist strength is inadequate for stabilization, manually stabilize it during exercises and splint it for functional usage.

Metacarpophalangeal Extension (Extensor Digitorum Communis, Indicis, and Digiti Minimi)

Place the hand on a table with the palm down and digits over the edge. Place a small strap over the distal end of the proximal phalanx with a small weight hanging from it, or secure an elastic band or tubing around the proximal phalanx and have the patient extend the MCP joint.

Interphalangeal Flexion (Flexor Digitorum Profundus and Superficialis)

Teach the patient to apply self-resistance by starting with the hands pointing in opposite directions and placing the pads of each finger of one hand against the pads of each finger of the other hand (or against your hand), and then curl the fingers against the resistance provided by the other hand (Fig. 19.26). The same technique is used to resist thumb flexion.

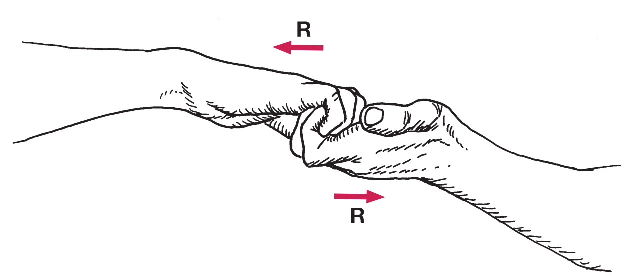

FIGURE 19.26 Self-resistance to strengthen extrinsic finger flexor muscles.

Mechanical Resistance Techniques for Combined Intrinsic and Extrinsic Muscle Function

NOTE: Proper stabilization is important; either the patient's stabilizing muscles must be strong enough or the weakened areas must be supported manually. If a weight causes stress because the patient cannot control it, the exercise is detrimental rather than beneficial.

Towel or Newspaper Crumple

Spread a towel out on a table. Have the patient place the palm of the hand down at one end of the towel and crumple the towel into the hand while maintaining contact with the heel of the hand. The same exercise can be carried out by placing a stack of newspapers under the hand. The patient crumples the top sheet into a ball, tosses it into a basket for coordination and skill practice, and repeats the exercise with each sheet in succession.

Disk Weight Resistance

Have the patient grasp a disk weight in the manner described in each of the following exercises.

- With the forearm pronated (palm down), pick up the disk with the tips of all five digits spread around the outer edge. Have the patient hold the position for isometric resistance. To increase the effect of the resistance to the flexors, have the patient extend one digit at a time.
- Pick up the side of the disk with either tip-to-tip or pad-to-pad prehension of thumb and fingers.
- With the hand palm down on a table, place the disk on the dorsum of the fingers; then lift the disk by hyperextending the fingers.

Other Resistance Aids

Resistive devices, such as putty, spring-loaded hand exercisers, and various grades and sizes of soft balls, can be used for specific muscles or general strengthening. Observe the pattern used by the patient and be sure he or she does not substitute or develop damaging forces.

Dexterity and Functional Activities

Fine-Finger Dexterity

Functional use of the hand for manipulating small objects or skillfully controlling delicate devices requires use of the thumb in opposition to the index and middle fingers. Have the patient perform activities such as picking up small objects of various sizes, twisting nuts on and off bolts, drawing, writing, tying a string or ribbon, opening, and closing small bottles or boxes, and typing on a keyboard.

Functional Activities

Progress to specific activities needed for ADL, work, hobbies, or recreational function. For the patient to return to independent function using the hand, he or she must not only have neuromuscular control and strength but must have muscular endurance, coordination, and fine finger dexterity for the desired activity. This requires careful questioning and analysis of the patient's desired outcomes. Consider each of the power grips and prehension patterns and adapt the exercises to meet the goals.

Independent Learning Activities

Critical Thinking and Discussion

1. Review all of the power grips and prehension patterns and identify the primary muscles that function when performing each action.
2. Summarize the sensory and motor impairments, deformities, and functional limitations that occur in the wrist and hand as the result of a lesion of: (1) the median nerve, (2) the radial nerve, and (3) the ulnar nerve.
3. Differentiate between a boutonnière deformity and a swan-neck deformity of the fingers. What are the underlying factors that contribute to these deformities? After surgical repair of each of these deformities, how should an exercise program be designed to increase hand function but prevent recurrence of these deformities?
4. Identify key structures by the zone in the hand and wrist that could be damaged as the result of a laceration at each zone of the dorsal and volar aspects of the hand and wrist. What functional impairments occur as the result of damage in each zone?
5. Make a case for the use of early controlled motion after surgical repair of a flexor or extensor tendon injury. Explain the key features of different approaches to the use of early motion in an exercise program. Also identify circumstances in which the use of early controlled motion would be inadvisable or not possible.
6. Analyze and summarize the similarities and differences in the components and progression of exercise programs after flexor or extensor tendon repairs using early controlled mobilization versus delayed mobilization approaches.

Laboratory Practice

1. Mobilize each forearm, wrist, and finger joint with joint mobilization and passive stretching techniques.
2. Practice each tendon-gliding exercise and identify the purpose for each one.
3. Teach your partner strengthening exercises for each muscle or muscle group in the hand using resistance putty.

4. Identify three alternative resistance devices that can be used to strengthen each muscle and pattern of motion in the hand.
5. Observe someone tying laces on a shoe, identify the muscles functioning, and design an exercise program that could be used to develop neuromuscular control or strengthen each of the muscles.

Case Studies

1. A patient is referred to you early in the development of symptoms that stem from RA. He currently is in remission after his first serious flare of the disease and desires a home exercise program to safely improve the use of his hands. He is a salesman who travels frequently. He keeps his records on a computer. His grip strength is reduced 50%; he has 25% loss of joint ROM and decreased joint play in the wrist, MCP, and IP joints. Detectable synovial hypertrophy is minimal, and there are no joint subluxations. Consider what precautions should be followed with this disease to prevent the deforming forces of improperly applied exercises and daily forces. Establish a program of intervention for this patient.
2. A patient is referred to you 2 months after a Colles' fracture. Her hand is swollen and sensitive to touch, and she currently is developing contractures and weakness in the hand related to reflex sympathetic dystrophy (see Chapter 13). Joint contractures exist in the forearm, wrist, and hand. You determine that the patient is in the second stage of the disease. Establish a plan for intervention.
3. A patient with RA who has just undergone MCP implant arthroplasties of the ring and small fingers has been referred to you for an exercise program. For the past four weeks, the patient has been wearing a dynamic extension splint that allows active MCP flexion and assists MCP extension. The patient is now allowed to remove the splint for active ROM of the wrist and hand. Your examination reveals that the patient has an extensor lag and also has restricted flexion of the fingers. Design and progress an exercise program for this patient. What precautions should be incorporated into each phase of the program?
4. A patient who underwent a ligament reconstruction tendon interposition arthroplasty for posttraumatic arthritis of the CMC joint of the thumb 4 weeks ago has been referred to you. The thumb spica cast was removed at 3½ weeks postoperatively, and the patient is now wearing a thumb spica splint that may be removed for exercise. Develop and progress an exercise program for the patient. The patient has already returned to his or her position in an office. The patient would like to be able to resume golf on a recreational basis.
5. An 8-year-old child who sustained a zone III laceration of the volar aspect of the index and middle fingers of the nondominant hand while carving a pumpkin has been referred to you after surgical repair of the FDP and FDS tendons. The child's hand has been immobilized in a cast for 3 weeks after the repair in a position of wrist and finger flexion. The child is now wearing a dorsal blocking splint that may be removed for exercise. The child's active and passive extension is significantly limited. Design and progress an exercise program for this child. Identify activities that the child must do under direct supervision and those that he or she may do independently.

CHAPTER

20

The Hip

The hip is often compared with the shoulder in that it is a triaxial joint, able to function in all three planes, and also the proximal link to its extremity. In contrast to the shoulder, which is designed for mobility, the hip is a stable joint, constructed for weight bearing. To carry out activities of daily living (ADL) in what is considered a "normal" manner, however, at least 120° of hip flexion and 20° each of abduction and external rotation are necessary.[110] Forces from the lower extremities are transmitted upward through the hips to the pelvis and trunk during gait and other lower extremity activities. Conversely, the hips support the weight of the head, trunk, and upper extremities, and therefore, the function of the lumbopelvic and hip muscles influences the mechanics and function of the entire lower extremity.

This chapter is divided into three major sections. The first section briefly reviews highlights of the anatomy and function of the hip and its relation to the pelvis, lumbar spine, and knee. The second section then describes common

disorders of the hip and provides guidelines for conservative and postoperative management, expanding on the information and principles of management presented in Chapters 10 through 13. The reader should be familiar with that material as well as the components of a comprehensive examination of the hip and pelvis before determining a diagnosis and establishing a therapeutic exercise program. The third section describes exercise interventions commonly used to meet the goals of treatment for the hip region.

Structure and Function of the Hip

The pelvic girdle links the lower extremity to the trunk and plays a significant role in the function of the hip as well as the spinal joints. The proximal femur and the pelvis comprise the hip joint (Fig. 20.1). The unique characteristics of the pelvis and femur that affect hip function are reviewed in this section. The function of the pelvis with respect to spinal mechanics is described in greater detail in Chapter 14.

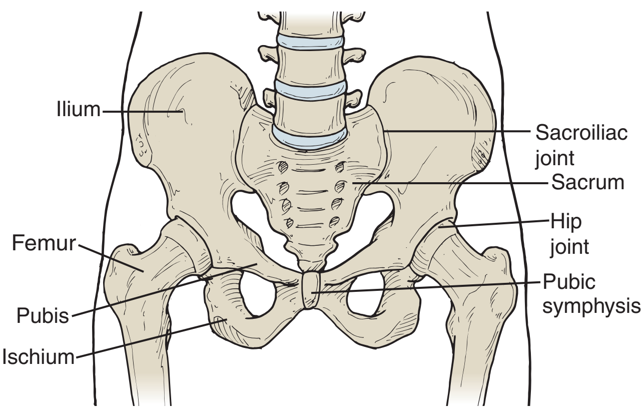

FIGURE 20.1 Bones and joints of the pelvis and hip.

Anatomical Characteristics of the Hip Region

Boney Structures

The structure of the pelvis and femur are designed for weight bearing and transmitting forces through the hip joint.

The Pelvis

Each innominate bone of the pelvis is formed by the union of the ilium, ischium, and pubic bones and therefore, is a structural unit. The right and left innominate bones articulate anteriorly with each other at the pubic symphysis and posteriorly with the sacrum at the sacroiliac joints.[86] Slight motion occurs at these three joints to attenuate forces as they are transmitted through the pelvic region, but the pelvis basically functions as a unit in a closed chain.

The Femur

The shape of the femur is designed to bear body weight and to transmit ground reaction forces through the long bone, neck, and head to the acetabulum of the pelvis. In the frontal plane, there is an angle of inclination (normally 125°) between the axis of the femoral neck and the shaft of the femur. The angle of torsion formed by the transverse axis of the femoral condyles and the axis of the neck of the femur ranges from 8° to 25°, with an average angle of 12°. There is also slight bowing of the shaft in the sagittal plane.[86]

Hip Joint Characteristics and Arthrokinematics

Characteristics

The hip is a ball-and-socket (spheroidal) triaxial joint made up of the head of the femur and acetabulum of the pelvis. It is supported by a strong articular capsule that is reinforced by the iliofemoral, pubofemoral, and ischiofemoral ligaments. The two hip joints are linked to each other through the boney pelvis and to the vertebral column through the sacroiliac and lumbosacral joints.[86]

Articular Surfaces

The concave boney partner of the hip joint, the acetabulum, is located in the lateral aspect of the pelvis and faces laterally, anteriorly, and inferiorly (see Fig. 20.1). The acetabulum is deepened by a ring of fibrocartilage, the acetabular labrum. The articular cartilage is horseshoe-shaped and thicker in the lateral region, where the major weight-bearing forces are transmitted. The central portion of the acetabular surface is nonarticular.

The convex boney partner is the spherical head of the femur, which is attached to the femoral neck. It projects anteriorly, medially, and superiorly.

The shapes of the articulating surfaces of the hip joint and the reinforcing properties of the capsule and ligaments, as well as the hip musculature, lend mobility coupled with stability for functional tasks that require wide ranges of combined movements, such as squatting, tying shoes while seated, standing up from a chair, or walking.

Ligaments

Three ligaments reinforce the joint capsule: the iliofemoral and pubofemoral ligaments are situated anteriorly (Fig. 20.2 A), and the ischiofemoral ligament is located posteriorly (Fig. 20.2 B).[86,106,111]

There is general agreement in the literature that these three capsular ligaments limit excessive extension of the hip, and the iliofemoral ligament, also known as the Y ligament of Bigelow, is the strongest of the hip ligaments.[58,86,106,111] There

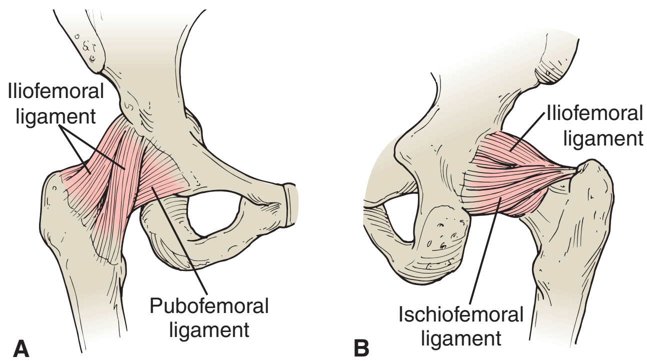

FIGURE 20.2 Ligaments supporting the hip joint. **(A)** Anterior view. **(B)** Posterior view.

is, however, some dispute as to the functions of each of these ligaments on an individual basis. The iliofemoral ligament, which reinforces the anterior portion of the capsule, also is thought to limit external rotation of the hip.[106,111] Lending support to the inferior as well as anterior portion of the capsule, the pubofemoral ligament is believed to limit abduction.[106,111] Lastly, the ischiofemoral ligament, although reinforcing the posterior aspect of the capsule, may also limit internal rotation and may limit adduction when the hip is flexed.[58,106,111]

Arthrokinematics of the Hip Joint

During many activities, such as squatting, walking, or doing leg-press exercises, both the pelvis and femur are moving. Therefore, joint mechanics can be described by the movement of the femur in the acetabulum or as the pelvis moving on the femur.

Motions of the femur. The convex femoral head slides in the direction opposite the physiological motion of the femur. Thus, with hip flexion and internal rotation, the articulating surface slides posteriorly; with extension and external rotation, it slides anteriorly; with abduction, it slides inferiorly; and with adduction, it slides superiorly (Box 20.1).

BOX 20.1 Summary of Arthrokinematics of the Femoral Head in the Hip Joint

Physiological Motions of the Femur	Roll	Slide
Flexion	Anterior	Posterior
Extension	Posterior	Anterior
Abduction	Lateral	Inferior
Adduction	Medial	Superior
Internal rotation	Medial	Posterior
External rotation	Lateral	Anterior

Motions of the pelvis. When the lower extremity is stabilized (fixated) distally, as when standing or during the stance phase of gait, the concave acetabulum moves on the convex femoral head, so the acetabulum slides in the same direction as the pelvis. The pelvis is a link in a closed chain; therefore, when the pelvis moves, there is motion at both hip joints as well as at the lumbar spine.

Influence of the Hip Joint on Balance and Posture Control

The joint capsule is richly supplied with mechanoreceptors that respond to variations in position, stress, and movement for control of posture, balance, and movement. Reflex muscle contractions of the entire kinematic chain, known as balance strategies, occur in a predictable sequence when standing balance is disturbed and regained. Joint pathologies, restricted motion, or muscle weakness can impair balance and postural control. Refer to Chapter 8 for an in-depth discussion of these concepts.

Functional Relationships in the Hip Region

The hip functions in both nonweight-bearing and weight-bearing activities, requiring the muscles to move the femur or control the femur and pelvis as outside forces are imposed on the region.

Motions of the Femur and Muscle Function

Motions of the femur and muscle actions are typically described as occurring in the three primary planes: flexion/extension in the sagittal plane, abduction/adduction in the frontal plane, and internal/external rotation in the transverse plane. Most of the muscles function in several planes. The primary and secondary actions are summarized in Table 20.1.[57,86,107]

Motions of the Pelvis and Muscle Function

The pelvis is the connecting link between the spine and lower extremities (Fig. 20.3 A). Movement of the pelvis causes motion at the hip joints and lumbar spine articulations. Contraction of the hip musculature causes pelvic motion through reverse action; therefore, to prevent excessive pelvic motion when moving the femur at the hip joint, the pelvis must be stabilized by the trunk musculature.

TABLE 20.1 Muscles of the Hip: Open-Chain (Nonweight-Bearing) Function

Action	Prime Movers	Secondary Movers (action depends on hip joint position)
Flexion		
	▪ Iliopsoas ▪ Rectus femoris (also extends knee) ▪ Tensor fasciae latae (also abducts and internally rotates hip and maintains tension in iliotibial band) ▪ Sartorius (also abducts and externally rotates hip and flexes and internally rotates knee)	Pectineus Adductor longus Adductor magnus Gracilis
Extension		
	▪ Gluteus maximus (also externally rotates hip; superior fibers insert into iliotibial band) ▪ Hamstrings: long head of biceps femoris, semitendinosus, semimembranosus (also flex knee)	Gluteus medius (posterior fibers) Adductor magnus Piriformis
Abduction		
	▪ Gluteus medius ▪ Gluteus minimus ▪ Tensor fasciae latae (also flexes hip)	Piriformis Sartorius Rectus femoris
Adduction		
	▪ Adductor magnus ▪ Adductor longus ▪ Adductor brevis ▪ Gracilis ▪ Pectineus	Biceps femoris (long head) Gluteus maximus (posterior fibers) Quadratus femoris Obturator externus
External (Lateral) Rotation		
	▪ Obturator internus and externus ▪ Gemellus superior and inferior ▪ Quadratus femoris ▪ Piriformis ▪ Gluteus maximus	Gluteus medius (posterior fibers) Gluteus minimus (posterior fibers) Sartorius Biceps femoris (long head)
Internal (Medial) Rotation		
	No prime movers	Gluteus medius (anterior fibers) Gluteus minimus (anterior fibers) Tensor fasciae latae Adductor longus and brevis Adductor magnus (posterior fibers) Pectineus

Note: Prime motions are described from the anatomic position; actions of some muscles change as the hip position changes.

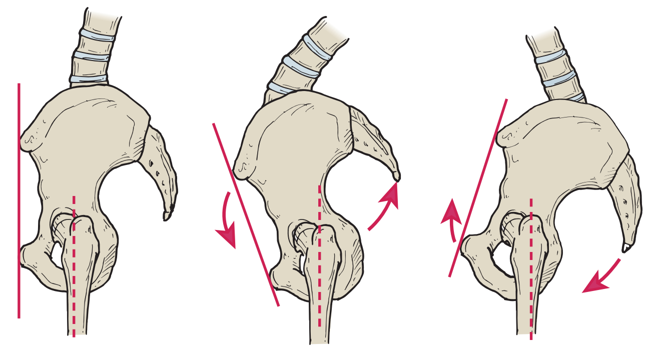

FIGURE 20.3 **(A)** Neutral position of the pelvis. **(B)** Anterior pelvic tilt. **(C)** Posterior pelvic tilt. With anterior pelvic tilt, the decreased angle between the pelvis and femur results in hip flexion, and with posterior pelvic tilt, the increased angle results in hip extension.

Anterior Pelvic Tilt

The anterior superior iliac spines of the pelvis move anteriorly and inferiorly and thus closer to the anterior aspect of the femur as the pelvis rotates forward around the transverse axis of the hip joints (Fig. 20.3 B). This results in hip flexion and increased lumbar spine extension.[86]

- Muscles causing this motion are the hip flexors and back extensors.
- When hip flexion is the desired motion, the pelvis must be stabilized by the abdominals to prevent anterior pelvic tilting.
- During standing, the line of gravity of the trunk falls anterior to the axis of the hip joints; the effect is an anterior pelvic tilt moment. Stability is provided by the abdominal muscles and hip extensor muscles.

Posterior Pelvic Tilt

The posterior superior iliac spines of the pelvis move posteriorly and inferiorly, thus closer to the posterior aspect of the femur as the pelvis rotates backward around the axis of the hip joints (Fig. 20.3 C). This results in hip extension and lumbar spine flexion.[86]

- Muscles causing this motion are the hip extensors and trunk flexors.
- When hip extension is the desired motion, the lumbar extensors contract to stabilize the pelvis.
- During standing when the line of gravity of the trunk falls posterior to the axis of the hip joints, the effect is a posterior pelvic tilt moment. Dynamic stability is provided by the hip flexors and back extensors and passive stability by the iliofemoral ligament.

Pelvic Shifting

During standing, a forward translatory shifting of the pelvis results in extension of the hip and extension of the lower lumbar spinal segments. There is a compensatory posterior shifting of the thorax on the upper lumbar spine with increased flexion of these spinal segments. This is often seen with slouched or relaxed postures (see Fig. 14.12 B in Chapter 14). Little muscle action is required; the posture is maintained by the iliofemoral ligaments at the hip, anterior longitudinal ligament of the lower lumbar spine, and posterior ligaments of the upper lumbar and thoracic spine.

Lateral Pelvic Tilt

Frontal plane pelvic motion results in opposite motions at each hip joint. Pelvic motion is defined by what is occurring to the iliac crest of the pelvis that is opposite the weight-bearing extremity (that is, the side of the pelvis that is moving). When the pelvis elevates, it is called hip hiking; when it lowers, it is called hip or pelvic drop. On the side that is elevated, there is hip adduction; on the side that is lowered, there is hip abduction (Fig. 20.4 A). During standing, the lumbar spine laterally flexes toward the side of the elevated pelvis (convexity of the lateral curve is toward the lowered side).[86]

- Muscles causing lateral pelvic tilting include the quadratus lumborum on the side of the elevated pelvis and reverse muscle pull of the gluteus medius on the side of the lowered pelvis.
- When hip abduction is the desired motion, the pelvis must be stabilized by the lateral abdominals (internal and external obliques) on the side of the moving femur to prevent the pelvis from tilting downward.
- With an asymmetrical slouched posture, the person shifts the trunk weight onto one lower extremity and allows the pelvis to drop on the other side. Passive support comes from the iliofemoral ligament and iliotibial band on the elevated side (stance leg).
- When standing on one leg, there is an adduction moment at the hip, tending to cause the pelvis to drop on the unsupported side (hip or pelvic drop). This is prevented by the gluteus medius stabilizing the pelvis on the stance side.

Pelvic Rotation

Rotation occurs around one lower extremity that is fixed on the ground. The unsupported lower extremity swings forward or backward along with the pelvis. When the unsupported side of the pelvis moves forward, it is called forward rotation of the pelvis.[86] The trunk concurrently rotates in the opposite direction, and the femur on the stabilized side concurrently rotates internally. When the unsupported side of the pelvis moves backward, it is called posterior rotation; the femur on the stabilized side concurrently rotates externally, and the trunk rotates opposite (Fig. 20.4 B).

- Muscles causing pelvic rotation are the hip rotators working in synergy with the oblique abdominal muscles, the transversus abdominis, and the multifidus.

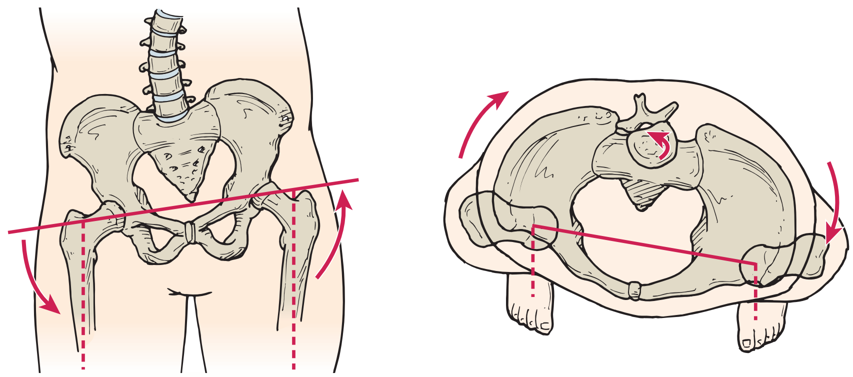

FIGURE 20.4 **(A)** Lateral pelvic tilt. Elevation of the iliac crest (hip liking) causes relative adduction of the hip on the elevated side, and lowering of the iliac crest (hip drop) causes relative abduction of the hip on the lower side. **(B)** Pelvic rotation. Forward motion (forward rotation) of the pelvis causes relative external rotation of the hip; and backward motion (posterior rotation) of the pelvis causes relative internal rotation of the hip.

- When hip rotation is the desired motion, the pelvis must be stabilized by the trunk musculature.

Pelvifemoral Motion

A combined movement occurs between the lumbar spine and pelvis during maximum forward bending of the trunk as when reaching toward the floor or the toes.[86] This motion is also known as lumbopelvic rhythm.[25] Although there is considerable variability in the participation of each of the joints, the motion typically is described as beginning with forward bending of the head.

- As the head and upper trunk initiate flexion, the pelvis shifts posteriorly to maintain the center of gravity over the base of support.
- The trunk continues to forward-bend, controlled by the extensor muscles of the spine, until at approximately 45°. At this point for an individual with relatively normal flexibility, the posterior ligaments become taut, and the facets of the zygapophyseal joints approximate. Both of these factors provide stability for the intervertebral joints, and the muscles relax.[141]
- Once all of the vertebral segments are at the end of the range and stabilized by the posterior ligaments and facets, the pelvis begins to rotate forward (anterior pelvic tilt), controlled by the gluteus maximus and hamstring muscles.
- The pelvis continues to rotate forward until the full length of the muscles is reached. Final range of motion (ROM) in forward bending is dictated by the flexibility of the various back extensor muscles and fasciae as well as hip extensor muscles.

The return to the upright position begins with the hip extensor muscles rotating the pelvis posteriorly through reverse muscle action (posterior pelvic tilt), then with the back extensor muscles extending the spine from the lumbar region upward. Variations in the normal synchronization of this activity occur because of training (as with dancers and gymnasts), faulty habits, restricted muscle or fascia length, or injury and faulty proprioception.

Hip, Knee, and Ankle Functional Relationships in Weight Bearing

During weight bearing, control of hip positions and motions affects the alignment and function of the entire lower extremity.

Hip flexion/extension. Hip flexion results in knee flexion and ankle dorsiflexion during weight bearing. This action is controlled by the hip extensor (gluteus maximus and hamstrings), knee extensor (quadriceps femoris), and ankle plantarflexor (gastrocnemius and soleus) muscles. Hip extension in weight bearing causes knee extension by pulling the femur posteriorly and contributes to the locking mechanism at the knee.

Hip abduction/adduction. With unilateral weight bearing, there is an adductor moment at the hip that is stabilized by the gluteus medius (preventing pelvic drop). Typically, this results in a varus moment at the knee. However, if the gluteus medius is weak, there is increased adduction of the femur and increased valgus moment at the knee, imposing greater stress on the medial collateral ligament, medial patellofemoral ligament, and anterior cruciate ligament.[122]

Hip rotation. Internal rotation of the hip results in the femur rotating medially on a fixed tibia at the knee. The force through the tibia causes eversion of the calcaneus and pronation of the foot when weight bearing. The reverse occurs with hip external rotation. This total chain response occurs repeatedly during the loading and terminal stance phases of gait as the ground reaction forces are absorbed and the body is moved forward. A total chain response also occurs during loading of the extremities when descending stairs or landing a jump.

Pathomechanics in the Hip Region

Abnormal structure or impaired function of the hip—such as a leg-length discrepancy, decreased flexibility, or muscle imbalances—can contribute to stress through the spine or other joints of the lower extremities.

Decreased Flexibility

Decreased flexibility of the structures around the hip joint causes weight-bearing forces and movement to be transmitted to the spine rather than absorbed by the pelvis. Tight hip extensors cause increased lumbar flexion when the thigh flexes, and tight hip flexors cause increased lumbar extension as the thigh extends. Hip flexion contractures with incomplete hip extension during weight bearing also place added stresses on the knee, because the knee cannot lock while the hip is in flexion unless the trunk is bent forward. During weight bearing, tight adductors cause lateral pelvic tilt opposite the side of tightness and side-bending of the trunk toward the side of tightness. The opposite occurs with tight abductors.

Muscle Weakness

Decreased strength of the hip abductor, extensor, and external rotator muscles has been identified as contributing to or resulting from valgus collapse at the knee (increased valgus and internal rotation of the femur) when flexing the knee during weight-bearing activities and may contribute to impairments throughout the lower extremity as described in the following examples.[122]

Patellofemoral impairment. Higher valgus moments at the knee as a result of weak hip abductors have been associated with patellofemoral impairments, which occur more often in women than in men (see Chapter 21).[122,123]

Anterior cruciate ligament strain. Valgus collapse and decreased use of the hip extensors have been reported to be more common in women than in men who have sustained an anterior cruciate ligament injury. It has been suggested that this is related to increased anterior shear of the tibia and strain of the anterior cruciate ligament during loading (hip-knee flexion when landing following a jump).[122]

Piriformis syndrome. A recent case report identified weakness of the hip extensors and abductors resulting in hip adduction and internal rotation (valgus collapse) during functional activities as the apparent causes of overuse of the piriformis muscle and compression of the sciatic nerve. Strengthening and functional retraining of the gluteus maximus and gluteus medius along with correction of the faulty movement patterns resulted in alleviation of symptoms and functional improvement.[146]

Hip Muscle Imbalances and Their Effects

It is important to recognize that imbalances in muscle function (dominance of one muscle over another when performing an activity) may be due to strength and length deficits as well as altered proprioception and neuromuscular control, resulting in faulty activity patterns.[57] Faulty mechanics from inadequate or excessive length, an imbalance in apparent strength, or poor movement patterns are described as the cause of hip, knee, or back impairments and pain.[131] Overuse syndromes, soft tissue stress, and joint pain develop in response to continued abnormal stresses. The muscle imbalances related to postural impairments are summarized in Box 20.2. The following are common imbalances in the hip muscles and resulting lower extremity impairments.

> **BOX 20.2 Hip Muscle Imbalances Related to Postural Impairments**
>
> **Anterior Pelvic Tilt Posture**
> - Short TFL and IT band
> - General limitation of hip external rotation
> - Weak, stretched posterior portion of the gluteus medius and piriformis
> - Excessive internal rotation of the femur during the first half of stance phase of gait with increased stress on the medial structures of the knee
> - Associated lower extremity compensations including internal rotation of the femur, genu valgum, lateral tibial torsion, pes planus, and hallux valgus
>
> **Slouched Posture**
> - Shortened rectus femoris and hamstrings
> - General limitation of hip rotators
> - Weak, stretched iliopsoas
> - Weak and shortened posterior portion of the gluteus medius
> - Weak, poorly developed gluteus maximus
> - Associated lower extremity compensations including hip extension, sometimes internal rotation of the femur, genu recurvatum, genu varum, and pes valgus
>
> **Flat Back Posture**
> - A shortened rectus femoris, IT band, and gluteus maximus
> - Variations of the above two postures

Shortened tensor fasciae latae (TFL) and/or gluteus maximus. The TFL and approximately one-third of the gluteus maximus insert into the iliotibial (IT) band. Decreased flexibility in either of these muscles has an effect on the tension transmitted through the IT band. Postural impairments often associated with a shortened TFL or gluteus maximus include an anterior pelvic tilt posture, slouched posture, or flat back posture (see Box 20.2 and Chapter 14).[131] Overuse syndromes associated with decreased mobility of the IT band include trochanteric bursitis in the hip region and IT band syndrome in the knee (see description of this in the patellofemoral impairment section in Chapter 21).

Dominance of the TFL over the gluteus medius. Apparent weakness of the gluteus medius and related dominance of the TFL as a hip abductor result in increased tension on the IT band,[131] valgus collapse of the knee during weight bearing with hip/knee flexion (see Fig. 21.9), and increased dynamic Q-angle.[57] This may lead to pain in the lateral retinaculum of the knee (IT band syndrome) or patellofemoral pain syndrome from increased bowstring effect on the extensor mechanism.

Dominance of the two-joint hip flexor muscles over the iliopsoas. Dominance of the TFL, rectus femoris, and/or sartorius muscles may cause faulty hip mechanics or knee pain from overuse of these muscles as they cross the knee.

Dominance of hamstring muscles over the gluteus maximus. Faulty posture and disuse of the gluteus maximus may result in decreased flexibility of this muscle and decreased range of hip flexion.[131] Compensation occurs with excessive lumbar spine flexion whenever full range of hip flexion is attempted. Limited mobility of the gluteus maximus also causes increased tension on the IT band with associated trochanteric or lateral knee pain.

With disuse of the gluteus maximus, the hamstrings dominate as hip extensors.[131] Overuse of the hamstring muscles may result in cramping of the muscle with high-intensity exercise[151] and cause decreased flexibility as well as muscle imbalances with the quadriceps femoris muscle at the knee.[131] The hamstrings dominate the stabilizing function by pulling posteriorly on the tibia to extend the knee in closed-chain activities. This alters the mechanics at the knee and may lead to overuse syndromes in the hamstring tendons or anterior knee pain from imbalances in quadriceps pull.[131]

Use of lateral trunk muscles for hip abductors. Relying on the lateral trunk muscles to perform the tasks of the hip abductors results in excessive trunk motion and increased stress on the lumbar spine.

Asymmetrical Leg Length

Functional as well as structural asymmetries of the lower extremities affect the posture of the pelvis.

Unilateral short leg. A unilateral short leg causes lateral pelvic tilting (drop on the short side) and side-bending of the trunk away from the short side (convexity of the lateral lumbar curve toward the side of short leg). This may lead to a functional—or eventually a structural—scoliosis. Causes of a short leg could be unilateral lower extremity asymmetries, such as flat foot, genu valgum, coxa vara, tight hip muscles, anteriorly rotated innominate bone, poor standing posture, or asymmetry in bone growth.

Coxa valga and coxa vara. A pathologically large angle of inclination between the femoral neck and shaft of the femur is called *coxa valga*, and a pathologically smaller angle is called *coxa vara*. Unilateral coxa valga results in a relatively longer leg on that side and associated genu varum. Unilateral coxa vara leads to a relatively shorter leg with associated genu valgum.

Anteversion and retroversion. An increase in the torsion of the femoral neck is called *anteversion* and causes the shaft of the femur to be rotated medially. A decrease in the torsion is called *retroversion* and causes the shaft of the femur to be rotated laterally. Anteversion often results in genu valgum and pes planus. Unilateral anteversion results in a relatively shorter leg on that side; retroversion causes the opposite effect.

The Hip and Gait

During the normal gait cycle, the hip goes through an ROM of 40° of flexion and extension (10° extension at terminal stance to 30° flexion at midswing and initial contact). There is also lateral pelvic tilt and hip abduction/adduction of 15° (10° adduction at initial contact, 5° abduction at initial swing) and hip internal/external rotation along with pelvic rotation totaling 15° transverse plane motion (peak internal rotation at the end of loading, peak external rotation at the end of preswing). Loss of any of these motions affects the smoothness of the gait pattern.[119]

Hip Muscle Function and Gait

Hip Flexors

The hip flexors control hip extension at the end of stance, then contract concentrically to initiate swing.[119] With loss of flexor function, a posterior lurch of the trunk to initiate swing is seen. Contractures of the hip flexors prevent complete extension during the second half of stance, thus shortening the stride. To compensate, a person increases the lumbar lordosis or walks with the trunk bent forward.

Hip Extensors

The hip extensors control the flexor moment during the loading response, and the gluteus maximus initiates hip extension.[113,119] With loss of extensor function, a posterior lurch of the trunk occurs at foot contact to shift the center of gravity of the trunk posterior to the hip. With contractures of the gluteus maximus, some decreased range occurs in the terminal swing as the femur comes forward, or the person may compensate by rotating the pelvis increasingly forward. The lower extremity may rotate outward because of the external rotation component of the muscle, or the gluteus maximus may place greater tension on the iliotibial band through its attachment, leading to irritation along the lateral aspect of the knee with excessive activity.

Hip Abductors

The hip abductors control the lateral pelvic tilt during swinging of the opposite leg.[113,119] With loss of function of the gluteus medius, lateral shifting of the trunk occurs over the weak side during stance when the opposite leg swings. This lateral shifting also occurs with a painful hip, because it minimizes the torque at the hip joint during weight bearing. The tensor fasciae latae also functions as an abductor and may become tight and affect gait with faulty use.

Effect of Musculoskeletal Impairments on Gait

Bone and joint deformities change alignment of the lower extremity and therefore the mechanics of gait. Painful conditions cause antalgic gait patterns, which are characterized by minimum stance on the painful side to avoid the stress of weight bearing.

Referred Pain and Nerve Injury

The hip is innervated primarily from the L3 spinal level; hip joint irritation is usually felt along the L3 dermatome reference from the groin, down the front of the thigh to the knee.[36,83] For a detailed description of referred pain patterns

and peripheral nerve injuries in the hip and buttock region, see Chapter 13.

Major Nerves Subject to Injury or Entrapment

Sciatic nerve. Entrapment may occur when the sciatic nerve passes deep to the piriformis muscle (occasionally it passes over or through the piriformis).

Obturator nerve. Isolated injury is rare, although uterine pressure and damage during labor may occur.

Femoral nerve. Injury may result from fractures of the upper femur or pelvis, reduction of congenital dislocation of the hip, or pressure during a forceps labor and delivery.

Common Sources of Referred Pain in the Hip and Buttocks Region

If painful symptoms are referred to the hip and buttocks region from other sources, primary treatment must be directed to the source of the irritation. Common sources of referred pain in the hip and buttocks region include:

- Nerve roots or tissues derived from spinal segments L1, L2, L3, S1, and S2.
- Lumbar intervertebral and sacroiliac joints.

Management of Hip Disorders and Surgeries

To make sound clinical decisions when treating patients with hip disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and identify presenting structural and functional impairments, activity limitations, and participation restrictions (functional limitations and possible disabilities). In this section, common pathologies and surgeries are presented and related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[1] (Table 20.2). Conservative and postoperative management of these conditions is also described in this section.

Joint Hypomobility: Nonoperative Management

Related Pathologies and Etiology of Symptoms

Osteoarthritis (OA), rheumatoid arthritis (RA), aseptic necrosis, slipped epiphyses, dislocations, and congenital deformities can lead to degenerative changes in the hip joint (see Fig. 11.2).

TABLE 20.2 Hip Pathologies and Related Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Patterns and Associated Impairments[1]
▪ Abnormal posture (anterior pelvic tilt posture, posterior pelvic tilt posture, rotated or shifted pelvis related to spinal and lower extremity flexibility and strength imbalances or structural malalignment)	Pattern 4B—Impaired posture
▪ Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) ▪ Aseptic necrosis ▪ Acetabular labral tear ▪ Slipped epiphyses ▪ Dislocation ▪ Postimmobilization arthritis (stiffness)	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
▪ Acute arthritis ▪ Acute tendonitis, bursitis, muscle pull ▪ Femoral acetabular impingement	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
▪ Fracture (femoral or pelvic)	Pattern 4G—Impaired joint mobility, muscle performance, and ROM associated with fracture
▪ Total hip arthroplasty ▪ Resurfacing arthroplasty ▪ Hemiarthroplasty	Pattern 4H—Impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
▪ Labral tear ▪ Osteotomy ▪ Open reduction and internal fixation of proximal femoral fracture or fracture-dislocation	Pattern 4I—Impaired joint mobility, motor function, muscle performance, and ROM associated with boney or soft tissue surgery
▪ Sciatic, obturator, or femoral nerve injury or entrapment in the pelvis and hip region	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

Osteoarthritis (Degenerative Joint Disease)

OA is the most common arthritic disease of the hip joint. The etiology may be the aging process, joint trauma, repetitive abnormal stresses, obesity, hip developmental disorders, or disease.[31] The degenerative changes include articular cartilage breakdown and loss, capsular fibrosis, and osteophyte formation at the joint margins.[43] These effects usually occur in regions undergoing the greatest loading forces, such as along the superior weight-bearing surface of the acetabulum (see Fig. 11.6).

Postimmobilization Hypomobility

A restriction in the capsular tissues leading to hypomobility of joints as well as tightness in the surrounding periarticular tissues may occur anytime the joint is immobilized after a fracture or surgery.

BOX 20.3 Clinical Prediction Rule for the Diagnosis of Osteoarthritis of the Hip[139]

Variables*

- Self-reported squatting aggravates symptoms.
- Active hip flexion causes lateral hip pain.**
- The scour test with adduction causes lateral hip or groin pain.
- Active hip extension causes pain.
- Passive internal rotation is less than or equal to 25°.**

*Results of the study indicated that if 3 of the 5 variables were present, the likelihood of having hip OA increased from 29% to 68% probability; if 4 of the 5 variables were identified, the likelihood increased to 91%.
**Interrater reliability for identifying the end feels of flexion and internal rotation was 0.85 and 0.88 respectively.

Common Structural and Functional Impairments

- Pain experienced in the groin and referred along the anterior thigh and knee in the L3 dermatome.
- Stiffness after rest.
- Limited motion with a firm capsular end-feel.[139] Initially, limitation is only in internal rotation; in advanced stages, the hip is fixed in adduction, has no internal rotation or extension past neutral, and is limited to 90° flexion.[36]
- Asymmetry in lower extremity weight bearing and an antalgic gait usually with a compensated gluteus medius (abductor) limp.
- Limited hip extension leading to increased extension forces on the lumbar spine and possible back pain.
- Limited hip extension preventing full knee extension when standing or during gait, leading to increased knee stresses.
- Impaired balance and postural control.

A clinical prediction rule recently developed by Sutlive and associates[139] (summarized in Box 20.3) identifies five examination variables that can be used for the diagnosis of OA of the hip. The diagnostic variables are based on a preliminary study of 72 subjects over the age of 40 with unilateral buttock, groin, or anterior thigh pain. Patients who had radiographic changes had an increased likelihood of having clinically relevant symptoms.

Other functional impairments, such as decreased muscle strength and limited functional abilities have been identified in individuals with hip OA.

FOCUS ON EVIDENCE

A recent cross-sectional study looked at 26 patients with hip OA who were not surgical candidates, compared them with a matched control group without OA, and summarized function and disability in both groups. Significant differences between the groups included mild to moderate pain level, decreased knee extension strength, and decreased hip ROM in those with hip OA. Functionally, those with OA walked a shorter distance in 6 minutes, but there were no significant differences in strength of the hip flexors/extensors, knee flexors, or ankle dorsiflexors/plantarflexors.[130]

Common Activity Limitations and Participation Restrictions (Functional Limitations/Disabilities)

Hip joint impairments interfere with many weight-bearing activities and ADL.[30,52,130]

Early stages. There is progressive pain with continued weight bearing and gait or at the end of the day after repetitive lower extremity activities. The pain may interfere with work (job-specific) or routine household activities that involve weight bearing, such as meal preparation, cleaning, and shopping.

Progressive degeneration. The individual experiences increased difficulty rising from a chair, walking long distances or on uneven surfaces, climbing stairs, squatting, and other weight-bearing activities as well as restricted routine ADL, such as bathing, toileting, and dressing (putting on pants, hose, socks).

CLINICAL TIP

It is important to point out that outcome measures used to evaluate functioning of individuals with lower extremity OA, such as the Western Ontario and McMaster Universities Arthritis Index (WOMAC) or the Arthritis Impact Measurement Scale (AIMS), typically include items that measure the extent of functional impairments (e.g., pain, ROM, strength) and activity limitations (e.g., walking distance or speed, ability to climb stairs). However, items to identify

participation restrictions (e.g., the impact of OA on a patient's societal roles) are notably absent from these measurement tools.[20]

Management: Protection Phase

Chapter 11 describes the general principles and plan of care in the treatment of osteoarthritis and rheumatoid arthritis, and Chapter 10 describes general management of joints during acute, subacute, and chronic stages of tissue injury and repair. In conjunction with medical management of the disease for inflammation and pain, correction of faulty mechanics is an integral part of decreasing pain in the hip. Faulty hip mechanics may be caused by conditions such as obesity, leg-length differences, muscle length and strength imbalances, sacroiliac dysfunction,[30,31] poor posture, or injury to other joints in the chain.[24] The following goals and interventions are emphasized during the acute stage of tissue healing and the protection phase of nonoperative management.

Provide Patient Education

- Explain how the stresses of weight bearing and other activities impact the joint and symptoms and the ways in which interventions may minimize symptoms.
- Teach safe ambulatory patterns and a home exercise program that emphasizes nonimpact activities and frequent ROM.

Decrease Pain at Rest

- Apply grade I or II oscillation techniques with the joint in the resting position.
- Have the patient rock in a rocking chair to provide gentle oscillations to the lower extremity joints and possibly a stimulus to the mechanoreceptors in the joints.

Decrease Pain During Weight-Bearing Activities

- Provide assistive devices for ambulation to help reduce stress on the hip joint. If the pain is unilateral, teach the patient to walk with a single cane or crutch on the side opposite the painful joint.
- If leg-length asymmetry is causing hip joint stress, gradually elevate the short leg with lifts in the shoe.
- Modify chairs to provide an elevated and firm surface, and adapt commodes with an elevated seat to make sitting down and standing up easier.

Decrease Effects of Stiffness and Maintain Available Motion

- Teach the patient the importance of frequently moving the hips through their ROM throughout the day. When the acute symptoms are medically controlled, have the patient perform active ROM if he or she can control the motion or with assistance if necessary.
- If a pool is available, have the patient perform ROM in the buoyant environment.
- Initiate nonimpact activities such as swimming, gentle water aerobics, or stationary cycling.

Management: Controlled Motion and Return to Function Phases

As healing progresses and symptoms subside, the emphasis of management includes the following goals and interventions.

Progressively Increase Joint Play and Soft Tissue Mobility

Joint mobilization techniques.[31] Progress joint mobilization to stretch grades (grade III sustained or grade III and IV oscillation) using the glides that stretch restricting capsular tissue at the end of the available ROM (see Box 20.1 and Figs. 5.45 through 5.47 in Chapter 5). Vigorous stretching should not be undertaken until the chronic stage of healing.

Stretching techniques. Stretch any range-limiting tissues. Suggested manual stretching techniques are described in Chapter 4 and self-stretching techniques in the exercise section later in this chapter.

Improve Joint Tracking and Pain-Free Motion

Mobilization with movement (MWM) techniques[99] may be applied through the use of a mobilization belt to produce a pain-free inferolateral glide and then superimposing motion to the end of the available range. As with all MWM techniques, no pain should be experienced during application of the technique. Principles of MWM are described in Chapter 5; specific MWM techniques for the hip are described here.

Increase Internal Rotation

Patient position: Supine with the involved hip flexed and a mobilization belt secured around the proximal thigh and your pelvis.
Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free, end-range internal rotation (Fig. 20.5 A).

Increase Flexion

Patient position: Supine with the involved hip flexed and a mobilization belt secured around the proximal thigh and the pelvis.
Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free inferolateral glide while the caudal hand grips around the flexed thigh and shin to create pain-free, end-range flexion (Fig. 20.5 B).

Increase Extension

Patient position: Supine with the pelvis near the end of the treatment table in the Thomas test position (opposite thigh held against the chest) and a mobilization belt secured around the proximal thigh and your pelvis.

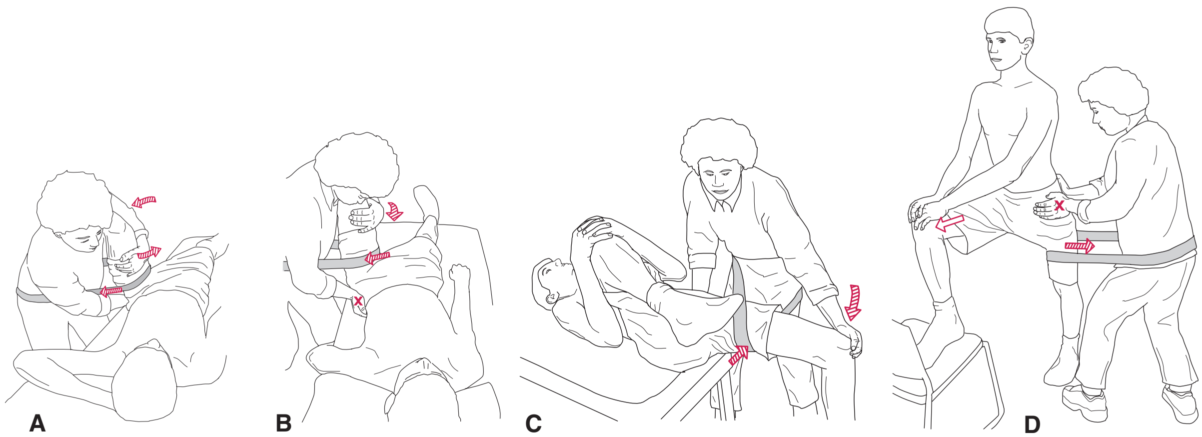

FIGURE 20.5 Mobilization with movement using an inferolateral glide increasing **(A)** pain-free internal rotation, **(B)** pain-free flexion, **(C)** pain-free extension, and **(D)** extension during weight bearing.

Procedure: Stabilize the patient's pelvis with the palm of the hand closest to the patient's head. Use the mobilization belt to produce a pain-free, inferolateral glide, while the caudal hand presses against the extended thigh to create pain-free, end-range extension (Fig. 20.5 C).

Increase Extension During Weight Bearing

Patient position: Standing with the unaffected foot up on a stool and a mobilization belt secured around the proximal thigh and your pelvis.
Procedure: Stabilize the pelvis with both hands and apply a pain-free, lateral glide with the mobilization belt, while the patient lunges forward to produce painless extension of the affected hip (Fig. 20.5 D).

Improve Muscle Performance in Supporting Muscles, Balance, and Aerobic Capacity

- Initiate exercises that develop strength and control of the hip musculature, especially the gluteus maximus, gluteus medius, and rotators, and that improve stability and balance when performing weight-bearing activities. Begin with submaximal isometric resistance; progress to dynamic resistance as the patient tolerates movement. If any exercises exacerbate the joint symptoms, reduce the intensity. Also reassess the patient's functional activities and adapt them to reduce the stress.
- Progress to functional exercises as tolerated using closed-chain and weight-bearing activities. The patient may require assistive devices while weight bearing. Use a pool or tank to reduce the effects of gravity to allow partial weight-bearing exercises without stress.
- Develop postural awareness and balance.
- Progress the low-impact aerobic exercise program (swimming, cycling, or walking within tolerance).

Provide Patient Education

Help the patient establish a balance between activity and rest and learn the importance of minimizing stressful, deforming forces by maintaining muscle strength and flexibility in the hip region.

FOCUS ON EVIDENCE

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.127,128 The consensus of expert opinion cited by Roddy and associates127 is that there are few contraindications and that exercise is relatively safe in patients with OA. However, exercise should be individualized and patient-centered with consideration for age, co-morbidity, and general mobility.

An outcome review[37] summarized that moderate- or high-intensity exercises in patients with RA have minimal effect on the disease activity, but there is insufficient radiological evidence on the effect in large joints. Long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being in patients with RA.

A committee appointed by the Osteoarthritis Research International (OARSI) performed an extensive systematic review and developed a consensus recommendation for the management of hip and knee OA.[156] Suggested interventions included referral to a physical therapist for evaluation and instruction in exercises to "reduce pain and improve functional capacity" as well as use of assistive devices when appropriate. The report also supported the importance of regular aerobic exercise, muscle strengthening and ROM.

Clinical practice guidelines for hip OA developed by the Orthopaedic Section of the American Physical Therapy Association31 and based on evidence identified in an extensive literature review recommend patient education

(moderate evidence), functional, gait, and balance training (weak evidence), manual therapy (moderate evidence) and flexibility, strengthening, and endurance exercises (moderate evidence).

Joint Surgery and Postoperative Management

A number of options for joint surgery are available to manage early- and late-stage joint disease of the hip and some fractures that compromise the vascular supply to the head of the femur. As a result of advances in arthroscopy of the hip over the past decade, small to medium-size, full-thickness lesions of the articular cartilage of the acetabulum and head of the femur as well as other joint pathologies, such as acetabular labral tears, femoral-acetabular impingement, and capsular laxity, now can be managed arthroscopically.[41] *Microfracture*, for example, involves creating small fractures of subchondral bone in the area of the chondral lesion to stimulate growth of fibrocartilage to replace the damaged hyaline cartilage.[41] Other arthroscopic procedures for the hip include *labral resection* or *repair* for an acetabular-labral tear, *osteoplasty* and *rim trimming* for femoral-acetabular impingement, and *capsulorrhaphy* or *plication* for capsular laxity.[41]

Surgical procedures to manage late-stage deterioration of the hip joint include *osteotomy* (which is actually an extra-articular procedure) and arthroplasty, specifically *hip resurfacing arthroplasty* (*surface replacement*),[50,64] *hemiarthroplasty*,[92] and *total hip arthroplasty*.[34,70,87] *Arthrodesis* and *resection arthroplasty* of the hip are considered salvage procedures after failure of arthroplasty and when revision arthroplasty is contraindicated or not feasible.[87]

The goals of joint surgery and postoperative management are to provide a patient with: (1) a pain-free hip, (2) a stable joint for lower extremity weight bearing and functional ambulation, and (3) adequate ROM and strength of the lower extremity for functional activities.

It is important for the therapist to have a basic understanding of the more common surgical procedures for management of joint disease and deformity of the hip and a thorough knowledge of appropriate therapeutic exercise interventions and their progression for an effective, safe postoperative rehabilitation program. An overview of two of the more common procedures—total hip arthroplasty and hemiarthroplasty—and guidelines for postoperative management are described in the following sections.

Total Hip Arthroplasty

One of the most widely performed surgical interventions for advanced arthritis of the hip joint is total hip arthroplasty (Fig. 20.6). Osteoarthritis is the underlying pathology that accounts for most primary total hip procedures.[34]

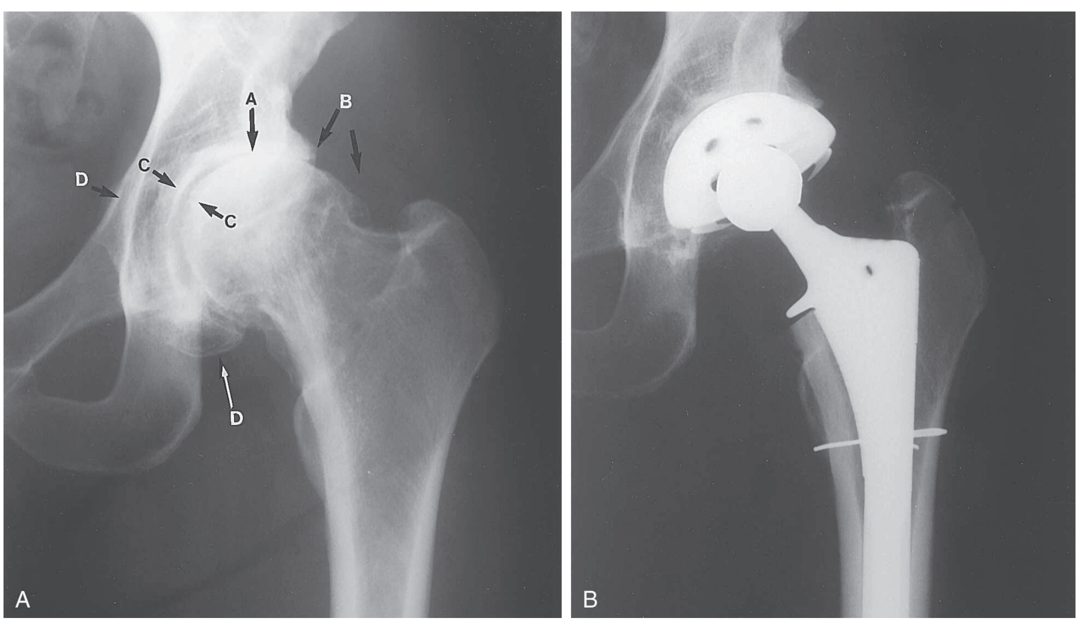

FIGURE 20.6 Total hip arthroplasty. **(A)** The preoperative film of a severely degenerative hip joint demonstrates the classic signs of degenerative joint disease. A, N; B arrowed, joint space with superior migration of the femoral head; B, osteophyte formation at the joint margins of both the acetabulum and femoral head; C, sclerosis of subchondral bone on both sides of the joint surface; D, acetabular protrusion (a boney out-pouching of the acetabular cup in response to the progressive superior and medial migration of the femoral head). **(B)** Postoperative film shows a total hip arthroplasty. Both the acetabular and femoral portions of the joint have been resected and replaced with prosthetic components. *(From McKinnis91 p. 312, with permission.)*

Indications for Surgery

The following are common indications for total hip arthroplasty (THA), sometimes referred to as total hip replacement.[34,42,46,94]

- Severe hip pain with motion and weight bearing and marked limitation of motion as the result of joint deterioration and loss of articular cartilage associated with osteoarthritis, rheumatoid or traumatic arthritis, ankylosing spondylitis, or osteonecrosis (avascular necrosis), leading to impaired function and health-related quality of life
- Nonunion fracture, instability or deformity of the hip
- Bone tumors
- Failure of conservative management or previous joint reconstruction procedures (osteotomy, resurfacing arthroplasty, femoral stem hemiarthroplasty, primary THA)

Historically, primary THA was reserved for patients older than 60 to 65 years of age or the very inactive younger patient with multiple joint involvement (for example as the result of RA), because the projected life span of primary THA procedures is about 20 years.[34,46] For the younger patient with significant hip joint deterioration, hip resurfacing arthroplasty, which unlike THA conserves the femoral head, is an alternative that may be considered.[50] Nevertheless, with advances in component design, materials, and fixation and improvements in surgical techniques, such as the use of minimally invasive approaches, patient selection criteria are broadening, making THA an option for some younger (< 60 years of age), moderately active individuals after evaluation on a case-by-case basis.[7] These individuals are counseled by the surgeon to anticipate the need for revision arthroplasty later in life.

There are a number of instances in which THA is contraindicated. Absolute and relative contraindications are noted in Box 20.4.[7,14,34]

BOX 20.4 Contraindications to Total Hip Arthroplasty

Absolute

- Active joint infection
- Systemic infection or sepsis
- Chronic osteomyelitis
- Significant loss of bone after resection of a malignant tumor or inadequate bone stock that prevents sufficient implant fixation
- Neuropathic hip joint
- Severe paralysis of the muscles surrounding the joint

Relative

- Localized infection, such as bladder or skin
- Insufficient function of the gluteus medius muscle
- Progressive neurological disorder
- Highly compromised/insufficient femoral or acetabular bone stock associated with progressive bone disease
- Patients requiring extensive dental work—dental surgery should be completed before arthroplasty
- Young patients who must or are most likely to participate in high-demand (high-load, high-impact) activities

Preoperative Management

Preoperative patient education has been advocated as an important aspect of the overall rehabilitation plan for many years.[10,126] Patient-related instruction in past years took place the day before surgery when patients were often admitted to the hospital for preoperative tests. In the current healthcare environment, preoperative contact with a patient prior to elective surgery now occurs on an outpatient basis individually or in a group several days before surgery. Patient information sessions often are coordinated and conducted by a team of professionals from multiple disciplines who are likely to be involved with a patient's postoperative care.

Preoperative management typically includes assessment and documentation of a patient's status as well as patient education about the procedure and what to expect during the early postoperative period.[13,87,101,126] Box 20.5 summarizes possible components of preoperative management.[13,60,87,101,126] Furthermore, an individualized exercise program prior to THA has been shown to have a positive impact on postoperative outcomes.[152]

FOCUS ON EVIDENCE

Wang and colleagues[152] conducted a randomized, controlled investigation to determine if a customized exercise program initiated before scheduled THA had an effect on the ambulatory abilities of patients after surgery. Gait velocity was measured by the 25-meter walk test, and walking endurance was measured by the 6-minute walk test. Participants in the exercise group ($n = 15$) took part in two facility-based and two home-based exercise sessions of stationary bicycling and resistance training two times per week for 8 weeks prior to surgery. At 3 weeks and continuing until 12 weeks postoperatively, these patients resumed their individualized exercise regimens, modified to incorporate postoperative precautions. Patients in the control group ($n = 13$) underwent no preoperative intervention

BOX 20.5 Components of Therapy-Related Preoperative Management: Preparation for Total Hip Arthroplasty

- Examination and evaluation of pain, ROM, muscle strength, balance, ambulatory status, leg lengths, gait characteristics, use of assistive devices, general level of function, perceived level of disability
- Information for patients and their families about joint disease and the operative procedure in nonmedical terms
- Postoperative precautions and their rationale including positioning and weight bearing
- Functional training for early postoperative days including bed mobility, transfers, gait training with assistive devices
- Early postoperative exercises
- Criteria for discharge from the hospital

and received routine post-THA functional training. At 3 weeks postoperatively, the exercise group demonstrated significantly greater gait velocity and stride length and at 12 weeks significantly greater 6-minute walking distance than the control group. The investigators concluded that a customized strength and endurance training program prior to and after THA improved the rate of recovery of ambulatory function.

Procedures

Background

Prosthetic designs and materials. THA has been performed successfully since the early 1960s.[34,46] Sir John Charnley,[28] a surgeon from England, is credited with the initial research and clinical application of total hip replacement, which subsequently has evolved into contemporary hip arthroplasty. A variety of implant designs, materials, and surgical approaches have been developed and modified over the years since the early replacements.[34,46,64] Today, total hip implant systems typically are composed of an inert metal (cobalt-chrome and titanium) modular femoral component and a high-density polyethylene acetabular component. Other implant designs in use are metal-on-metal systems[64,137] and systems that utilize ceramic surfaces in the design.[34,64]

Cemented versus cementless fixation. The revolutionary aspect of the early THA procedures was the use of acrylic cement, methyl methacrylate, for prosthetic fixation. Cement fixation allowed very early postoperative weight bearing and shortened the period of rehabilitation, whereas prior to the use of cement fixation, patients were subjected to months of restricted weight bearing and limited mobility.[34] Cement fixation continues to be in common use today, particularly in THA for elderly and physically inactive younger patients, but has been shown to have its drawbacks.[15,64,114,124]

A significant postoperative complication associated with cemented fixation is aseptic (biomechanical) loosening of the prosthetic components at the bone-cement interface. It has been shown that loosening subsequently leads to a gradual recurrence of hip pain and the need for surgical revision.[15,34,124] Patients who most often develop implant loosening are the younger, physically active patients. In contrast, loosening has not been shown to be a particularly prevalent problem in elderly patients or in young patients with multiple joint involvement who typically have a limited degree of physical activity.[46,124]

The long-term problem of mechanical loosening of cemented implants gave rise to the development and use of cementless (biological) fixation.[34,46] Cement-free fixation is achieved either by use of porous-coated implants that allow osseous ingrowth into the beaded or textured surfaces of an implant or by a precise press-fit technique.[16,78,147] Smooth (nonporous) femoral components also are being used with cementless arthroplasty. Some components are manufactured with a coating of a bioactive compound called hydroxyapatite, designed to promote initial osseous ingrowth.[27] Ingrowth of boney tissue occurs over a 3- to 6-month period with continued bone remodeling beyond that time period. Initial long-term studies of cementless fixation have demonstrated better durability of the fixation of the acetabular component than the femoral stem component.[64]

Improvements in cemented and noncemented fixation continue, as does debate over the indications, benefits, and disadvantages of both forms of fixation. Cementless fixation is more often the choice for the patient under 60 years of age who is physically active and has good bone quality.[16,78,147] Its use continues to grow as the average age of the patient undergoing THA decreases and improvements in femoral stem fixation evolve.[64] However, cement fixation continues to be used routinely for patients with osteoporosis and poor bone stock and with elderly patients.[15,114,124] In some cases a combination of fixation procedures, known as a hybrid procedure, involving a noncemented acetabular component and a cemented femoral stem component is selected.[102]

Operative Overview

The operative approaches used to gain access to the involved joint and to implant the prosthetic components during THA can be divided into two broad categories: *traditional (conventional)* and *minimally invasive* approaches. For decades, hip arthroplasty procedures have involved the use of rather long surgical incisions (15 to 25 cm) to expose the joint. Although long-term outcomes have been successful, *traditional* surgical approaches impose substantial trauma to soft tissues and contribute to a lengthy postoperative recovery period.

A recent advance in primary hip arthroplasty—the use of minimally invasive approaches through "mini-incisions"—allows adequate exposure of the joint for insertion of the prosthetic components, but reportedly lessens the trauma of soft tissues. Brief overviews of the various types of *traditional* and minimally invasive surgical approaches follow, focusing on which muscles are incised or left intact during the procedure.[2,39,54,64,66,81] The integrity of the muscles and other soft tissues surrounding the prosthetic hip influences its postoperative stability and the extent of restrictions placed on the patient, most notably during the early phase of postoperative recovery.

Traditional surgical approaches. There are several *traditional* (conventional) approaches that may be used during traditional THA procedures: posterior (or posterolateral), lateral, anterolateral, anterior, and transtrochanteric. Each has its advantages and disadvantages.[2,39,54] Table 20.3 summarizes the key features of each approach and their potential impact on function.

- ***Posterior or posterolateral approaches.*** These are the most frequently used approaches for primary THA. To access the joint through a posterior approach, the gluteus maximus is split in line with the muscle fibers. With a posterolateral approach, the interval between the gluteus maximus and medius is split. The piriformis and short external rotator tendons are transected near their insertion. Consequently, this approach preserves the integrity of the gluteus medius and vastus lateralis muscles. The capsule is incised, and the

TABLE 20.3 Features of Traditional (Conventional) Surgical Approaches for THA and Potential Impact on Postoperative Function

Surgical Approach	Involvement of Hip Muscles and Other Soft Tissues	Impact on Postoperative Function
Posterior or Posterolateral[34,39,54,66,75,96,97]		
	■ Gluteus maximus divided in line with its fibers with a posterior approach ■ Interval between the gluteus maximus and medius divided in a posterolateral approach ■ Short external rotators and piriformis released and repaired ■ Gluteus maximus tendon possibly released from femur; repaired at conclusion ■ Posterior capsule incised and repaired ■ Gluteus medius and TFL left intact	■ Possible earlier recovery of a normal gait pattern because gluteus medius and TFL left intact ■ Highest risk of dislocation or subluxation of prosthetic hip
Direct Lateral[34, 54]		
	■ Longitudinal division of the TFL ■ Release of up to one-half of the proximal insertion of the gluteus medius and minimus; reattached prior to closure ■ Longitudinal splitting of the vastus lateralis ■ Capsulotomy and repair	■ Weakness of the hip abductors ■ Possible pelvic obliquity ■ Delayed recovery of symmetrical gait
Anterolateral[34,54,66,81,89]		
	■ Incision centered over the greater trochanter and lateral to the TFL ■ Anterior one-third of the gluteus medius and minimus and sometimes the vastus lateralis released; reattached prior to closure ■ External rotators usually remain intact ■ Anterior capsulotomy and repair	■ Weakness of the hip abductors ■ Delayed recovery of gait symmetry ■ Lower incidence of hip dislocation than posterior approach
Direct Anterior[34,54,81]		
	■ Incision made anterior and distal to the ASIS, slightly anterior to the greater trochanter, and medial to the TFL ■ No muscles incised or detached, but rectus femoris and sartorius retracted medially to access the joint ■ Anterior capsulotomy and repair	■ Weight bearing as tolerated immediately after surgery ■ More rapid recovery of hip muscle strength and normal gait pattern compared with anterolateral approach
Transtrochanteric[34,54,66]		
	■ Osteotomy of the greater trochanter at the insertion of the gluteus medius and minimus ■ Anterior capsulotomy and dislocation ■ Greater trochanter reattached and wired in place prior to closure	■ Extended period of nonweight bearing on the operated extremity ■ Necessity for abduction precautions ■ Possible pain due to irritation of soft tissues from internal fixation device

ASIS=anterior superior iliac spine; TFL= tensor fasciae latae

gluteus maximus tendon may be released from its insertion on the femur (and later repaired) in preparation for posterior dislocation of the hip and insertion of the components. Although an intact gluteus medius may result in earlier recovery of a normal gait pattern after surgery, the primary disadvantage of this approach is that it is associated with the highest incidence of postoperative joint instability and resulting subluxation or dislocation of the hip.[66,75,96,97] To reduce the risk of postoperative dislocation, repair of the posterior capsule (posterior capsulorrhaphy) is advocated to provide maximal soft tissue constraint to the posterior aspect of the capsule.[29]

- ***Direct lateral approach.*** This approach requires longitudinal division of the tensor fasciae latae (TFL), release of up to one-half of the proximal insertion of the gluteus medius, and longitudinal splitting of the vastus lateralis.[2,54] The gluteus minimus also is partially detached from the trochanter. A lateral approach may—but typically does not—involve a trochanteric osteotomy. Disruption of the abductor mechanism is associated with postoperative weakness of the abductors (positive Trendelenburg sign) and gait asymmetry.
- ***Anterolateral approach.*** With this approach, an incision is centered over the greater trochanter, lateral to the TFL. The IT band is split. The anterior one-third of the gluteus medius and minimus are detached from their insertion on the greater trochanter and reattached at closure.[66,81,89] In some instances, the anterior one-third of the vastus lateralis is detached as well.[89] Unlike the posterior/posterolateral approach, the external rotators usually remain intact in the anterolateral approach. A capsulotomy is performed and the hip dislocated anteriorly for adequate exposure of the joint. Although this approach allows for precise implant positioning and leg length correction and provides excellent postoperative stability, it is associated with delayed recovery of the abductor muscles. Consequently, postoperative gait asymmetries persist for a longer period of time than with an anterior approach.[81] Compared with the posterior approach, the incidence of postoperative dislocation is lower in the anterolateral approach (and anterior approach as well).[34,54] Therefore, it is also indicated for patients with muscle imbalances associated with stroke or cerebral palsy whose standing posture is characterized by hip flexion and internal rotation.[2,54] Understandably, patients exhibiting this posturing are at high risk of dislocation with a posterior approach.
- ***Anterior approach.*** An incision is made lateral and distal to the anterior superior iliac spine, slightly anterior to the greater trochanter, and medial to the TFL. Although no muscles are detached with this approach, the rectus femoris and sartorius are retracted medially for exposure of the joint. The capsule is incised and the hip is dislocated anteriorly in preparation for insertion of the components.[81] A key advantage of the direct anterior approach is that weight bearing as tolerated on the operated extremity is permitted immediately after surgery. However, this approach is used infrequently for primary THA, because during surgery, muscle retraction rather than detachment makes visualization of the surgical field more challenging.
- ***Transtrochanteric approach.*** This approach was first used with very early primary THA.[28] Today, however, it is used primarily in complex revision arthroplasty. The transtrochanteric approach involves an osteotomy of the greater trochanter at the boney insertion of the gluteus medius and minimus and affords excellent exposure for insertion of the prosthetic components.[66] Following implantation of the components, the trochanter is reattached and wired in place to stabilize the osteotomy site. The trochanter is often reattached in a position to improve the mechanical efficiency of the gluteus medius muscle.[2,54] An extended period of nonweight-bearing on the operated limb and adherence to abduction precautions are required until boney healing has occurred. Complications associated with trochanteric osteotomy include nonunion and greater than usual soft tissue irritation and pain from a considerable amount of internal fixation.

Minimally invasive approaches. As with traditional THA, minimally invasive THA is an open procedure. With minimally invasive procedures, however, the joint is approached through one or two small incisions, usually defined as less than or equal to 10 cm in length.[14] The characteristics of minimally invasive approaches for THA are summarized in Box 20.6.

BOX 20.6 Features of Minimally Invasive Total Hip Arthroplasty

- Length of incision: < 10 cm, depending on the location of the approach and the size of the patient[14,66]
- Most, if not all, muscles and tendons left intact
- Single-incision or two-incision surgical approach
  - *Single incision*: posterior,[47] anterior,[88,89,120] or occasionally lateral.[9,63]
  - *Two-incision*: two 4- to 5-cm incisions, one anterior for insertion of acetabular component and one posterior for placement of femoral component.[4,13,129,140]
- Incision location and muscles disturbed
  - *Posterior approach*: an incision extending mostly distal to the greater trochanter between the gluteus medius and piriformis muscles; short external rotators may or may not be incised (later repaired); abductor mechanism consistently is left intact.[47,155]
  - *Anterior approach*: an incision beginning just lateral and distal of the anterior superior iliac spine extending in a distal and slightly posterior direction along the belly of the tensor fasciae latae (TFL); sartorius and rectus femoris retracted medially and the TFL laterally; leaves all muscles intact; no postoperative precautions.[13,88,89,120]
  - *Lateral approach*: least commonly used; splits the middle-third of the gluteus medius; anterolateral incision into the capsule leaves the posterior capsule intact, eliminating the need to observe postoperative precautions for prevention of posterior dislocation.[9,63]

The rationale for minimally invasive THA (as opposed to traditional THA through one of the aforementioned conventional surgical approaches) is that the use of smaller incisions and muscle-sparing techniques reduces soft tissue trauma during surgery and potentially improve and accelerate a patient's postoperative recovery.[8,14]

Benefits cited by advocates of minimally invasive THA are:[3,8,13,14,66,129]

- Decreased blood loss.
- Reduced postoperative pain.
- Shorter length of hospital stay and lower cost of hospitalization.
- More rapid recovery of functional mobility.
- Better cosmetic appearance of the surgical scar.

Proponents, however, also have noted that when compared with traditional THA, minimally invasive procedures are more technically challenging, specifically with regard to insertion and alignment of the prosthetic components.[3,9,155] Depending on the surgeon's experience with the new approach and selection of patients, there has been speculation that there could be a higher rate of postoperative complications.[3,9]

Initially, reports on minimally invasive THA provided data about a variety of positive outcomes,[13,14,88] but many of these reports were limited to descriptions of practitioner or institutional experiences with selected patient populations and did not include a comparison group. Reports of complications also were anecdotal.

Since the publication of these first reports, many studies that include comparison groups, some of which are randomized, have been reported in reviews of the literature.[64,66] Findings support as well as call into question some of the purported benefits and drawbacks of minimally invasive approaches. In general, the results of studies have supported the in-hospital benefits of minimally invasive THA, such as less blood loss, less postoperative pain, and shorter hospital stay, when compared with traditional THA.[112,155] However, the claim of rapid recovery of functional mobility, typically measured by gait analysis following minimally invasive versus traditional THA, has yet to be determined.[39,89,120] Details of these studies are summarized in the outcomes section on THA.

Implantation of components and closure. After dislocation of the joint, an osteotomy is performed at the femoral neck, and the head is removed. Another option used by some surgeons for minimally invasive procedures is to cut the femoral neck *in situ* without dislocating the hip.[13,88,140] The acetabulum is reamed and remodeled, and a high-density polyethylene cup is inserted into the prepared acetabulum.[114] A patient with developmental dysplasia of the hip may require acetabular bone grafting to improve the stability of the prosthetic joint. To prepare the femoral shaft for the implant, the intramedullary canal may be broadened, primarily when cement fixation is to be used; then the stemmed, metal prosthesis is inserted into the shaft of the femur.[15,124] It is important to note that trial components are inserted and checked radiographically to verify alignment of the components, and the hip is moved through a full ROM to assess its stability before the permanent implants are inserted.

After the prosthetic hip is reduced, the capsule typically is repaired. The remaining layers of soft tissues that were incised or detached are securely repaired and appropriately balanced prior to closure.

CLINICAL TIP

Although published resources contain a wealth of information about implant design, methods of fixation, and soft tissues incised or detached in the various conventional and minimally invasive surgical approaches for THA, the best resource a therapist can use to understand the unique features of a patient's surgery and then plan an individualized postoperative rehabilitation program is the operative report found in the patient's medical record.

Complications

The incidence of intraoperative and early and late postoperative complications after primary, traditional THA is relatively low. Some surgeons have raised concerns, however, that a higher incidence of complications, in particular malpositioning of the prosthetic components, could occur with minimally invasive procedures due to decreased exposure of the hip joint during surgery and the more technically demanding nature of the approaches.[3,9] To date, these concerns have not been consistently supported by evidence-based studies.[64,66] Although only a small percentage of complications require revision arthroplasty, any complication can hamper rehabilitation and restoration of functional mobility.

Intraoperative complications. Intraoperative complications associated with THA include malpositioning of the prosthetic components, femoral fracture, insufficient equalization of leg lengths, and nerve injury.

Early postoperative complications. In addition to medical complications, such as infection, deep vein thrombosis (DVT), or pneumonia that can occur after any surgery, postoperative complications that may occur during the early period of recovery (before 6 weeks or up to 2 to 3 months) include wound healing problems or infection, dislocation of the prosthetic joint, disruption of a bone graft site before sufficient bone healing has occurred, and a persistent functional leg-length discrepancy.[96]

Late complications. Late complications include mechanical loosening of either implant at the bone-cement or bone-implant interface; polyethylene wear atraumatic or traumatic periprosthetic fracture; and in rare instances, heterotopic ossification.[66] Of these late complications, mechanical loosening of the components is by far the most common and typically requires revision arthroplasty.

Dislocation: a closer look. Dislocation of the operated hip is a complication that occurs most frequently during the first

2 to 3 months postoperatively when soft tissues around the hip joint are healing. The frequency of early dislocation after current-day primary THA is reported to be < 1% to slightly more than 10%, with a mean of just less than 2%.[93] During the first postoperative year, there is a higher rate of dislocation following revision arthroplasty (5.1%) than primary THA (1.7%).[68] Most dislocations are nontraumatic and occur in a posterior direction.[75,97] Posterior dislocations are often but not always associated with a posterior surgical approach.[2,54] Dislocation also occurs after anterior, anterolateral, and direct lateral approaches.[75,97,118] Patient-related and surgery/prosthesis-related risk factors that may contribute to dislocation are noted in Table 20.4.[68,93] Precautions to reduce the risk of dislocation after THA are addressed in the following section on postoperative management (see Box 20.8). Although a first-time dislocation usually can be managed with closed reduction and conservative treatment, recurrent dislocation after THA typically requires additional surgically.

Leg length inequality: a closer look. Inequality of leg lengths is one of the more common complaints during the early period of recovery after THA and is associated with pain and a sense of instability and exertion while walking.[32,117] A functional leg length discrepancy and pelvic obliquity that is evident during standing and walking in most instances is the result of muscle spasm, muscle weakness (particularly the gluteus medius), and residual contracture of hip muscles, which were often present prior to surgery. This type of leg length discrepancy usually resolves with conservative management during the first postoperative year.[32] However, a true leg-length discrepancy may be the result of over-lengthening the limb during surgery, malpositioning of the prosthetic implants (usually the acetabular component), or recurrent postoperative dislocation. If significant, it may necessitate further surgery or revision arthroplasty.[117]

Postoperative Management

Immobilization

After THA, there is no need for immobilization of the operated hip. To the contrary, postoperative rehabilitation emphasizes early movement. Depending on the type of surgical approach used and the stability of the prosthetic hip, the operated limb may need to remain in a position of slight abduction and neutral rotation when the patient is lying in bed in the supine position. An abduction pillow or wedge typically is sufficient to maintain the position.[87]

Weight-Bearing Considerations

After cemented THA, patients usually are permitted to bear as much weight as tolerated almost immediately after surgery.[15,114,124] In contrast, with cementless or hybrid THA, weight bearing on the operated limb is often restricted for the first few weeks or more. A number of factors affect the extent and duration of postoperative weight-bearing restrictions and the need for an ambulation aid during transfers, walking, and ascending and descending stairs. Box 20.7 summarizes these factors.

Although it has been customary to limit weight bearing after cementless and hybrid THA,[16,147] this practice deserves a closer look. The rationale for restricted weight bearing is based on the assumption that early, excessive loading of the operated limb could cause micromovement at the bone-implant interface, thereby jeopardizing the initial stability of the implant(s), interfering with osseous ingrowth, and contributing to eventual loosening of the prosthetic implants. There is little evidence, however, to support these concerns.[59]

Moreover, there are potential benefits of safe levels of early weight bearing after THA, specifically the reduction of bone demineralization from decreased weight bearing and the earlier recovery of functional mobility.[18,21] Gradually progressed weight bearing also promotes activation of the weakened hip abductor muscles for stabilization of the pelvis and a more symmetrical gait pattern.[59]

To further strengthen the case for early weight bearing as tolerated, it has been established that many patients have difficulty learning and integrating prescribed weight-bearing limitations into daily functional activities and consequently place greater loads than recommended on the operated extremity, particularly once postoperative pain has subsided.[149]

TABLE 20.4 Risk Factors Contributing to Joint Dislocation after Total Hip Arthroplasty

Patient-Related Factors	Surgery/Prosthesis-Related Factors
■ Age > 80 to 85 years[93,97] ■ THA for femoral neck fracture	■ Surgical approach: higher risk with posterior than anterior, anterolateral, or lateral approaches
■ Medical diagnosis: higher risk in patients with inflammatory arthritis (mostly RA) than patients with OA[68,157]	■ Design of femoral component: higher risk with smaller-sized femoral head[68] ■ Malpositioning of the acetabular component
■ Poor quality soft tissue from chronic inflammatory disease ■ History of prior hip surgery ■ Preoperative and postoperative muscle weakness (particularly the abductor mechanism)[64] and contractures ■ Cognitive dysfunction, dementia	■ Inadequate soft tissue balancing during surgery or poor quality soft tissue repair ■ Experience of the surgeon

BOX 20.7 Early Postoperative Weight-Bearing Restrictions After Total Hip Arthroplasty

Method of Fixation

- *Cemented.* Immediate postoperative weight bearing as tolerated.[15,87,114]
- *Cementless and hybrid*. Recommendations vary from partial weight bearing (toe-touch or touch-down) for at least 6 weeks[16,70,75,90] to weight bearing as tolerated (no restrictions) immediately after surgery.[13,18,21]

Surgical Approach

- *Traditional versus minimally invasive*. Weight-bearing usually more restricted after standard (traditional) approach because of more extensive surgical disturbance and repair than minimally invasive approach.[14] Weight bearing as tolerated may be permissible immediately after minimally invasive procedure.[13]
- *Trochanteric osteotomy*. Although used infrequently, restricted weight bearing at least 6 to 8 weeks or possibly 12 to 16 weeks for bone healing

Other Factors

- *Use of bone grafts*. Nonweight-bearing or restricted weight bearing during bone healing.
- *Poor quality of patient's bone*. Extended restrictions so as not to jeopardize the stability of the prosthetic implants.

It is also known that some resisted movements of the lower extremity performed in the supine position impose loads on the hip considerably greater than body weight.[110]

In light of these considerations, the need for weight-bearing restrictions after cementless THA is being re-examined.

FOCUS ON EVIDENCE

A systematic review of the literature recently was undertaken to determine if weight bearing to tolerance (unrestricted weight bearing) immediately after surgery adversely affects the outcomes of cementless THA.[59] In two of the randomized, controlled investigations analyzed in the review,[18,21] the effects of immediate weight bearing as tolerated during ambulation and other functional activities after cementless or hybrid arthroplasty were compared with the effects of restricted weight bearing. No short-term or long-term adverse effects from immediate weight bearing were identified in either study. For example, there was no evidence that osseous ingrowth of the femoral stem prosthesis was adversely affected. It is important to note that patients in both studies were relatively young compared with most patients undergoing hip arthroplasty, and their bone quality was described as excellent. In addition, all patients in both studies participated in a comprehensive, supervised postoperative rehabilitation program.

In one study,[21] patients assigned to the immediate weight-bearing group were placed on no weight-bearing restrictions. These patients also were encouraged to discontinue use of ambulation aids as soon as possible. In contrast, those in the restricted weight-bearing group were required to ambulate with two crutches and were limited to toe-touch weight bearing for 6 weeks. After 6 weeks, these patients were permitted to bear weight as tolerated. In the other study,[18] patients in the immediate weight-bearing group initially used one crutch, but were encouraged to place as much weight as tolerated on the operated lower extremity. Patients in the delayed weight-bearing group ambulated with two crutches and were allowed to place only 10% of body weight on the operated leg for 3 months.

There were no significant differences found between the two groups in either study on several follow-up evaluations. Authors of both studies suggested that early weight bearing as tolerated after cementless or hybrid primary THA can be safe in a young patient population (< 60 to 65 years of age) with excellent bone quality.

In summary, there is moderate to strong evidence to support the case for immediate weight bearing to tolerance for a young, healthy population following noncemented primary THA.[59] However, in the clinical setting, the responsibility of determining the need for protected weight bearing during the early phase of postoperative rehabilitation after THA remains with the surgeon.

Exercise Progression and Functional Training

The use of therapeutic exercise interventions and functional training for patients after THA has been reported in the literature for several decades.[35,125] Although the time frame and extent of patient-therapist contact have diminished substantially since these early descriptive reports were published, the goals and elements of postoperative rehabilitation programs have changed very little.

A report from the National Institutes of Health (NIH) has identified the need for consistently applied and evaluated long- and short-term intervention strategies for rehabilitation after THA.[108] This is because more often than not rehabilitation programming has centered on protocols developed by and based on the opinions or assumptions of individual surgeons or therapy departments rather than on evidence-based research on the effects of specific exercises or weight-bearing activities on the hip joint or on functional outcomes.

A consensus survey on physical therapy-related intervention for early inpatient total hip (and knee) rehabilitation is a step forward in the development of consistent guidelines for postoperative management.[40] The exercises and functional activities identified in the consensus document were elements common to most postoperative programs and only those agreed upon by the participating physical therapists.

The goals, guidelines, and precautions for exercise and functional activities after primary THA discussed in this section represent not only those interventions identified in the aforementioned consensus survey but also exercises selected from other resources in the current literature.[23,62,87,101,152] The

suggested exercises, functional activities, and precautions also are based on the results of the available, albeit limited, research on the impact of specific exercises and functional activities on the hip joint.

FOCUS ON EVIDENCE

Several related, single-subject studies have measured *in vivo* forces acting on the hip and acetabular contact pressures during exercise and gait.[48,73,74,138] Although these studies involved only two patients after insertion of a femoral endoprosthesis, not a total joint replacement, the results raise questions about assumptions made by clinicians with regard to the selection and progression of common exercises and functional activities during rehabilitation after hip arthroplasty. The results of these studies suggest that active or resistive exercises, performed isometrically or dynamically, should be initiated and progressed cautiously. During the acute or post-acute phases of rehabilitation, some exercises, such as maximal effort gluteal setting or unassisted heel slides, typically used during the initial phase of rehabilitation—and manually resisted isometric abduction during the post-acute stage in preparation for gait and other weight-bearing activities—may actually generate greater acetabular contact pressures than the weight-bearing activities themselves.[48,138]

Accelerated Rehabilitation

One change that has occurred in postoperative management during the past decade is the trend toward advocating accelerated rehabilitation, particularly for patients under 60 to 65 years of age who have undergone minimally invasive THA and wish to resume an active lifestyle as quickly as possible following surgery.[13,38] Although "accelerated rehabilitation" following minimally invasive THA has not been clearly defined, two characteristics stand out—a rapid progression to full weight bearing during ambulation and discontinuing crutch and cane use as soon as possible in the rehabilitation program.

There is concern, however, that progressing ambulation at this rate in the presence of postoperative strength and balance deficits could result in persistent gait asymmetries and possibly increase the risk of injury or jeopardize optimal short- and long-term outcomes.[39] In addition, it has been suggested that during functional activities that require endurance, persistent muscular weakness and fatigue may increase the stresses placed on the prosthetic hip, thereby contributing to biomechanical loosening of the components over time.[135]

Therefore, before discontinuing use of an ambulation aid, it is important to regain sufficient strength of the hip abductors and extensors to maintain stability and symmetry during ambulation. With this in mind, it is clear that an individualized program of strengthening exercises must be an integral component of accelerated rehabilitation.[59]

Exercise: Maximum Protection Phase After Traditional THA

Common structural and functional impairments exhibited by patients during the acute and subacute stages of soft tissue healing and the initial phase of postoperative rehabilitation after THA are pain secondary to the surgical procedure, decreased ROM, muscle guarding and weakness, impaired postural stability and balance, and decreased functional mobility (transfers and ambulation activities). Depending on the type of component fixation used and the surgeon's preference, weight-bearing restrictions initially may interfere with some functional activities.

The emphasis of this phase of rehabilitation after a conventional surgical approach is on patient education to reduce the risk of early postoperative complications, in particular dislocation of the operated hip. (Risk factors for dislocation after THA were noted in Table 20.4.) Precautions during functional activities are determined by the surgical approach used and input from the surgeon about the intraoperative stability of the hip replacement (Box 20.8).[75,87,96,97,118]

Selected exercises and functional training begin as soon as the patient is medically stable, usually the day of or after surgery. The frequency of treatment by a therapist is often twice a day until the patient is discharged from the hospital,[40] typically by 2 to 4 days postoperatively.

Goals and interventions. The following goals and interventions apply to the initial postoperative days while the patient is hospitalized and continue through the first few weeks after surgery when the patient is at home or in a subacute healthcare or skilled nursing facility.

- *Prevent vascular and pulmonary complications.*
  - Ankle pumping exercise to prevent venous stasis, thrombus formation, and the potential for pulmonary embolism.
  - Deep breathing exercise and bronchial hygiene to prevent postoperative atelectasis or pneumonia continued until the patient is up and about on a regular basis.
- *Prevent postoperative dislocation or subluxation of the operated hip.*
  - Patient and caregiver education about motion restrictions, safe bed mobility, transfers, and precautions during other ADL (see Box 20.8).
  - Monitor the patient for signs and symptoms of dislocation, such as shortening of the operated lower extremity not previously present.
- *Achieve independent functional mobility prior to discharge.*
  - Bed mobility, rising from and sitting down in a chair, and transfer training, emphasizing proper trunk and lower extremity alignment and integrating weight-bearing and motion restrictions.

CLINICAL TIP

Rising from a low chair imposes particularly high-loads across the hip joint, producing loads approximately eight times the patient's body weight.110 If the posterior capsule was incised

BOX 20.8 Early Postoperative Motion Precautions After Total Hip Arthroplasty*

Posterior/Posterolateral Approaches

ROM

- Avoid hip flexion > 90° and adduction and internal rotation beyond neutral.

ADL

- Transfer to the sound side from bed to chair or chair to bed.
- Do not cross the legs.
- Keep the knees slightly lower than the hips when sitting.
- Avoid sitting in low, soft chairs.
- If the bed at home is low, raise it on blocks.
- Use a raised toilet seat.
- Avoid bending the trunk over the legs when rising from or sitting down in a chair or dressing or undressing.
- When bathing, take showers, or use a shower chair in the bathtub.
- When ascending stairs, lead with the sound leg; when descending, lead with the operated leg.
- Pivot on the sound lower extremity.
- Avoid standing activities that involve rotating the body toward the operated extremity.
- Sleep in supine position with an abduction pillow; avoid sleeping or resting in a side-lying position.

Anterior/Anterolateral and Direct Lateral Approaches

ROM

- Avoid flexion > 90°.**
- Avoid hip extension, adduction, and external rotation past neutral.
- Avoid the combined motion of hip flexion, abduction, and external rotation.
- If the gluteus medius was incised and repaired or a trochanteric osteotomy was done, do not perform active, antigravity hip abduction for at least 6 to 8 weeks or until approved by the surgeon.

ADL

- Do not cross the legs.
- During early ambulation, step to, rather than past, the operated hip to avoid hyperextension.
- Avoid activities that involve standing on the operated extremity and rotating away from the involved side.

Transgluteal Approach (trochanteric osteotomy)***

ROM

- Avoid adduction past neutral
- No active, antigravity hip abduction for at least 6 to 8 weeks or until approved by the surgeon
- No exercises that involve weight bearing on the operated leg

ADL

- Sleep in supine position with abduction pillow
- Do not cross legs
- Maintain weight-bearing restrictions during all ADL

*Precautions apply to traditional total hip arthroplasty and may or may not be necessary after minimally invasive procedures, depending on the surgeon's guidelines.

**Although a posterior surgical approach is associated with the highest risk of dislocation, all patients routinely are asked to limit hip flexion to < 90° and rotation to < 45° for about 6 weeks regardless of the surgical approach used.[118]

*** Follow weight-bearing restrictions for 6–8 weeks or up to 12 weeks for bone healing to occur.

during surgery, this places the involved hip at a high risk of posterior dislocation until soft tissues around the hip joint have healed sufficiently (at least 6 weeks) or until the surgeon indicates that unrestricted functional activities are permissible. Therefore, teach the patient the importance of sitting only on a chair that is elevated and to avoid sitting on soft, low furniture.

- Ambulation with an assistive device (initially a walker or two crutches) immediately after surgery, adhering to weight-bearing restrictions and gait-related ADL precautions. Emphasize a stable, symmetrical gait pattern. Progress to one crutch or a cane depending on pain, strength of hip abductors, and gait symmetry.
- Ascending and descending stairs with an assistive device, initially one step at a time.

PRECAUTION: Even if a patient is permitted to bear full weight on the operated extremity and discontinue crutch or cane use as tolerated, have the patient continue to use an ambulation aid for protected weight bearing during the first few weeks after surgery when ascending and descending stairs to reduce the risk of placing excessive torsional forces on the prosthetic hip joint.[59]

- ***Maintain a functional level of strength and muscular endurance in the upper extremities and nonoperated lower extremity.***
  - Active-resistive exercises in functional movement patterns, targeting muscle groups used during transfers and ambulation with assistive devices.
- ***Prevent reflex inhibition and atrophy of musculature in the operated limb.***
  - *Submaximal* muscle-setting exercises of the quadriceps, hip extensor, and hip abductor muscles—just enough to elicit a muscle contraction.

PRECAUTION: If a trochanteric osteotomy was performed, avoid even low-intensity isometric contractions of the hip abductors during the early postoperative phase unless initially approved by the surgeon and performed strictly at a minimum intensity. (See Box 20.8 for additional precautions after trochanteric osteotomy.)

- ***Regain active mobility and control of the operated extremity.***
  - While in bed, A-AROM exercises of the hip within protected ranges.

- Active knee flexion and extension exercises while seated in a chair, emphasizing terminal knee extension.
- Active hip rotation in the supine position between external rotation or internal rotation to neutral depending on the surgical approach.
- If the status of the abductor muscles permits, active, gravity-eliminated hip abduction in the supine position by sliding the leg on a low-friction surface or active antigravity abduction combined with external rotation (clam exercise) in the side-lying position (with a pillow between the thighs to prevent hip adduction past neutral).
- Active hip ROM (forward and backward pendular motions) in the standing position with the knee flexed and extended and hands on a stable surface to maintain balance.
- Bilateral, closed-chain, weight-shifting balance activities, heel raises, and mini-squats, while maintaining symmetrical alignment but placing only the allowable amount of weight on the operated extremity.
- Hip hiking while bearing the allowable amount of weight on the operated extremity.

- ***Prevent a flexion contracture of the operated hip.***
  - Avoid use of a pillow under the knee of the operated extremity.

Criteria to progress. The criteria to advance to the next phase of rehabilitation is highly dependent on weight-bearing and ROM restrictions; however, the following criteria typically must be met.

- Well-healed incision; no signs of wound drainage or infection
- Independent level-ground ambulation with one crutch or a cane or no assistive device if weight-bearing restrictions permit
- Ability to bear full weight on the operated extremity without pain and with the knee fully extended
- Functional ROM of the hip
- Muscle strength of operated hip: at least 3/5

Exercise: Moderate Protection Phase After Traditional THA

After traditional THA, the intermediate phase of rehabilitation begins at about 4 to 6 weeks postoperatively. Full weight bearing may be permitted for some patients, but some degree of protection may be necessary for 12 weeks postoperatively for others. The extent of protection of the operated hip varies substantially based on the surgical approach, the type of fixation used, and the surgeon's preference. Full healing of soft tissue and bone continues for up to a year after surgery.

The exercises described for this phase may be carried out under therapist supervision or as part of a home program that a patient learns during home-based or outpatient therapy or while in an extended care facility. Exercises and functional training focus on restoration of strength (particularly in the hip abductor and extensor muscles), postural stability and balance, a symmetrical gait pattern, muscular and cardiopulmonary endurance, and ROM to functional levels. Postoperative precautions during ADL may be continued for at least 12 weeks and sometimes considerably longer.[87,101] Patient education also continues as long as the patient has access to supervised therapy in preparation for a return to anticipated activities in the home, workplace, or recreational setting.

Goals and interventions. The following are the goals and interventions for the intermediate (moderate protection) phase of rehabilitation.

- ***Regain strength and muscular endurance, emphasizing strength of hip abductors and extensors.***

PRECAUTION: The initiation and progression of resistance training to strengthen hip abductor muscles are contingent on the integrity of the abductor mechanism, which may or may not have been left intact during the surgical approach. Likewise, progressing from bilateral to unilateral closed-chain training depends on when full weight bearing on the operated extremity is permitted.

- While standing on the sound lower extremity, open-chain exercises within the permissible ranges in the operated leg against light resistance. Initially, emphasize increasing the number of repetitions rather than the resistance to improve muscular endurance.
- Bilateral, closed-chain exercises to strengthen hip and knee extensors, such as mini-squats against light-grade elastic resistance or while holding light weights in both hands when unsupported standing is permitted. Reinforce symmetrical alignment of the lower extremities in standing.
- Unilateral, closed-chain exercises, such as hip hiking or forward and lateral step-ups (to a low step) while standing on the operated extremity and partial lunges with the involved foot forward when full weight bearing is permitted on the operated lower extremity. During step-ups and lunges, apply elastic resistance around the lateral thigh of the operated extremity to simultaneously strengthen the hip abductors and hip extensors.
- Resistive exercises to other involved areas in order to improve function.

- ***Improve cardiopulmonary endurance.***
  - Nonimpact aerobic conditioning program, such as progressive stationary cycling, swimming, or water aerobics.
- ***Restore ROM while adhering to precautions.***
  - Gravity-assisted supine stretch to neutral in the Thomas test position. Pull the uninvolved knee to the chest while relaxing the operated hip. (At least 10° of hip extension beyond neutral is needed for a normal gait pattern.)
  - Resting in a prone position for a prolonged passive stretch of the hip flexor muscles when rolling to prone-lying is permissible and is also tolerable.
  - Integrate gained ROM into functional activities.

PRECAUTION: Check with the surgeon before initiating a stretch of the hip flexors to neutral or into hyperextension, particularly if an anterior or anterolateral approach was used during surgery.

- ***Improve postural stability, balance, and gait.***
  - Progressive balance activities in standing (see Chapters 8 and 23.)
  - Gait training, emphasizing an erect trunk, vertical alignment, equal step lengths, and a neutral symmetrical alignment of the pelvis and extremities.
  - If full weight bearing is not yet permitted, continue or progress to use of a cane (in the hand *contralateral* to the operated hip) and progress weight bearing on the operated limb. Practice walking on uneven and soft surfaces to challenge the balance system.
  - Continue cane use until weight-bearing restrictions are discontinued or if the patient exhibits gait deviations, such as a positive Trendelenburg sign on the operated lower extremity, indicating hip abductor weakness. Cane use is also recommended during extended periods of ambulation to decrease muscle fatigue.
  - For selected patients, consider treadmill walking to practice a symmetrical gait pattern when full weight bearing is permitted.

FOCUS ON EVIDENCE

Use of a cane in the contralateral hand by patients after a hip replacement has been shown to decrease electromyographic (EMG) activity in the hip abductor muscles to a significant degree regardless of whether moderate or near-maximum force is applied on the cane.[105] In the same study, ipsilateral cane use produced no significant decrease in EMG activity in the hip abductor muscles. The degree to which the decreases in EMG activity reflected a reduction in forces imposed on the prosthetic hip joint was not determined in this study. However, in single-subject studies of two patients with femoral endoprostheses, acetabular contact pressures were reduced by using a cane in the contralateral hand.[48,73,74]

Criteria to progress. The criteria to progress to advanced training during a final phase of rehabilitation include the following.

- Pain-free ambulation with or without a cane and previous exercises
- Functional ROM and strength of the operated hip
- Independence in ADL

Exercise: Minimum Protection Phase and Resumption of Full Activity

After traditional THA, the final phase of rehabilitation begins when the patient has met the criteria to progress. This usually occurs around 12 weeks postoperatively. Continued training for restoration of strength, muscular and cardiopulmonary endurance, balance, and a symmetrical gait pattern should be the focus of this phase coupled with a gradual resumption or modification of functional activities. Return to a full level of functional activities may take at least a year.[121]

Extended rehabilitation and modification of activities. Weakness of the hip abductors leading to pelvic obliquity and an asymmetrical gait pattern often presents preoperatively in patients with hip OA and has been shown to persist in some patients for months—or even a year and beyond—following THA.[135] With this in mind, patients, especially those wishing to return to an active lifestyle, may benefit from an extended strength training program that targets the hip musculature.

If ongoing rehabilitation services are available to a patient, the following activities should be considered.

- Integrate strength, endurance, and balance training into simulated functional activities to prepare for independent activities.
- To improve muscular and cardiopulmonary endurance, progressively increase the length of time and distance of a low-intensity walking program 2 to 4 days a week.
- Through patient education, reinforce the importance of selecting or modifying activities to reduce or minimize the forces and demands placed on the prosthetic hip. If a patient's employment involves heavy labor, vocational retraining or an adjustment in work-related activities is advised.

CLINICAL TIP

When walking and carrying a heavy object in one hand, suggest that the patient hold it on the same side as the operated hip. EMG studies have shown that under these circumstances the forces imposed on the abductor muscles of the operated hip are significantly lower than when the load is carried on the contralateral arm. This was found to hold true with and without cane usage.[103,104] Theoretically, this reduces the amount of stress imposed on the hip replacement over time.

Return to sport activities. The younger, active patient, who has undergone THA, usually has a desire to resume sport-related or fitness activities at some point following surgery. Several factors, including the level of demand or degree of impact or twisting movements involved in the activity, the frequency of repetitive motions, and the potential for falls or contact, influence a surgeon's recommendation or approval for a patient to participate in various athletic activities. A patient's body weight, overall level of fitness, and his or her experience with the activity prior to surgery also affect whether or not an activity is allowable.[33,56,69,90]

To prolong the life of the hip replacement, a patient is routinely advised to refrain from high-impact sports and recreational activities. Activities that impose heavy rotational forces on the operated hip are of particular concern and could contribute to long-term loosening and wear of the prosthetic implants and eventual failure of the hip replacement. However, with a foundation of sufficient strength, endurance, balance, and use of proper biomechanics during functional activities developed in a supervised rehabilitation program, a

patient can gradually and safely return to low- and moderate-impact sports and fitness activities following THA.

Table 20.5 lists the sports-related, recreational, and fitness activities highly recommended, recommended with caution, or not recommended based on a 2007 survey and the consensus of arthroplasty surgeons' opinions.[69] Ninety percent of the surgeons responding agreed that patients could return to selected activities by 6 months after undergoing THA. When compared with the results of a 1999 survey,[56] the results of the more current survey,[69] described in Table 20.5, show the addition of intermediate-impact activities, such as hiking and use of weight machines, to the list of allowable activities. The expansion of allowable activities may be the result of advances in surgical technique and prosthetic design.

Outcomes

The assessment of outcomes of THA has been directed toward numerous variables, ranging from patient satisfaction and the impact of THA on function and quality of life to the assessment of prosthetic designs, materials, methods of fixation, and rates of complications. The number of follow-up studies in any one of these areas is extensive. A 1990s NIH report pointed out that THA and subsequent rehabilitation have resulted in a high degree of success related to pain reduction, improvement in physical function, and health-related quality of life.[108] The report went on to say that THA results in good to excellent long-term results for 90% to 95% of patients. However, the findings of numerous follow-up studies reflect considerable variability of outcomes.

Pain relief, patient satisfaction, and quality of life. Patient satisfaction after THA as well as the perceived levels of pain, function, and quality of life as judged by the patient and/or the surgeon generally reflect a marked decrease in pain and improvement in function.[77,121] However, sometimes there is disparity between a patient's and surgeon's perceptions. A study by Lieberman and associates[80] demonstrated that during postoperative follow-up, when a patient reported little or no pain, the patient's and surgeon's assessments of pain and level of satisfaction were similar. However, as a patient's report of continuing pain increased, the disparity increased between the patient's and surgeon's assessment of the level of patient satisfaction. The results point out why there is a need for assessment of outcomes by both the patient and the healthcare professional.

Several factors may contribute to unsatisfactory outcomes. Fortin and colleagues[44] investigated the timing of THA and subsequent outcomes. Although intuitively known by experienced practitioners, this study confirmed that patients who had the worst physical function and pain before surgery had the poorest outcomes 2 years after surgery. The findings of a long-term, prospective study (mean 3.6 years) by Nilsdotter and associates[109] of patients who had undergone unilateral THA for OA also confirmed that a higher preoperative level of pain predicted poorer outcomes. In addition, their study revealed that an older age at the time of surgery and postoperative low back pain were predictors of poor self-assessed outcomes.

Physical functioning. Improvements in ROM, postural stability, strength, and functional mobility are significant but occur gradually after THA. Patients typically achieve 90% of their expected level of overall functional improvement by the end of the first year. During the next 1 to 2 years, patients have reported additional gains in strength with improvement in function, reaching a plateau at approximately 2 to 3 years.[121]

Trudelle-Jackson and colleagues[148] compared ROM, static muscle strength, and postural stability (balance during one-leg stance) in a group of 15 patients with a mean age 62 years (range 51 to 77 years) 1 year after unilateral, primary THA. They found no significant differences in ROM for the operated and uninvolved hips and small—but not statistically significant—differences in the strength of hip and knee musculature. However, they did find substantial differences

TABLE 20.5 Guidelines for Participation in Sport, Recreational, and Fitness Activities Following THA[69]

Allowed	Allowed with Caution and Prior Experience	Not Allowed*
■ Golf	■ Pilates	■ Jogging/running
■ Swimming	■ Cross-country skiing	■ Baseball/softball
■ Walking (outdoor/treadmill)	■ Rollerblading	■ Racquetball/squash
■ Stationary cycling or use of elliptical trainer	■ Ice skating	■ Snow boarding
■ Cross country ski unit	■ Downhill skiing	■ High-impact aerobics
■ Bowling		■ Contact sports (football,basketball, soccer)
■ Low-impact aerobics		
■ Speed walking		
■ Hiking		
■ Stair-climbing or rowing units		
■ Doubles tennis		
■ Use of weight machines		

Note: Whether singles tennis or martial arts was allowable was not determined in the survey.

between the operated leg and the uninvolved leg for all parameters of balance measured during a one-leg stance. In addition, patients' self-assessed level of physical function was moderately associated with muscle strength but only weakly with postural stability.

Implant design, fixation, and surgical approach. Several decades of studies indicate that both cemented and cementless THA have yielded equally positive postoperative outcomes in all areas of assessment, with the most consistent being reduction of pain.[78,124] Despite the success of both cemented and noncemented THA, debate continues as to the benefits and limitations of both types of fixation. As surgical techniques, prosthetic designs, and materials continue to evolve, the rate of failure due to wear and loosening continues to decrease. In-depth analyses and current information on outcomes of specific prosthetic designs as well as outcome assessments of cemented, cementless, and hybrid procedures can be found in the references previously cited in the operative overview of THA presented earlier in this chapter.

Outcomes of minimally invasive THA compared with traditional THA are just beginning to be reported. Woolson and associates[155] conducted a retrospective comparative study of 135 patients who had undergone primary, unilateral THA with either a standard posterior approach or a minimally invasive posterior approach. The participating surgeons determined which patients met the criteria for the minimally invasive procedure with regard to health history and body mass index. Consequently, the minimally invasive group was thinner and healthier than the conventional THA group. Despite this weakness that led to demographic differences in the groups, there were no significant differences found between the groups with respect to the surgery itself (operating time, blood loss, need for transfusion), nor were there significant differences in length of hospital stay or the percentage of patients discharged directly home. However, an independent investigator, who was blind to the type of approach used, identified a higher rate of complications in the minimally invasive group, including wound complications, component malpositioning, and leg-length discrepancy.

Ogonda and colleagues[112] reported the first randomized controlled trial comparing minimally invasive and traditional THA in 219 patients who underwent primary, unilateral, hybrid THA performed by the same surgeon. In both groups, a single incision, posterior approach was used, with the only differences being the length of the skin incision (the minimally invasive incision ≤10 cm and the standard incision 16 cm) and the extent of TFL disturbance during the approach (less in the mini-incision group). All patients participated in exercise and functional training after surgery. The only significant difference identified was less blood loss in the minimally invasive group. No significant differences, including postoperative pain and use of pain medication, ability to transfer and ambulate with an assistive device, length of hospital stay, and discharge to home or transitional facility, were found between groups. At 6 weeks postsurgery, there continued to be no significant differences between groups related to function or complications. Dorr and co-investigators[39] reported similar in-hospital findings (less pain on each postoperative day and a shorter hospital stay) for a minimally invasive group compared with a traditional THA group.

A number of prospective, randomized studies have been conducted to compare improvements in gait following minimally invasive versus traditional, unilateral THA. Results of a study by Mayr and co-investigators[89] demonstrated significant improvement in several gait parameters at 6 weeks in the group that underwent minimally invasive THA but not in the traditional THA group. At 12 weeks, however, both groups showed significant improvements in gait, but the minimally invasive group improved in a larger number of the parameters measured. In contrast, in another gait study, there were no significant differences in gait characteristics between the minimally invasive and traditional THA groups at 10 days and 12 week after surgery.[120] It is important to note that postoperative rehabilitation in both studies was uniform between groups, which may have contributed to the similarity of outcomes in the minimally invasive and traditional THA groups.

Lastly, Dorr and colleagues[39] also investigated improvements in functional mobility following THA and found that 87% of patients in the minimally invasive group used just one assistive device (crutch or cane) for ambulation at the time of discharge, whereas only 53% of the traditional THA group ambulated with one crutch or cane at discharge. However, there was no significant difference in walking distance at the time of discharge between the two groups. With the mixed findings from studies such as these, it is difficult to draw evidence-based conclusions about the impact of minimally invasive procedures versus traditional THA on early postoperative ambulation.

Impact of rehabilitation. Despite the number of sources in the literature that emphasize the importance of rehabilitation programs or, more specifically, a postoperative exercise and ambulation program after THA, the impact of these postoperative interventions has not been clearly established. In 1995, the NIH reported there is currently insufficient evidence to determine what constitutes an appropriate level of physical therapy utilization after THA. The report went on to say that there does appear to be a role for these interventions, but the efficacy of these postoperative programs has not yet been determined.[108] Studies have demonstrated that access to inpatient physical therapy services does[45,100] and does not[76] decrease a patient's length of stay in an acute care facility after THA. The use of physical therapy services after THA also has been shown to increase the probability of discharge to the home setting rather than to another healthcare facility.[45]

In a nonrandomized study of the effectiveness of a 6-week home exercise program with patients who were 6 to 48 months post-THA, the two exercise groups (one performing ROM and isometric exercises of the hip and the other performing ROM, isometric, and eccentric exercises) increased their walking speed, whereas a control group (no exercise program) did not. Interestingly, strength improvements were

noted in all three groups.[132] Studies such as these provide some insight into the efficacy of exercise following THA, but considerably more research needs to be carried out.

Hemiarthroplasty of the Hip

Indications for Surgery

The following are possible indications for prosthetic replacement of the proximal femur.[49,70,72]

- Acute, displaced intracapsular (subcapital, transcervical) fractures of the proximal femur in an elderly patient with poor bone stock and an anticipated low-demand level of activity after surgery[49,70,94,115,116,142]
- Failed internal fixation of intracapsular fractures associated with osteonecrosis of the head of the femur[70,94,115]
- Severe degeneration of the head of the femur (but an intact acetabulum) associated with long-standing hip disease or deformity, resulting in disabling pain and loss of function that cannot be managed with nonoperative procedures[70, 94,116]

NOTE: Patients with preexisting degenerative hip disease who sustain a femoral fracture are candidates for primary THA rather than hemiarthroplasty.[42,94] Acute, severely comminuted intertrochanteric fractures are *infrequently* managed by primary hemiarthroplasty.[94,143]

Procedures

Background. Historically, acute displaced fractures of the proximal femur in the elderly were treated with unipolar (fixed head), uncemented metal-stemmed endoprostheses with marginal results. With the introduction of cement fixation during the 1960s, these results improved.[94] The primary complication associated with the single-component, unipolar implants, regardless of design or fixation, was progressive erosion of the acetabular cartilage and subsequent pain.

To decrease the problem of acetabular wear, the bipolar hemiarthroplasty was developed. The bipolar design is composed of multiple components: a metal ball-and-stem femoral prosthesis (may be modular) that moves within a free-riding polyethylene shell, which in turn inserts into a metal cup that moves within the acetabulum. The purpose of the multiple-surface, load-bearing design is to displace forces incurred by the acetabulum through the interposed components rather than directly to the acetabulum to lessen erosion of the acetabular cartilage.[65,94,115] Contemporary modular unipolar and bipolar prostheses are both in use today. Considerable differences of opinion exist among surgeons regarding the advantages and disadvantages of one design versus the other.[65,94,115]

Operative procedure. As with THA, a posterolateral approach is most commonly used. After removing the head of the femur, the metal-stemmed prosthesis is inserted into the shaft of the proximal femur. The femoral stem usually is cemented in place, although bio-ingrowth fixation has also been used. Procedures for closure are consistent with THA.

Postoperative Management

There are no studies in the literature that have examined the effects of comprehensive postoperative exercise programs exclusively for patients who have undergone current-day hemiarthroplasty. This is because, for the most part, considerations and precautions for positioning and ADL as well as the components and progression of the exercise and ambulation program are similar to those for postoperative management of traditional THA. These guidelines are detailed in the previous section of this chapter. As with postoperative management after THA, selection and progression of exercises and functional activities after hemiarthroplasty also tend to be based on the opinions of surgeons and therapists as to the potential of specific exercises to remediate impairments and improve functional performance. Consequently, the effectiveness of exercise after hemiarthroplasty also remains unclear. Only limited information on the impact of specific exercises and gait-related activities on the hip joint per se after hemiarthroplasty is available in the literature. Some findings from several single-subject studies of two patients with femoral endoprostheses have already been discussed in the previous section of this chapter on THA.[48,73,74,138]

PRECAUTION: Given the significant concerns for long-term erosion of acetabular cartilage after hemiarthroplasty, avoiding exercises that impose the greatest compressive or shearing forces across the hip joint and therefore, pose the greatest potential for eroding the cartilaginous surface of the acetabulum may be most critical. Exercises should be performed initially at a *submaximal* level and then progressed gradually. *Unassisted* heel slides and *maximum* effort gluteal setting exercises may need to be avoided during the acute phase of postoperative rehabilitation.[138] In the post-acute period of rehabilitation, manually resisted hip abduction should be progressed gradually, because maximum-effort hip abduction is thought to generate greater forces across the hip joint than protected weight-bearing activities.[48]

Outcomes

Present-day modular, unipolar, and bipolar hemiarthroplasty procedures appear to yield similar results in pain relief, functional outcomes, and type and rate of complications.[70,94,115] Although acetabular wear was identified as the primary concern after the unipolar replacement used several decades ago, the mechanical effectiveness of the bipolar prosthesis in preventing acetabular erosion has yet to be firmly established.[70] In a study of community-dwelling patients age 65 years or older (mean age 80 years) who had undergone hemiarthroplasty with either a bipolar implant or a modular unipolar implant, there were no significant differences between the two groups at 1 year and 4 to 5 years of follow-up with regard to functioning in daily activities or rates of dislocation, infection, or mortality.[153] Results of another study have suggested that joint ROM may decrease over time after bipolar hemiarthroplasty, possibly due to the design of the implants. This decreased range was not associated with diminished functional abilities.[65]

Lastly, the use of hemiarthroplasty versus screw fixation for displaced femoral neck fractures in elderly patients was examined in a large (over 4,000 patients), retrospective study conducted in Norway.[49] Results of the study showed that the patients who had undergone hemiarthroplasty had significantly less postoperative pain, fewer secondary surgeries, and were more satisfied with the outcome of the surgery than the group who had undergone internal fixation (screw fixation) of the fracture site.

Hip Fractures: Surgical and Postoperative Management

Hip Fracture: Incidence, Risk Factors, and Impact on Function

One of the more common musculoskeletal problems in the elderly is fracture of the hip or, more correctly, fracture of the most proximal portion of the femur in the hip region. The acute signs and symptoms of hip fracture are pain in the groin or hip region, pain with active or passive motion of the hip, or pain with lower extremity weight bearing. The lower extremity appears to be shorter by several centimeters and assumes a position of external rotation.[70,116]

In the United States, the vast majority of hip fractures occur in the elderly population, particularly in individuals between the ages of 75 to 85 years with women accounting for 77.2% of hip fractures in this age group.[22] Worldwide, the incidence of hip fracture has stabilized and, in the United States, appears to have decreased slightly between 1985 and 2005.[22] However, the total number of hip fractures per year is expected to increase, in part, because of the aging of the population.[70,116] Fewer than 2% to 3% of fractures are sustained by persons less than 50 years of age.[70,116] Hip fractures or fracture-dislocations in this age group usually are associated with high-force, high-impact trauma but also may be seen with repetitive micro-trauma, for example from distance running.

Multiple risk factors, including those related to fall risk, contribute to the increase in the incidence of hip fracture with age.[26] Risk factors for falls and the potential for hip fractures in the elderly include age-related loss of muscle strength and flexibility, balance and gait deficits associated with musculoskeletal or neurological disorders, low vision, cognitive decline, and medications (see Chapter 8). Age-related osteoporosis, a loss of bone density and strength, typically occurs in the proximal femur, distal radius, and spine.[70,116] A sudden twisting motion of the lower extremity or the impact from a fall can cause pathological fracture of a fragile proximal femur. Although 90% of all hip fractures in the elderly are associated with a fall,[70] there is always the question of whether trauma from the fall caused the hip fracture, or a pathological fracture of the hip caused the fall.

In addition to balance, protective reactions, and muscle strength and power deteriorating with age and thus increasing the likelihood of a fall, the inability to absorb the impact of a fall contributes to the risk of sustaining a fracture.[116] Characteristics of falling change as well with age. As walking speed decreases with age, particularly past 70 to 80 years, when a loss of balance and a resulting fall occur, an older person usually drops and falls to the side, rather than falling forward on outstretched hands as occurs with faster walking speeds.[70,116]

Hip fracture in the elderly is associated with significant functional impairments and loss of independence. Many patients who survive for more than one year following hip fracture have limitations in daily living activities and functional mobility deficits and require assistance to transfer, dress, walk, and climb stairs.[82,136] Limitations attributable to the hip fracture (not simply age) coupled with reduced activity and subsequent deconditioning during the recuperative period and avoidance of activities for fear of falling make it difficult to return to pre-fracture activities in the home and community.[82,84] Consequently, patients often require long-term nursing care with some being permanently institutionalized in skilled nursing or assisted living facilities.

Post-fracture mortality rates decreased in the United States from 1985 to 2005.[22] This decline may be the result of improved surgical techniques, which have decreased the need for prolonged immobilization or restricted weight bearing, thus decreasing postoperative complications, such as pneumonia and thromboemboli.

Sites and Types of Hip Fracture

Fractures of the proximal femur are broadly classified as *intracapsular* or *extracapsular* and then further subdivided by specific location (Fig. 20.7). Sites and specific types of hip fracture are noted in Box 20.8.[70,91,94,142–144] Of these sites, fractures in the intertrochanteric region are most common, accounting for approximately 50% of all fractures of the proximal femur.[91] Intracapsular fractures can potentially compromise the vascular supply to the head of the femur, which in turn increases the risk of delayed healing, nonunion, or osteonecrosis (avascular necrosis) of the head

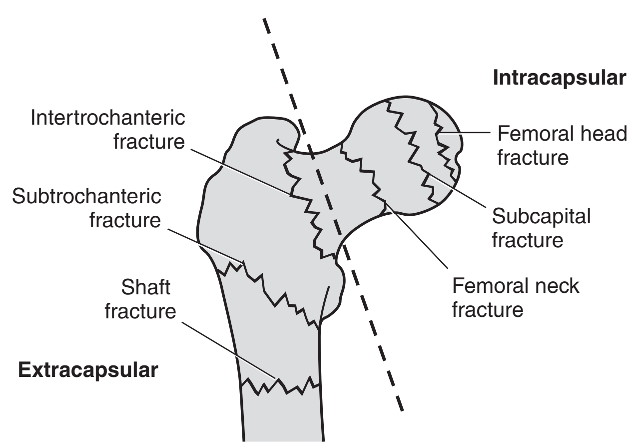

FIGURE 20.7 Fractures of the proximal femur are broadly divided into *intracapsular* and *extracapsular* sites. *(From McKinnis, 91 p. 350, with permission.)*

BOX 20.9 Common Sites and Types of Hip Fracture

Intracapsular
- Fracture site proximal to the attachment of the hip joint capsule
- Further subdivided into *femoral head, subcapital* and *femoral neck* (*transcervical* or *basicervical* fractures)
- May be displaced, nondisplaced, or impacted
- May disturb the blood supply to the head of the femur resulting in avascular necrosis or nonunion

Extracapsular
- Fracture site distal to the capsule to a line 5 cm distal to the lesser trochanter
- Further subdivided into *intertrochanteric* (between the greater and lesser trochanters) or *subtrochanteric* and *stable* or *unstable* (comminuted)
- Does not disturb the blood supply to the head of the femur, but nonunion may occur as the result of fixation failure

of the femur. These complications occur far more frequently with displaced versus nondisplaced intracapsular fractures.[70,94] Intracapsular fractures are most often sustained by elderly women.[70,94]

In contrast, fracture-dislocation and acetabular trauma are most common in the young, active individual.[70] Most fracture-dislocations occur in a posterior direction. This type of fracture often causes traumatic disruption of the vascular supply to the head of the femur and damage to joint cartilage, resulting in osteonecrosis and posttraumatic arthritis, eventually necessitating prosthetic replacement of the hip joint. However, this need may not arise for many years.

Open Reduction and Internal Fixation of Hip Fracture

Indications for Surgery

Surgical intervention by means of open (or possibly closed) reduction followed by stabilization with internal fixation (Figs. 20.8 and 20.9) is indicated for the following types of fractures of the proximal femur.[70,116,142–144]

- Displaced or nondisplaced intracapsular femoral neck fractures
- Fracture-dislocations of the head of the femur
- Stable or unstable intertrochanteric fractures
- Subtrochanteric fractures

In the elderly patient, displaced intracapsular fractures often are managed with prosthetic replacement of the femoral head (hemiarthroplasty), rather than internal fixation, to avoid a relatively high incidence of nonunion.[49,115] There is, however, no definitive determination as to which procedure provides superior results.[49] Some severely comminuted (unstable) intertrochanteric fractures also may be managed with hemiarthroplasty.[70,94,143]

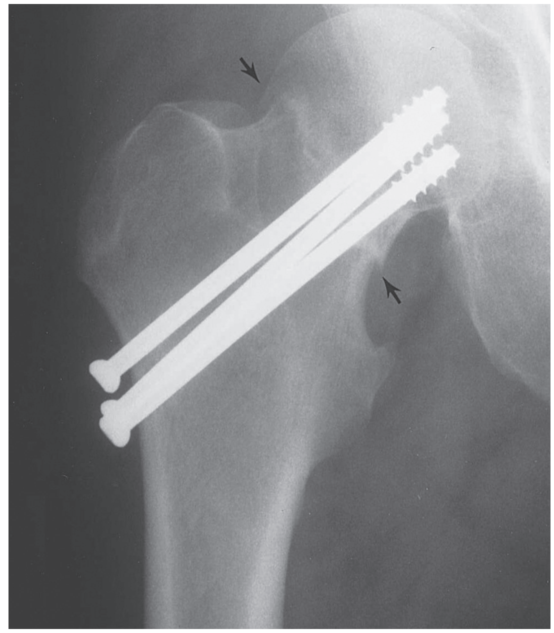

FIGURE 20.8 Reduction and internal fixation of a complete fracture of the femoral neck. Restoration of alignment and good compression is obtained via fixation with three compression screws. The black arrows mark the extent of the fracture line. *(From McKinnis, 91 p. 351, with permission.)*

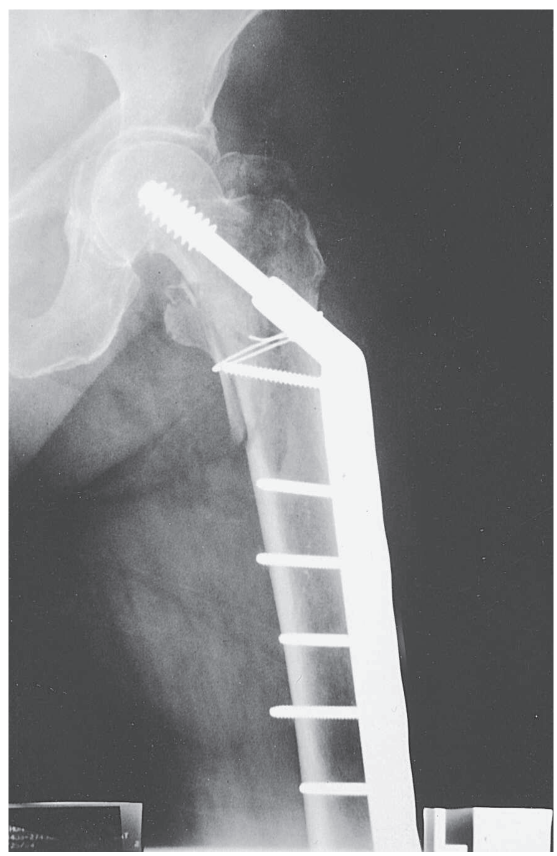

FIGURE 20.9 Intertrochanteric fracture of the hip. This postoperative image shows fracture fixation via a side plate and screw combination device. The fracture line is evident, extending through the intertrochanteric region to the proximal femoral shaft. Some comminution is evident, and a large fragment on the medial shaft is noted. The imposed added densities of soft tissue are seen. *(From McKinnis, 91 p. 353, with permission.)*

In a few situations, nonoperative management is the only option for treatment after hip fracture. Traction is an appropriate alternative for nonambulatory individuals or for medically unstable patients who cannot undergo a surgical procedure.[70,116] The patient remains in bed in traction just long enough for early healing to occur. Bed-to-chair mobilization follows. If weight bearing or ambulation is feasible, it is delayed until bone healing is sufficient, usually 10 to 12 weeks or as long as 16 weeks postoperatively.

Procedures

The goal of surgery is to achieve maximum stability and restore alignment of boney structures of the hip. Surgery is indicated during the first 24 to 48 hours after injury, particularly with femoral neck fractures, where the risk of disruption of the vascular supply to the head of the femur is high. A variety of internal fixation devices are used after open or closed reduction to stabilize the many types of fracture of the proximal femur. The type and severity of the fracture and the associated injuries as well as the patient's age and physical and cognitive status all influence the surgeon's choice of procedure.[70,116] The type of procedure performed, in turn, affects the progression of postoperative rehabilitation.

Types of fixation and surgical approach. The most common modern, internal fixation devices used, based on the type of fracture, include the following.[1a,70,116,142–144]

- Intramedullary nail fixation that interlocks proximally in the femoral head or a sliding compression screw for intertrochanteric or subtrochanteric fractures.
- *In situ* fixation with multiple parallel cancellous lag screws or pins for nondisplaced or impacted femoral neck fractures and possibly for displaced femoral neck fractures in active patients less than 65 years of age.
- Dynamic extramedullary fixation with a sliding (compression) hip screw and lateral side plate for stable intertrochanteric fractures; may be combined with an osteotomy for unstable (comminuted) fractures. The dynamic hip screw allows sliding between the screw and plate and creates compression across the fracture site during early weight bearing.

An open surgical approach along the lateral aspect of the hip is used for these procedures. Aspects of some of the procedures may be performed percutaneously. Soft tissue disruption differs with each procedure. The tensor fasciae latae, vastus lateralis, or gluteus medius may be incised (parallel to the fibers); a capsulotomy generally is performed with femoral neck fractures.

Postoperative Management

The ultimate goal of surgical intervention and postoperative care after hip fracture is to return a patient to his or her preferred living environment[98] at a pre-injury level of function.[70,116] With this goal in mind, a national, interdisciplinary consensus conference of health professionals met and developed recommendations for optimal care. Among the recommendations was the need for rehabilitation services during recovery, including postoperative exercise and functional training across the continuum of care.[98]

During the initial phase of postoperative rehabilitation, which begins in the acute care setting, the focus is to get the patient up and moving as quickly as possible to prevent or minimize the adverse effects of prolonged bed rest, including thromboemboli and pulmonary complications, while protecting the surgically stabilized fracture site. In addition to helping the patient learn to move safely in bed, transfer, and ambulate independently with an assistive device, early postoperative rehabilitation typically includes patient or caregiver education, deep breathing and coughing exercises, lower extremity edema control (use of compressive stockings), proper positioning in bed to avoid contractures, and an exercise program.

After discharge from the hospital, postoperative functional training and a progression of exercises typically continue in a transitional, subacute rehabilitation or skilled nursing facility or at home. Despite consensus that rehabilitation after hospital discharge is an essential aspect of postoperative care,[98] according to the results of a recent systematic review of the literature,[12] there is neither little evidence derived from randomized controlled investigations of patients' functional outcomes to support that one setting for rehabilitation is superior to another nor is there sufficient evidence to identify the optimal timing for or components of subacute rehabilitation.

What is known, however, is that most patients are discharged from rehabilitation services after achieving independence in ambulation using an assistive device and necessary daily living activities, parameters typically set by healthcare plans. It was recently reported, for example, that 85% to 95% of patients receiving physical therapy in the home setting are discharged from services by 7 to 9 weeks after hip fracture.[85] Often, services must be discontinued despite persistent impairments and functional deficits (e.g., impaired strength, muscular endurance, and balance) and well before patients have attained a pre-injury level of function, which in turn increases the risk of future injury.[17]

Weight-Bearing Considerations

The amount of weight bearing permissible during early ambulation and transfers is always determined by the surgeon for each patient on an individual basis. Factors that influence the decision are the patient's age and bone quality, the fracture location and pattern, the type of fixation used to stabilize the fracture site, and the degree of intraoperative stability achieved.[70,72,116] Recommendations range from nonweight-bearing, toe-touch, or touch-down weight bearing (< 10 lb) to weight bearing as tolerated. Current methods of internal fixation of the fracture site have decreased the need for an extended nonweight-bearing or toe-touch status after surgery.

Many fixation procedures used today make early weight bearing possible. Some examples of fractures and fixation procedures in which weight bearing as tolerated is permissible immediately after surgery are:

- Nondisplaced, rigidly fixed, or impacted femoral neck fractures managed with in situ fixation.[70,72,116,142]

- Stable (noncomminuted) intertrochanteric fractures managed with a dynamic (sliding) compression screw and lateral side plate fixation.[70,116,143]
- Stable intertrochanteric and subtrochanteric fractures managed with interlocking intramedullary nailing and bone-to-bone fixation.[1a,70,116,144]

Even when weight bearing is curtailed during ambulation and transfers, the fracture site is still subjected to significant forces. For example, moving in bed, sitting up at the edge of the bed, and active and resisted ROM exercises all generate forces across the hip that approach or even exceed those incurred during unsupported (full weight-bearing) ambulation.[110] Considering this, studies have been implemented to investigate the risks associated with early weight bearing after open reduction and internal fixation of hip fractures.

FOCUS ON EVIDENCE

In one such study, elderly patients with stable as well as comminuted intertrochanteric fractures treated with dynamic compression screw and plate fixation were all allowed to bear weight as tolerated during ambulation with an assistive device immediately after surgery. One year postoperatively, there was no significant difference between the rate of implant failure and revision surgery in the patients with stable fractures and those with comminuted fractures. The investigators concluded that, at least in elderly patients with comminuted and noncomminuted intertrochanteric fractures that could be stabilized intraoperatively, there was little biomechanical justification for nonweight-bearing restrictions postoperatively.[72]

Excluded from this generalization were patients with complex fractures in whom satisfactory intraoperative stabilization could not be achieved, young patients with displaced femoral neck fractures with in situ fixation, and patients with severe bone disease (e.g., as the result of malignancy).

Despite the findings of this study and the recognized benefits of early ambulation and exercise, there is always a risk, albeit small, of failure of an internal fixation device in some patients. Therefore, it is important to recognize the signs of possible displacement or loosening of the fracture stabilization device as summarized in Box 20.10. The presence of any of these signs or symptoms should be reported immediately to the surgeon.[70,116]

Exercise and Functional Training

Impaired joint mobility, ROM, muscle performance, balance, and loss of functional mobility are the most common physical impairments after open reduction and internal fixation of hip fracture. Similar to postoperative care provided several decades ago,[11,67] exercise and functional training continue to be the interventions routinely included throughout current-day postoperative rehabilitation to reduce impairments and improve functional outcomes.[85]

During the initial postoperative period, hip and even knee motions are quite painful, affecting ROM and strength of the operated lower extremity. In addition, some degree of protection is necessary over the course of soft tissue healing (approximately 6 weeks) and bone healing (10 to 16 weeks).[142–144] All of these factors affect the progression of exercise and functional training, as do the location and stability of the fracture site, type of internal fixation used, and the soft tissues traumatized at the time of the injury and during surgery. Special considerations for exercise and ambulation after various types of hip fracture and with specific surgeries are noted in Box 20.11.[70,116,142–144]

BOX 20.10 Signs and Symptoms of Possible Failure of the Internal Fixation Mechanism

- Severe, persistent groin, thigh, or knee pain that increases with limb movement or weight bearing
- Progressive limb length inequality (shortening of the involved lower extremity) that was not present immediately after surgery
- Persistent external rotation of the operated limb
- A positive Trendelenburg sign during weight bearing on the involved limb that does not resolve with strengthening exercises

BOX 20.11 Special Considerations for Exercise and Gait After Internal Fixation of Fractures of the Proximal Femur

- Multiple hip muscles are traumatized by fracture of the hip, leading to postoperative pain, reflex inhibition, and weakness. Fractures that involve the following sites cause damage to the following muscles.
  - Greater trochanter: gluteus medius
  - Lesser trochanter: iliopsoas
  - Subtrochanteric region: gluteus maximus
- The tensor fasciae latae (TFL) and vastus lateralis (VL) are usually incised during surgery, causing postoperative pain, inhibition, and weakness during hip abduction and knee flexion.
- Adhesion formation may develop between the incised TFL and VL and restrict motion. Hip adduction and internal rotation and knee flexion place a stretch on the TFL and VL, respectively, during ROM exercises and therefore are often painful.
- If there is shortening of the involved limb after fracture and internal fixation, the distance between the distal insertion of the gluteus medius on the greater trochanter and the center of axis of hip motion is often decreased, thus diminishing the mechanical advantage of the muscle and causing weakness and a positive Trendelenburg sign during ambulation.
- Intracapsular fractures typically traumatize the capsule, and internal fixation requires an incision into the capsule (capsulotomy). Both predispose the capsule to postoperative restriction.

The following sections outline a progression of exercises and functional training after open reduction and internal fixation of hip fractures.

Exercise: Maximum Protection Phase

Exercises begin on the first postoperative day to prevent postoperative complications and to restore a patient's control of the operated hip during functional activities. Initially, exercises are directed toward restoring ROM of the operated hip and developing balance and strength in the upper extremities and sound lower extremity to facilitate ambulation with an assistive device. It is reasonable to expect to achieve 80° to 90° of active hip flexion (with the knee flexed) by 2 to 4 weeks postoperatively.[70]

There is lack of consensus about the appropriate time to begin resistance exercises to strengthen the operated lower extremity. Low-intensity resistance exercises *of the operated hip* may be delayed until 4 to 6 weeks postoperatively to allow time for the hip muscles incised during surgery to heal. However, resistance exercises of knee and ankle musculature may be initiated sooner.

FOCUS ON EVIDENCE

Mitchell and colleagues[95] conducted a randomized, controlled trial to determine the effects of 6 weeks of quadriceps resistance exercises during the early phase of postoperative rehabilitation after hip fracture. The study's 80 patients, described as "frail elderly" (all > 65 years of age, mean 80 years), began a program of ROM exercises and functional training (described as "standard" therapy) after surgery. In addition, at 16 days postoperatively, half of the patients (intervention group) performed three sets of 12 repetitions of resisted knee extension of the operated and sound lower extremities initially at the 50% 1-RM intensity twice a week, progressing to 80% intensity by the fifth week. Of the 80 patients in the study, 75% completed the 6-week study.

After 6 weeks of resistance training, the quadriceps strength of the intervention group increased bilaterally to a significantly greater extent than that of the control group. Based on a functional mobility test measurig locomotion, balance, and transfer, the intervention group also demonstrated significantly greater improvement and, as such, a greater reduction in functional impairments and activity limitations than the control group. However, there were no significant differences in improvement between groups regarding gait velocity or test scores measuring independence in ADL. There were no training-related adverse events during the study.

The authors concluded that moderate- to high-intensity postoperative quadriceps resistance training during early recovery after hip fracture was functionally beneficial and well tolerated by the participants despite their age and frailty.

Goals and interventions. The following are goals, exercise, and functional training interventions typically initiated in the hospital setting and continued in the home setting or an extended care facility following discharge from the hospital.[11,12,67,85] Patient education, emphasizing progressive use of the operated extremity, safety, the prevention of postoperative complications, and reducing the risk of a future fall, occurs throughout this phase of rehabilitation.

- ***Prevent vascular and pulmonary complications.***
  - Ankle pumping exercises performed regularly throughout the day to maintain circulation and reduce the risk of DVTs and thromboemboli.
  - Deep breathing exercises and airway clearance to prevent pulmonary complications.
- ***Improve strength in the upper and sound lower extremities.***
  - Exercises against progressive levels of resistance targeting key muscle groups used to lift body weight during bed mobility, standing transfers, and ambulation with assistive devices.
  - Emphasis on closed-chain training with most weight on the sound extremity, such as bridging exercises, to simulate the movement patterns used during these activities.
- ***Re-establish balance, postural stability, and safe and independent functional mobility within weight-bearing restrictions.***
  - Weight-shifting activities in bilateral stance.
  - Heel and toes raises in bilateral stance.
  - Stabilization exercises in bilateral stance (alternating isometrics/rhythmic stabilization).
  - Balance activities with self-initiated perturbations by reaching in various directions.
  - Bed mobility, transfers, and gait training with an assistive device.
- ***Prevent postoperative reflex inhibition of hip and knee musculature.***
  - Low-intensity isometric (setting) exercises of the hip and knee musculature of the operated extremity. Depending on the fracture site and its stability, perform submaximal gluteal, abductor, adductor, and quadriceps and hamstring setting exercises.
- ***Restore mobility and control of the operated hip and adjacent joints.***
  - Assisted, progressing to active ROM of the involved hip and knee in progressively more challenging positions as pain and fracture healing permit. For example, in the supine position, perform heel slides before straight leg raises (SLRs). When the knee is flexed, the shorter moment arm places lower rotational loads on the fracture site than a long moment arm.
  - Pelvic tilts and knee-to-chest movements with the *uninvolved* leg to prevent stiffness in the low back region.
  - Unassisted SLRs (flexion, abduction, extension) *while standing* on the sound leg and holding onto a stable surface for balance before progressing to SLRs in a horizontal position.
  - Low-intensity, dynamic resistance exercises in weight-bearing and nonweight-bearing positions as the stability of the fracture site allows.

PRECAUTION: When initiating setting and dynamic exercises of the operated hip after comminuted subtrochanteric fractures that required medial cortex reconstruction, postpone contractions of the abductor and adductor muscles for 4 to 6 weeks to avoid stresses across the fracture site.[144]

Exercise: Moderate and Minimum Protection Phases

By 6 weeks, soft tissues are healed; by 8 to 12 weeks, depending on the age and health of the patient, some degree of bone healing has occurred. By the sixth week of rehabilitation, except in unusual situations, at least partial weight bearing or full weight bearing as tolerated is now permissible. By 8 to 12 weeks, although a patient gradually can be weaned from use of an assistive device during ambulation, most continue to use at least a cane well beyond this time frame.

During the intermediate and final phases of rehabilitation, the emphasis is on increasing strength and functional control of the involved lower extremity and gradually increasing the patient's level of functional activities. However, patients often are discharged from supervised therapy by 7 to 9 weeks or no later than 12 weeks postoperatively.

Extended exercise programs after surgery for hip fracture. For many years, there has been lack of agreement about the value of an extended exercise program or if it was appropriate to include moderate-intensity resistance exercises of the operated extremity in an elderly patient's rehabilitation program before and even after the fracture site has fully healed. (Bone healing typically takes between 8 to 16 weeks or as many as 6 months in some patients.) However, during the past decade, the findings of several studies have demonstrated that after a standard course of postoperative rehabilitation and with clearance from the patient's surgeon, an extended program of properly supervised, carefully progressed resistance exercises for strength training, begun as early as 6 weeks or as late as 5 to 7 months postoperatively (depending on the intensity of the exercise program), is safe and effective.[17,55,61,84,133,134]

The intensity, frequency, and duration of the extended exercise program varied in these studies, and the equipment used for resistance training ranged from elastic resistance products to weight machines. Features of the exercise programs implemented in three of the studies are summarized in Table 20.6. Additional details and outcomes of these studies are addressed at the conclusion of this section on postoperative management after hip fracture.

CLINICAL TIP

After hip fracture surgery, if a mildly to moderately frail, elderly individual completes a standard course of postoperative therapy followed by an extended exercise program that lasts approximately 6 months and includes progressive resistance exercise training, it is reasonable to expect that the fractured extremity will achieve a level of strength at least equivalent to that of the nonfractured extremity.[61]

Goals and interventions. The following goals and exercises are appropriate during the intermediate and advanced phases of rehabilitation.

- ***Increase flexibility of any chronically shortened muscles.*** Muscles typically involved include the ankle plantarflexors,

TABLE 20.6 Summary of Studies of Extended Exercise Programs Following Surgery for Hip Fracture

First Author and Type of Study	Subjects: (n) and Mean Age	Setting, Format, and Timing of Intervention	Frequency, Duration, and Types of Exercise	Features of PRE Training
Binder[17] RCT with two groups	$n = 90$ Intervention group: $n = 46$; 80 years Control group: $n = 44$; 81 years	Facility-based; group format for intervention group and home-based program for control group Begun no more than 16 weeks postsurgery	*Intervention group*: Two 3-month phases, three weekly sessions Phase 1: total of 22 exercises (flexibility, balance, aerobic training, low-intensity resistance exercises) Phase 2: Moderate- to high-intensity PRE added to shortened phase 1 program *Control group*: A portion of phase 1 exercises, no PRE	One or two sets, six to eight reps at 65% of initial 1-RM progressing to three sets, 8 to 12 reps at 85%–100% initial 1-RM Weight machines Exercises: bilateral knee flexion and extension, leg press, seated bench press, biceps curl, seated rowing

TABLE 20.6 Summary of Studies of Extended Exercise Programs Following Surgery for Hip Fracture—cont'd

First Author and Type of Study	Subjects: (n) and Mean Age	Setting, Format, and Timing of Intervention	Frequency, Duration, and Types of Exercise	Features of PRE Training
Hauer[55] RCT with two groups	$n = 28$; all at least 75 years Intervention group: $n = 15$; 81.7 years Control group: $n = 13$; 80.8 years	Facility-based; group format; begun 6–8 weeks postfracture	*Intervention group*: Three weekly sessions for 3 months; PRE, balance, and functional training *Control group*: Stretching, seated calisthenics, memory tasks.	Two sets at 70%–90% of 1-RM intensity Weight machines and body weight resistance Exercises: leg press, hip/knee extension, plantarflexion
Mangione[84] RCT with three groups	$n = 33$ Resistance group: $n = 11$; 77.9 years Aerobic group: $n = 12$; 79.8 years Control group: $n = 10$; 77.8 years	Home-based; individual format; begun 19.4, 19.7, and 12.6 weeks after surgery, respectively, for resistance, aerobic, and control groups	Total of 3 months: two sessions weekly for 2 months, followed by 1 session weekly for 1 month	Three sets of eight reps at the 8-RM intensity Portable resistance unit or body weight resistance Exercises: supine hip and knee extension, hip abduction, standing hip extension; standing plantarflexion (heel raises)

hip flexors, and hamstrings. Suggested stretching techniques include:

- Heel cord stretching with a towel or with the assistance of a caregiver while sitting on a bed with the knee extended and later while standing.
- Hip flexor stretching in the supine (Thomas test) position.
- Hamstring stretching by sitting on the edge of a table with one leg supported in hip flexion and knee extension and the other in extension over the side of the support surface (see Fig. 20.18).

- ***Improve strength and muscular endurance in the lower extremities for functional activities.*** Refer to the section on exercise interventions later in the chapter for descriptions of the following exercises.
  - Bilateral, closed-chain active exercises, such as mini-squats and heel raises using a table or walker for support and balance and body weight as the source of resistance as soon as partial weight bearing on the operated lower extremity is permissible.
  - Lunges and forward and lateral step-ups when weight bearing to tolerance is allowable.
  - Open-chain hip and knee exercises initially against light to moderate resistance (up to 5 lb) with elastic resistance or cuff weights. Emphasize hip extension and abduction for a positive impact on ambulation.
  - Task-specific training, such as stair-climbing or carrying small loads while ambulating.
- ***Improve postural stability, neuromuscular responses, standing balance, and functional mobility.***
  - A progression of balance activities appropriate for the patient's age and desired activity level. (Refer to Chapters 8 and 23.)
  - Progressive ambulation on various surfaces and at varying speeds.
- ***Increase aerobic capacity/cardiopulmonary endurance.***
  - Stationary bicycling, upper body ergometry, or treadmill walking.
  - Aerobic conditioning activities, possibly in an age-appropriate, community-based exercise class, to increase walking distance and velocity.

Outcomes

General outcomes. The true measure of success of surgical intervention and postoperative rehabilitation after hip fracture is the extent to which a patient can return to his or her pre-fracture level of function. The level of pre-injury functional mobility in patients with femoral neck fractures has been shown to be a critical factor in postoperative survival.[60] In one follow-up study of patients after hip fracture, only 33% had regained their pre-injury level of function in basic ADL and

IADL 1 year postoperatively.[67] Given the advanced age and health status of the "average" patient who sustains a hip fracture, it is not surprising that mortality rates 1 year postoperatively are high, ranging from 12% to 36% depending on the mean age, general health status, and severity of the fracture.[70] However, after 1 year, mortality rates are equal to age-matched subjects who have not sustained a hip fracture.[70]

Among patients who survive 1 year postoperatively, 83% demonstrated the ability to ambulate independently (50 feet on an uncarpeted surface) in one study.[11] In a later study, 92% of patients returned to independent ambulation, but only 41% regained their prefracture level of ambulation.[71] In a study of 90 community-dwelling older adults (mean age 83.4 years) 6 months after discharge from the hospital following a fall-related hip fracture, 53.3% (48/90) had experienced one or more falls.[136] The need for an assistive device during ambulation after hip fracture and the patient's prefracture fall history were predictors of a fall after hospital discharge.

Impact of rehabilitation. According to a report of the National Center for Medical Rehabilitation Research (NCMRR), the use of therapeutic exercise is one of the least examined factors affecting outcomes after hip fracture.[154] However, there are a few studies, some of which are randomized controlled trials, available that have addressed the impact of exercise and functional training on outcomes. For example, the number of visits to physical therapy has been positively associated with the ability to ambulate independently.[11] The results of another study indicated that the frequency of physical therapy visits increased the likelihood of regaining functional independence and going directly home from an acute care setting after hip fracture surgery.[53]

As noted previously, the benefits and risks of resistance training have been investigated. In an early randomized, controlled study, subjects (most of whom were living in the community and were an average of 7 months postfracture surgery) who participated in a 1-month home exercise program increased the strength of the knee extensors and increased their walking velocity to a greater extent than the control group.[133] Another study compared the effects of a 2-week program of weight-bearing versus nonweight-bearing exercises initiated during inpatient rehabilitation. The study found that both groups demonstrated substantial improvements in lower extremity muscle strength, balance, gait, and other functional tasks. However, there were no significant differences between groups.[134] This study lends support to the value of both types of exercise during early rehabilitation.

Recently, studies of the effects of extended, comprehensive exercise programs after hip fracture have included moderate- to high-intensity resistance training of multiple muscle groups. In the three studies summarized previously in this section (see Table 20.6), muscle strength and performance on a variety of functional mobility and ADL tests improved to a significantly greater extent in the groups who participated in resistance training than in the groups who participated in low-intensity or no resistance training.[17,55,84] The resistance training group in the study by Binder and colleagues[17] also reported a significant decrease in the perceived levels of disability, whereas the control group, who performed only low-intensity exercises, did not. The resistance training group in the investigation by Hauer and associates[55] noted improved perception of walking steadiness but no change in fear of falling.

Moderate- to high-intensity resistance training after discharge from a "standard" postoperative program of exercise and functional training appears to be not only feasible but safe. Other than reports of mild muscle soreness during the early weeks of resistance exercise programs, training-related adverse events were reported in only one study (3 of 46 participants in the resistance training group).[17] One individual fell during exercise and sustained a rib fracture; another incurred a metatarsal fracture that was discovered a few days after an exercise session; and a third developed ecchymosis at the ankle after an exercise session. All three participants chose to complete the program.

Not all types of extended rehabilitation after hip fracture have been shown to be effective. The results of a study of individuals enrolled in a long-term, home-based, multifaceted rehabilitation program (including extensive ADL and IADL training) for 6 months postoperatively in comparison to a traditional postoperative exercise and ambulation program for an equal period of time demonstrated no significant differences.[145]

Painful Hip Syndromes: Nonoperative Management

Related Pathologies and Etiology of Symptoms

Painful symptoms in the hip region other than arthritis may be caused by pathologies involving the muscles, tendons, bursae, or the acetabular labrum. Often, symptoms occur as a result of overuse or repetitive trauma to the tissues and may have underlying structural or faulty mechanical predisposing factors.

Musculotendinous Factors

Overuse or trauma to any of the musculotendinous units in the hip region can result from excessive strain while the muscle is contracting (often in a stretched position) or from repetitive use with inadequate time allowed for the injured tissue to heal between activities.

Tendinopathies and muscle strains. Common problems include hip flexor, adductor, and hamstring strains. Decreased flexibility and fatigue may predispose an individual to strain and injury during an activity or sporting event; sudden falls, such as slipping on ice, may cause a strain.

Repetitive trauma. Imbalances in flexibility and strength of the hip musculature may result in overuse of muscles from repetitive or high-intensity activities. Common overuse syndromes are associated with dominance of the tensor fasciae latae and rectus femoris as hip flexors, abductors, and internal rotators with apparent weak gluteus medius and gluteus minimus muscles and dominance of the hamstrings over the gluteus

maximus with apparent weakness of the gluteus maximus.[131] Overuse of the piriformis muscle with apparent weakness of the gluteus maximus and medius also has been reported.[146] Because of the relationship of these muscles with the pelvis and knee as well as the effect of faulty mechanics on weight-bearing function, patients may present with low back or knee symptoms.

Bursitis

Trochanteric bursitis. With inflammation in the trochanteric bursa, pain is experienced over the lateral hip and possibly down the lateral thigh to the knee when the iliotibial band rubs over the trochanter. Discomfort may be experienced after standing asymmetrically for long periods with the affected hip elevated and adducted and the pelvis dropped on the opposite side. Ambulation and climbing stairs aggravate the condition. Muscle flexibility, strength imbalances, and the resulting faulty posture of the pelvis may be the predisposing factors leading to bursal irritation (see Box 20.2).

Psoas bursitis. Pain is experienced in the groin or anterior thigh and possibly into the patellar area when there is inflammation of the psoas bursa. Activities requiring excessive, repetitive hip flexion aggravate the condition.

Ischiogluteal bursitis (Tailor's or Weaver's Bottom). When there is inflammation of the ischiogluteal bursa, pain is experienced around the ischial tuberosity, especially when sitting. If the adjacent sciatic nerve is irritated from the swelling, symptoms of sciatica may occur.

Femoroacetabular Impingement (FAI)

Trauma, acetabular labral impingement, capsular laxity, dysplasia and degeneration are causative factors for tears in the acetabular labrum typically leading to anterior hip or groin pain.[5,51,79,150] There may be associated structural abnormalities in the acetabulum or femur.[5] Acetabular labral pathology is associated with hip osteoarthritis in older patients.[51] Patients usually present with pain that is activity-dependent and describe mechanical symptoms such as clicking, locking, catching, or giving way.[79] Groin pain typically is related to an anterior tear, buttock pain to a posterior tear. With an anterior lesion, positive tests typically include: pain with the impingement test (combined flexion, adduction, and internal rotation) and with the scour test.[5] The log roll test may elicit pain or clicking when rolling the femur into internal rotation, and there may be restricted mobility and groin pain with the FABER (flexion, abduction, external rotation) test. Muscle flexibility and strength imbalances have been reported, including tightness of hip flexors and lumbar extensors and weak, inhibited gluteal and abdominal muscles.[51] Radiographic imaging and MRI (using gadolinium contrast) are usually performed to diagnosis labral pathology.

CLINICAL TIP

Although FAI is often treated surgically, a period of conservative management is advocated that addresses the biomechanical impairments. Emphasize alignment of the hip joint, reduce anteriorly directed forces on the joint, and develop a length/strength balance in the muscles of the hip. Strengthen the hip abductors, gluteus maximus, iliopsoas, and external rotators and develop flexibility in the hamstring muscles. Avoid hip rotation under loads (pivoting) and correct faulty gait, such as knee hyperextension, which causes hip hyperextension during stance.[79] No exercise should cause pain.

Common Structural and Functional Impairments

Pain. With musculotendinous strains, symptoms occur when the involved muscle is contracted or stretched or when the provoking activity is repeated, often restricting participation in daily activities or sports. With impingement (bursa or labral tears), symptoms typically occur when the involved tissue is pinched between opposing structures.

Gait deviations. Slightly shorter stance occurs on the painful side. There may be a slight lurch when the involved muscle contracts to protect the muscle, resulting in impaired gait.

Imbalance in muscle flexibility and neuromuscular control. Muscle flexibility or altered dominance in use of related muscles may be the precipitating factor in many painful hip syndromes. Imbalances are described in the introductory section of this chapter and summarized in the descriptions of painful hip syndromes.

Decreased muscular endurance. Muscle fatigue may lead to faulty postures, stress, and imbalances in muscle use as described previously.

Management: Protection Phase

Control Inflammation and Promote Healing

When there is chronic irritation or inflammation from an acute injury, follow the guidelines as described in Chapter 10, with emphasis on resting the involved tissue by not stressing or putting pressure on it. Have the patient avoid the provoking activity; if necessary, decrease the amount of time spent walking or use an assistive device.

Develop Support in Related Areas

Initiate exercises to develop neuromuscular control for alignment of the pelvis and hip, and develop strength in weak muscles. Avoid stressing the inflamed tissue. Patient education and cooperation are necessary to reduce repetitive trauma.

Management: Controlled Motion Phase

When acute symptoms have decreased, initiate a progressive exercise program within the tolerance of the involved tissues to improve muscle performance. The program should emphasize regaining a balance in length, neuromuscular control, strength, and endurance in the muscles of the hip and the rest of the lower extremity.

Develop a Strong Mobile Scar and Regain Flexibility

Remodel the scar in muscle or tendon by applying cross-fiber massage to the site of the lesion (if accessible) followed by multiple-angle submaximal isometrics in pain-free positions.

Develop a Balance in Length and Strength of the Hip Muscles

Specific exercises are described in the exercise sections of this chapter.

- Stretch any muscles that are restricting motion with gentle, progressive techniques. Instruct the patient to do self-stretching with proper stabilization to ensure that the stretches are performed safely and effectively.
- Begin developing neuromuscular control to train muscles to align the femur. A common faulty pattern is hip adduction and internal rotation due to weak gluteus medius, gluteus minimus, and external rotators, with overuse of the tensor fascia lata. Overuse of the hamstrings, rather than the gluteus maximus, for hip extension is another common faulty pattern. Initially, the emphasis is on control, not strengthening.
  - ***External rotation:*** Initiate external rotation control prone lying, with knees extended by rolling the thighs outward, and pressing the heels together, causing an isometric contraction.
  - ***External rotation combined with abduction:*** Initiate training the gluteus medius and minimus by performing anti-gravity external rotation in side-lying with the heels placed together and lifting the top knee upward (clam exercises) (see Fig. 20.23). Progress to straight-leg abduction in the side-lying position. Avoid internal rotation when performing abduction exercises in order to minimize use of the tensor fasciae latae.
  - ***Hip extension:*** Initiate training the gluteus maximus setting exercises; progress to prone-lying hip extension with the knees flexed. If there is cramping in the hamstrings, the patient is attempting to use the hamstrings rather than the gluteus maximus; help him or her refocus on the maximus by returning to the gluteal setting exercises in various positions.
- When the patient is aware of proper muscle control and is able to maintain alignment, progress to strengthening the weakened muscles through the range.
- Initiate controlled weight-bearing exercises when tolerated. Because the individual is probably standing and walking during daily activities, he or she may not tolerate more closed-chain activities than those previously initiated early during the healing stage, so proceed with caution. Carefully observe the exercises so proper movement patterns are used.

CLINICAL TIP

Because of the common faulty pattern of hip adduction and internal rotation when bearing weight, valgus collapse at the knee may occur. Increase awareness of knee alignment by having the patient focus on maintaining the knee in line with the foot when descending stairs or sitting down.

- Muscles not directly injured should be stretched and strengthened if they are contributing to asymmetrical forces. The patient may not have sufficient trunk coordination or strength, which may be contributing to the overuse because of compensations in the hip. See Chapter 16 for suggestions for developing control and stabilizing function in the trunk muscles.
- Use exercises, such as biking or partial weight-bearing and weight-shifting activities in the parallel bars. Observe coordination between trunk, hip, knee, and ankle motions; and exercise only to the point of fatigue, substitute motions, or pain in the weakest segment in the chain.

Develop Muscle and Cardiopulmonary Endurance

- For muscle endurance, teach the patient how to perform each exercise safely for 1 to 3 minutes before progressing to the next level of difficulty.
- Determine aerobic activities that do not exacerbate the patient's symptoms. It may be that the patient just needs to modify the intensity of the techniques used in his or her current program.

Patient Education

Initiate a home exercise program as soon as the patient has learned neuromuscular control techniques and correct stretching, strengthening, and aerobic activities. Provide follow-up instruction for modification and progression of the program.

Management: Return to Function Phase

- Progress closed-chain and functional training to include balance, neuromuscular control, and muscular endurance.
- Use specificity principles; increase eccentric resistance and demand for controlled speed if necessary for return-to-work activity or sporting events.
- Progress to patterns of motion consistent with the desired outcome. Use acceleration/deceleration drills and plyometric training; assess the total body functioning while doing the desired activity. Practice timing and sequencing of events.
- Prior to returning to the desired function, have the patient practice the activity in a controlled environment and for a limited period. As tolerated, introduce variability in the environment and increase the intensity of the endurance activities.

Exercise Interventions for the Hip Region

No matter what the cause, muscle strength or flexibility imbalance in the hip can lead to abnormal lumbopelvic and hip mechanics, which predisposes a patient to or perpetuates low

back, sacroiliac, or hip pain (see Chapters 14 through 16). Abnormal hip mechanics from muscle flexibility and strength imbalances can also affect the knee and ankle during weight-bearing activities, causing overuse syndromes or stress to these regions (see Chapters 21 and 22).

Exercise Techniques to Increase Flexibility and Range of Motion

The exercise techniques in this section are suggestions for correcting limited flexibility of the musculature and periarticular tissues crossing the hip. Principles and techniques of passive stretching and neuromuscular inhibition are presented in Chapter 4 and those of joint mobilization in Chapter 5. Specific manual and self-stretching techniques are described in this section.

Flexibility (self-stretching) exercises, chosen according to the degree of limitation and ability of the patient to participate, can be valuable for reinforcing therapeutic interventions performed by the therapist. Not all of the following exercises are appropriate for every patient. Consequently, the therapist should select each exercise and intensity appropriate for each patient's level of function and progress each exercise as indicated. Whenever the patient is able to contract the muscle opposite the range-limiting muscle, there are the added benefits of reciprocal inhibition of the shortened muscles as well as training the agonist (the muscle opposite the tight muscle) to function for effective control in the gained ROM.

Techniques to Stretch Range-Limiting Hip Structures

NOTE: Two-joint muscles can restrict full ROM of the hip. This first section describes stretches to increase solely hip motions. Therefore, the two-joint muscles must be kept on a slack across the knee during these stretches. Techniques to stretch specific two-joint muscles are described in the second section.

To Increase Hip Extension

Prone Press-Up

Patient position and procedure: Prone with hands on a table at shoulder level. Have the patient press the thorax upward and allow the pelvis to sag (see Fig. 15.4).

PRECAUTION: This exercise also moves the lumbar spine into extension; if it causes radiating pain down the patient's leg, rather than just a stretch sensation in the anterior trunk, hip, and thigh, it must not be performed.

"Thomas Test" Stretch

Patient position and procedure: Supine with the hips near the end of the treatment table, both hips and knees flexed, and the thigh on the side opposite the tight hip held against the chest. Have the patient slowly lower the thigh to be stretched toward the table in a controlled manner and allow the knee to extend, so the two-joint rectus femoris does not limit the range. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg cause the stretch force and to relax the tight muscles at the end of the range (Fig. 20.10). A passive stretch force may be applied manually, or a hold-relax technique may be used by applying a force to the distal thigh (see Fig. 4.26).

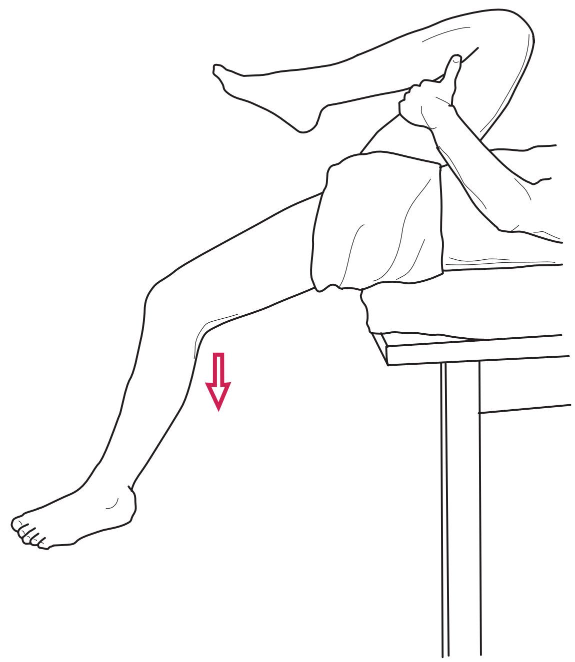

FIGURE 20.10 Self-stretching to increase hip extension. The pelvis is stabilized by holding the opposite hip in flexion. The weight of the thigh provides a stretch force as the patient relaxes. Allowing the knee to extend emphasizes the one-joint hip flexors (iliopsoas), whereas maintaining the knee in flexion and hip neutral to rotation as the thigh is lowered emphasizes the two joint rectus femoris and tensor fasciae latae muscles.

Modified Fencer Stretch

Patient position and procedure: Standing in a fencer's lunge-like posture, with the back leg in the same plane as the front leg and the foot pointing forward. Have the patient first do a posterior pelvic tilt and then shift the body weight onto the anterior leg until a stretch sensation is felt in the anterior hip region of the back leg (Fig. 20.11). If the heel of the back foot is kept on the floor, this exercise may also stretch the gastrocnemius muscle.

Kneeling Fencer Stretch

Patient position and procedure: Kneel on side to be stretched, with the other leg forward in hip/knee flexion and foot on the ground. Have the patient first do a posterior pelvic tilt and then shift the body weight onto the anterior leg until

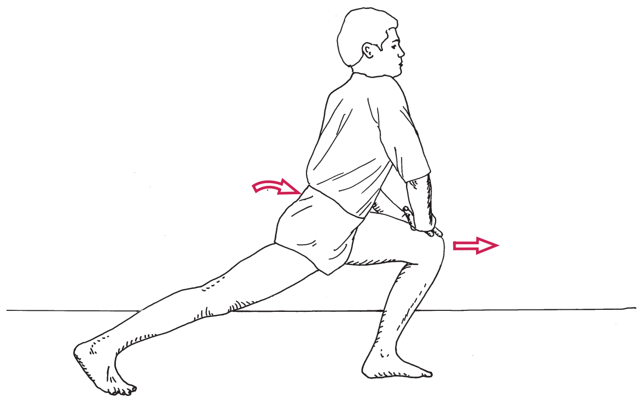

FIGURE 20.11 Self-stretching of the hip flexor muscles and soft tissue anterior to the hip using a modified fencer's squat posture.

a stretch sensation is felt in the anterior hip region of the back leg.

To Increase Hip Flexion

Bilateral Knee to Chest Stretch

Patient position and procedure: Supine. Have the patient bring both knees toward the chest and grasp the thighs firmly until a stretch sensation is felt in the posterior hip region. Monitor the position carefully, because if the pelvis lifts up off the mat, the lumbar spine flexes, and the stretch force is transmitted there instead of to the hips.

Unilateral Knee to Chest Stretch

Patient position and procedure: Supine. Have the patient bring one knee to the chest and grasp the thigh firmly against the chest while keeping the other lower extremity extended on the mat. This position isolates the stretch force to the hip being flexed and helps stabilize the pelvis.

To emphasize a stretch of the gluteus maximus muscle, have the patient pull the knee toward the opposite shoulder.

Quadruped (All Fours) Stretch

Patient position and procedure: On hands and knees. Have the patient rock the pelvis into an anterior tilt, causing lumbar extension (Fig. 20.12 A); then maintain the lumbar extension and shift the buttocks back in an attempt to sit on the heels. The hands remain forward (Fig. 20.12 B). It is important not to let the lumbar spine flex while holding the stretch position, so the stretch affects the hip.

Short-Sitting Stretch

Patient position and procedure: Sitting in a chair or at edge of elevated exercise mat (so that the hips are positioned in 90º of flexion) with the pelvis rotated anteriorly and the low back extended to stabilize the spine. Have the patient grasp the front of the chair seat (or mat) and lean or pull the trunk forward, keeping the back arched, so the motion occurs only at the hips.

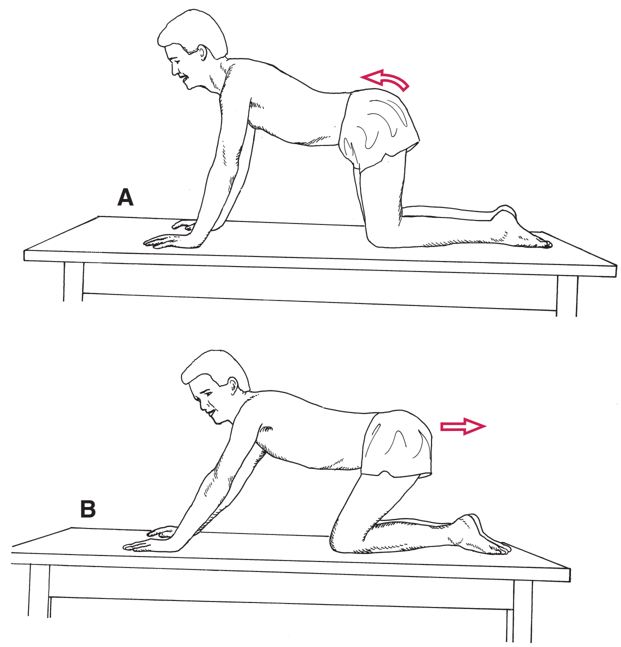

FIGURE 20.12 Gluteus maximus self-stretch with lumbar spine stabilization. **(A)** The patient on all fours rocks into an anterior pelvic tilt, causing lumbar extension. **(B)** While maintaining lumbar extension, the patient shifts the buttocks back, attempting to sit on the heels. When lordosis can no longer be maintained, the end-range of hip flexion is reached; this position is held for the stretch.

To Increase Hip Abduction

Patient position and procedure: Supine with both hips flexed 90˚, knees extended, and legs and buttocks against the wall. Have the patient abduct both hips as far as possible with gravity causing the stretch force (Fig. 20.13).

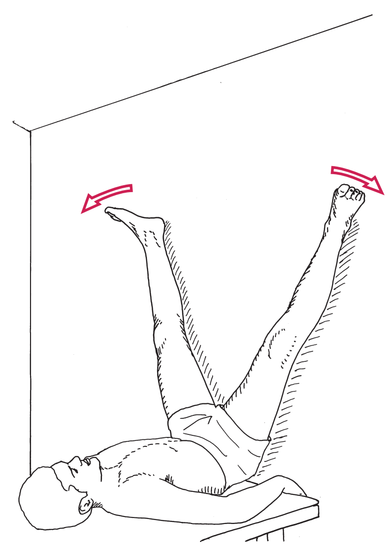

FIGURE 20.13 Self-stretching of the adductor muscles with the hips at 90˚ of flexion.

To Increase Hip Abduction and External Rotation Simultaneously

- *Patient position and procedure:* Sitting or supine with soles of feet together and hands on the inner surface of the knees. Have the patient push the knees down toward the floor with a sustained stretch. The stretch can be increased by pulling the feet closer to the trunk.

NOTE: When this stretch is performed supine, teach the patient to stabilize the pelvis and lumbar spine by actively contracting the abdominal muscles and maintaining a neutral spinal position.

- *Patient position and procedure:* Sitting or supine hook-lying, with ankle of extremity to be stretched placed on the opposite thigh (FABER or figure-4 position) (Fig. 20.14). Have the patient push the knee down with one hand while stabilizing the ankle on the thigh with the other hand.

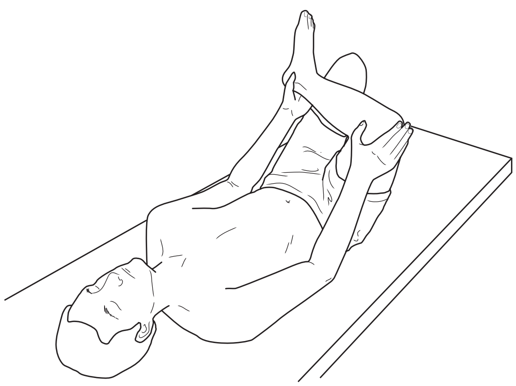

FIGURE 20.14 Self-stretching to increase hip abduction and external rotation using the figure-4 position.

  - To increase the stretch on the posterior hip musculature, have the patient bend forward at the hips (or bring the flexed knee toward the chest if in hook-lying) while maintaining the lumbar spine in extension and pelvis in midline (not tipping to one side).
- *Patient position and procedure:* Standing in a fencer's position but with the hind leg externally rotated. Have the patient shift the weight onto the front leg until a stretch sensation is felt along the medial thigh in the hind leg.

To Increase Hip Internal Rotation

Patient position and procedure: Long-sitting position on a mat with the leg of the hip to be stretched flexed and crossed over the opposite leg (Fig. 20.15). Keep the foot planted and adduct and internally rotate the hip by moving the knee medially.

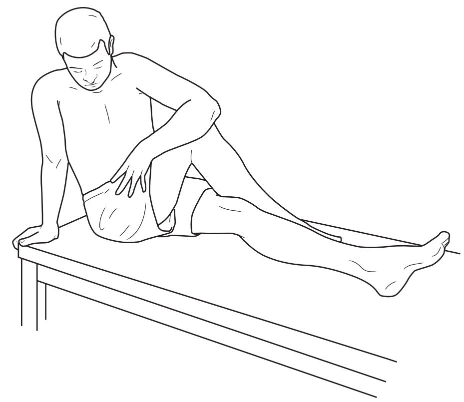

FIGURE 20.15 Self-stretching to increase internal rotation of the hip.

Techniques to Stretch Range-Limiting, Two-Joint Muscles

Rectus Femoris Stretches

"Thomas Test" Stretch

Patient position and procedure: Supine with the hips near the end of the treatment table, both hips and knees flexed, and the thigh on the side opposite the tight hip held against the chest with the arms. While keeping the knee flexed, have the patient lower the thigh to be stretched toward the table in a controlled manner. Do not allow the thigh to externally rotate or abduct. Direct the patient to let the weight of the leg cause the stretch force and to relax the tight muscles at the end of the range. The patient can attempt to further extend the hip by contracting the extensor muscles. (See Fig. 20.10 but with the knee flexed.)

NOTE: This is the same stretch used to increase hip extension—except to stretch the rectus femoris, the knee is kept flexed so the range for hip extension is less.

Prone Stretch

Patient position and procedure: Prone with the knee flexed on the side to be stretched. Have the patient grasp the ankle on that side (or place a towel or strap around the ankle to pull on) and flex the knee. As the muscle increases in flexibility, place a small folded towel under the distal thigh to further extend the hip.

NOTE: Do not let the hip abduct or externally rotate or let the spine hyperextend.

Standing Stretch

Patient position and procedure: Standing with the hip extended and knee flexed and grasping the ankle. Instruct the patient to maintain a posterior pelvic tilt and not let the back arch or the side bend during this stretch (Fig. 20.16).

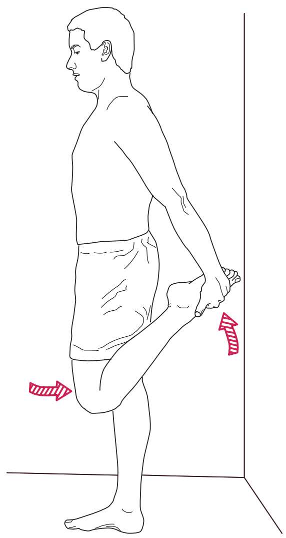

FIGURE 20.16 Self-stretching of the rectus femoris while standing. The femur is kept in line with the trunk. Care must be taken to maintain a posterior PT and not arch or twist the back.

NOTE: If the rectus femoris is too tight to stretch safely in this manner, the patient may place his or her foot on a chair or bench located behind the body rather than grasping the ankle.

Hamstrings Stretches

Straight Leg Raising

NOTE: Straight leg raising (SLR) exercises elongate the hamstrings by stretching them across the hip, using hip flexion while maintaining the knee in extension.

Patient position and procedure: Supine with a towel under the thigh. Have the patient perform SLR with one extremity and apply the stretch force by pulling on the towel to move the hip into more flexion.

Hamstrings Stretch in Doorway

Patient position and procedure: Supine, on the floor, with one leg through a doorway and the other leg (the one to be stretched) propped up against the door frame. For an effective stretch, the pelvis and opposite leg must remain on the floor with the knee extended.

- To increase the stretch when the patient is able, have the patient move the buttock closer to the doorframe, keeping the knee extended (Fig. 20.17 A).
- Teach the patient to perform the hold-relax/agonist contraction technique by pressing the heel of the leg being stretched against the doorframe, causing an isometric contraction, relaxing it, then lifting the leg away from the frame (Fig. 20.17 B).

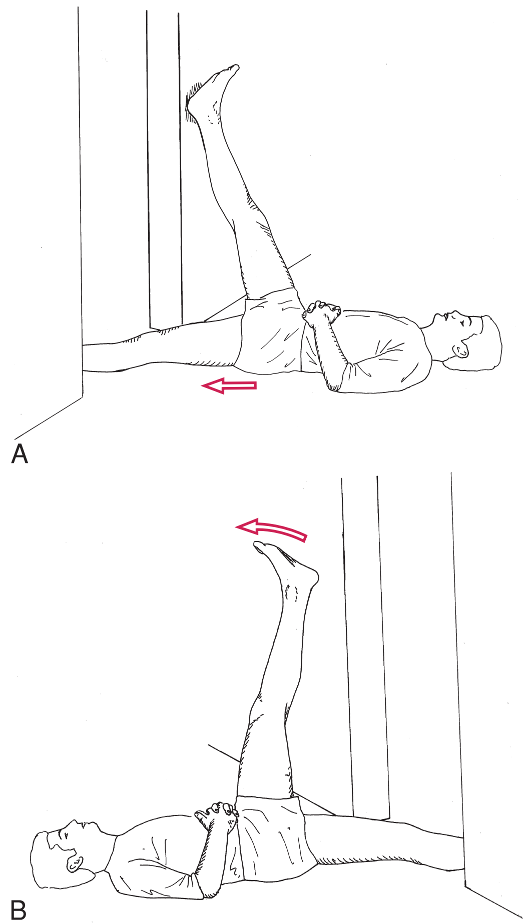

FIGURE 20.17 Self-stretching of the hamstring muscles. Additional stretch can occur if the person either **(A)** moves the buttock closer to the door frame or **(B)** lifts the leg away from the doorframe.

Hamstrings Stretch on Chair or Table

- *Patient position and procedure:* Sitting with the leg to be stretched extended to another chair, or sitting at the edge of a treatment table, with the leg to be stretched on the table and the opposite foot on the floor. Have the patient lean the trunk forward toward the thigh, keeping the back extended so there is motion only at the hip joint (Fig. 20.18).
- *Alternate position:* Standing with the extremity to be stretched on a stool or the seat of a chair. Have the patient lean the trunk forward toward the thigh, keeping the back extended so that motion is only at the hip joint

Bilateral Toe Touching

NOTE: Bilateral toe touching exercises are often used to stretch the hamstring muscles in exercise classes. It is important to recognize that having the patient reach for the toes does not selectively stretch the hamstrings but stretches the low back and mid-back as well. Toe touching is considered a general flexibility exercise and tends to mask shortening of

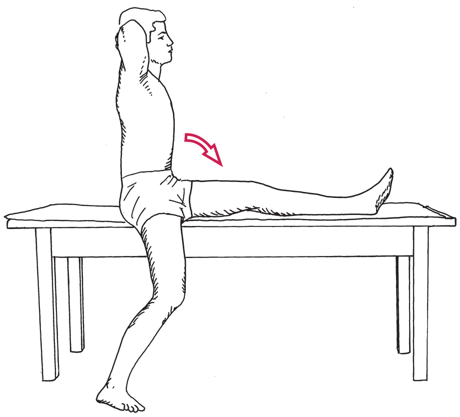

FIGURE 20.18 Self-stretching the hamstring muscles by leaning the trunk toward the extended knee, flexing at the hips.

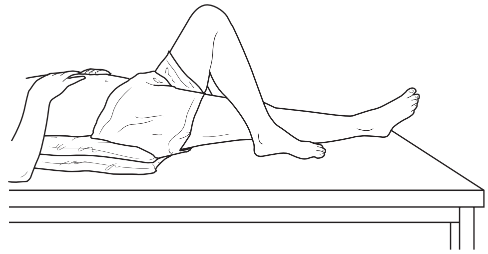

FIGURE 20.19 Self-stretching of the tensor fascia latae: supine. Pillows support the spine and pelvis, allowing the hips to extend. The crossed-over foot stabilizes the femur in adduction and external rotation.

soft tissues in one region and overstretch areas already flexible. Whether a person can touch the toes depends on many factors (e.g., body type; arm, trunk, and leg length; flexibility in the thoracic and lumbar regions; hamstring and gastrocnemius length).

Patient position and procedure: Standing. To discourage the "toe touch" idea, teach the patient to place the hands on the hips when bending forward. To specifically stretch the hamstrings using the forward-bend method in standing, teach the patient to first do an anterior pelvic tilt to extend the spine; then keep the back stable and bend only at the hips ("hinge at the hips") and move only through the range of forward bending in which the spine can be maintained in extension. The stretch sensation should be felt in the hamstring region.

PRECAUTION: This stretching technique should not be used when the patient has low back impairments, because forward bending greatly increases mechanical stress to the tissues of the low back.

Tensor Fasciae Latae and Iliotibial Band Stretches

NOTE: The tensor fasciae latae (TFL) inserts into the iliotibial (IT) band, which inserts into the extensor mechanism and lateral fascia of the knee. The TFL is a hip flexor, abductor and internal rotator; for an effective stretch, all *three* components must be addressed. In addition, for an effective stretch of the muscle, the IT band must be positioned across the greater trochanter, and the knee must be flexed.

Supine Stretch

Patient position and procedure: Supine with two pillows under the hips and back to position the hips in extension. Instruct the patient to cross the uninvolved extremity over the top of the involved extremity, so the involved thigh has room to move into adduction and internal rotation. The foot of the uninvolved extremity is placed lateral to the knee of the adducted thigh and assists in holding the stretch position (Fig. 20.19).

Side-Lying Stretch

- *Patient position and procedure:* Side-lying, with the leg to be stretched uppermost. The bottom extremity is flexed for support, and the pelvis tilted laterally, so the waist is against the mat or floor. Abduct the top leg and align it in the plane of the body (in extension). While maintaining this position, have the patient externally rotate the hip and then gradually lower (adduct) the thigh to the point of stretch (Fig. 20.20 A).

NOTE: It is critical to keep the trunk aligned and not allow it to roll backward. If the trunk rolled backward, the hip would then flex, and the iliotibial tract would slip in front of the greater trochanter, preventing an effective stretch.

- *Progression:* Secure a belt or sheet around the ankle and have the patient hold onto the other end placed over the shoulder (Fig. 20.20 B). Instruct the patient to first flex the knee and abduct the hip and then extend the hip. (This ensures that the IT band is positioned over the greater trochanter.) Then have the patient adduct the hip in slight external rotation until tension is felt along the lateral aspect

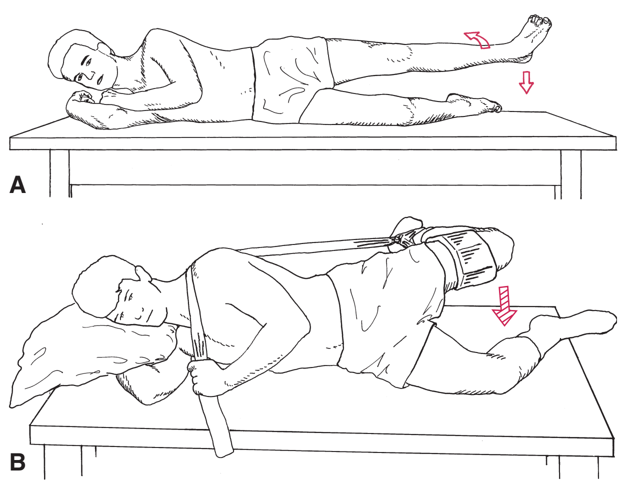

FIGURE 20.20 Self-stretching of the tensor fascia latae: side-lying. **(A)** The thigh is abducted in the plane of the body; then it is extended and externally rotated, then slowly lowered. Additional stretch occurs by flexing the knee. **(B)** Progress the intensity of a sustained stretch by pulling the hip into extension with a strap and adding a weight.

of the knee. If tolerated, a 2- to 5-lb weight is placed distally over the lateral thigh for added stretch, and the position maintained for 20 to 30 minutes. (Also see manual stretching Fig. 4.29.)

- ***Fascial release procedure for the IT band in side-lying.*** Refer to the description and illustration of the foam roller release in Chapter 21 (see Fig. 21.22).

Standing Stretch

Patient position and procedure: Standing with the side to be stretched toward a wall and the hand on that side placed on the wall. Have the patient extend, adduct, and externally rotate the extremity to be stretched and cross it behind the other extremity. With both feet on the floor, have the patient shift his or her pelvis toward the wall and allow the normal knee to bend slightly (Fig. 20.21). There is a slight side-bending of the trunk away from the side being stretched.

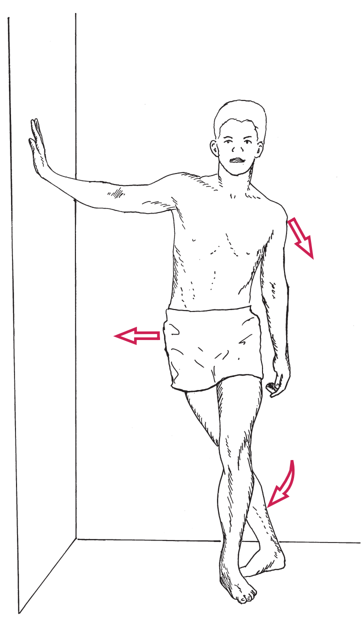

FIGURE 20.21 Self-stretching of the tensor fasciae latae: standing. The pelvis shifts toward the tight side with a slight side bend of the trunk away from the tight side. Increased stretch occurs when the extremity is positioned in external rotation prior to the stretch.

Exercises to Develop and Improve Muscle Performance and Functional Control

During the controlled motion and return to function phases of intervention, when only moderate or minimum protection of healing tissues is necessary, the patient must learn to develop control of hip movement while using good trunk stability. For a muscle that has not been properly used or that has been dominated by another muscle, exercises begin with developing patient awareness of muscle contractions and movements through controlled ROM exercises. If muscle shortening has prevented full ROM, development of muscle control in any new range must immediately follow stretching activities. Principles for improving muscle performance as well as techniques for manual resistance exercise and methods of mechanical resistance are described in Chapter 6. Manually applied resistance should be used when muscles are weak or when helping the patient focus on specific muscles.

Exercises described in the following sections may be adapted for home exercise programs and progressed by integrating advanced function training exercises described in Chapter 23. Choose exercises that challenge the patient to progress toward the functional goals established in the plan of care.

Open-Chain (Nonweight-Bearing) Exercises

Even though weight-bearing activities dominate lower extremity function, when a patient is weak or has poor control of specific muscles or movement patterns, it is advantageous to begin exercises in nonweight-bearing positions, so the individual can learn to isolate muscle activity and control specific motions. In addition, many functional activities have a nonweight-bearing component, such as the swing phase in gait, lifting the leg up to a step when going upstairs, and lifting the lower extremity into a car or onto a bed.

To Develop Control and Strength of Hip Abduction (Gluteus Medius, Gluteus Minimus, and Tensor Fasciae Latae)

NOTE: Muscle imbalances of the hip that contribute to hip and/or low back pain may be seen if abduction is dominated by TFL, and the stabilizing forces from the gluteus medius are poorly controlled.[131] This is seen if the patient flexes and internally rotates the thigh when abducting the hip. The posterior fibers of the gluteus medius and minimus must be trained to contract while the TFL relaxes. These techniques are described in the following sections. If there is sufficient control of rotation, abduction is performed utilizing the synergy between these muscles.

Supine Abduction

Patient position and procedure: Supine with the hips and knees extended. Have the patient concentrate on isolated hip abduction while keeping the trunk still. Do not let the femur roll outward into external rotation. Supine abduction is the easiest position in which to initiate motion, because the influence of gravity on the abductors is eliminated.

- For very weak abductors (< 3/5 manual muscle test grade), provide assistance or place a skate or towel under the leg to minimize the effects of friction.
- If the abductors are not strong enough to progress to antigravity training in the side-lying position, place a weight, such as a sandbag, along the lateral aspect of the thigh or ankle and have the patient push the weight outward.

Side-Lying Abduction

NOTE: If the TFL is tight, the range into extension or adduction may be limited. It is important to stretch this muscle (see Figs. 20.19, 20.20, and 20.21) prior to performing hip abduction to strengthen the gluteus medius. Be certain that the patient does not let the hip flex or internally rotate during these exercises to minimize action of the TFL. If the patient has difficulty controlling hip rotation while abducting in the side-lying position, first develop strength in the external rotators as described later in this section.

- *Patient position and procedure:* Side-lying with the bottom leg flexed for stability. Have the patient lift the top leg into abduction, keeping the hip neutral to rotation and in slight extension. Do not allow the hip to flex or the trunk to roll backward. Add ankle weights to provide resistance as the patient's strength improves.

Standing Abduction

Patient position and procedure: In single-leg stance, have the patient move the nonweight-bearing lower extremity out to the side. Instruct the patient to maintain the trunk upright in neutral alignment and avoid hiking the pelvis and flexing or rotating the abducting hip.

- Add resistance by applying an ankle weight on the moving leg or by using pulleys or elastic resistance applied at right angles to the moving extremity.
- The abductors on the weight-bearing lower extremity contract isometrically to stabilize the pelvis (see Fig. 20.26 B).

To Develop Control and Strength of Hip Extension (Gluteus Maximus)

Gluteal Muscle Setting

Patient position and procedure: Supine or prone. Use gluteal setting exercises to increase awareness of the contracting muscle; teach the patient to "squeeze" (contract) the buttocks.

Standing Leg Lifts with Trunk Support

Patient position and procedure: Standing at the edge of a treatment table with the trunk flexed and supported on the table. Have the patient alternately extend one hip, then the other. This is done with the knee flexed to train the gluteus maximus while relaxing the hamstrings. To progress, add weights or elastic resistance to the distal thigh.

CLINICAL TIP

When attempting hip extension with the knee flexed, if the hamstrings cramp from active insufficiency, the patient is using the hamstrings rather than the gluteus maximus and should practice relaxing them before progressing with this exercise.

Quadruped Leg Lifts

Patient position and procedure: In the quadruped position, have the patient alternately extend each hip while keeping the knee flexed (Fig. 20.22). Combine this exercise with trunk stabilization by first having the patient find the neutral pelvic position, drawing in the abdominal muscles, then extending the hip (see Chapter 16).

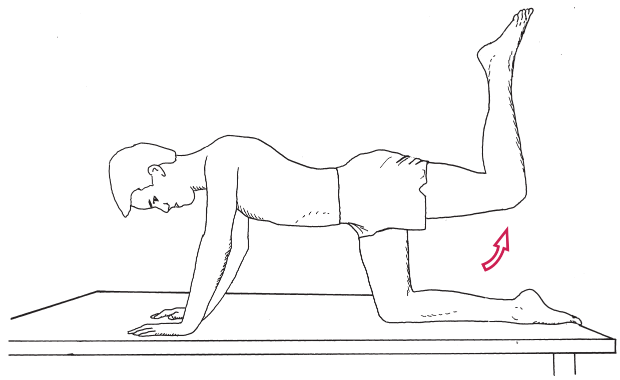

FIGURE 20.22 Isolated training and strengthening of the gluteus maximus. Starting in the quadruped position, extend the hip while keeping the knee flexed to rule out use of the hamstring muscles. Do not to extend the hip beyond the available ROM to avoid causing stress to the sacroiliac or lumbar spinal joints.

CLINICAL TIP

When instructing a patient in hip extension exercises, care is taken not to extend the hip beyond the available range of hip extension; otherwise, the motion causes stress in the sacroiliac joint or lumbar spine. Emphasize spinal stabilization when performing hip extension.

Standing Extension

Patient position and procedure: In single-leg stance, have the patient extend the opposite hip (see Fig. 20.6 A). Instruct the patient to maintain the trunk upright in neutral alignment and not allow the moving hip to extend beyond the normal range.

- To add resistance, apply an ankle weight on the moving leg or by using pulleys or elastic resistance applied at right angles to the moving extremity.
- The hip musculature on the weight-bearing lower extremity must contract isometrically to stabilize the pelvis.

To Develop Control and Strength of Hip External Rotation

Prone External Rotation: Isometric

Patient position and procedure: Prone with knees flexed and about 10 inches apart. Have the patient press the medial aspect of the heels together, causing an isometric contraction of the external rotators. This also may be done with the knees extended; emphasize the sensation of the thighs rolling outward, not adducting.

Side-Lying External Rotation: Clam Exercise

Patient position and procedure: Lower extremities partially flexed at the hips and knees and the heel of the top leg resting on the heel of the bottom leg. Have the patient lift the knee

of the top leg, keeping the heels together. Add resistance by tying an elastic band around the thighs or by placing a cuff weight around the distal thigh of the top leg (Fig. 20.23).

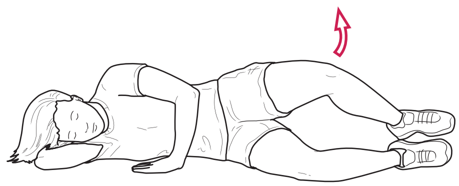

FIG. 20.23 Clam exercises to develop control and initiate antigravity strengthening of the external rotators. Wrap an exercise band around the thighs or add a weight to top leg to increase resistance.

Side-Lying External Rotation: Progression

Patient position and procedure: Hip and knee of top leg extended and aligned with the trunk. First, have the patient roll the leg outward. Then progress to lifting the lower extremity into abduction with the hip externally rotated. Apply elastic resistance or a cuff weight around the thigh when resistance is tolerated.

NOTE: Do not allow the patient to roll the trunk backward or flex the hip, as this exercise is done to minimize substitution with the tensor fasciae latae.

Sitting: External Rotation

Patient position and procedure: Sitting with knees flexed over the edge of a treatment table. Secure an elastic band or tubing around the patient's ankle and the table leg on the same side. For resisted external rotation have the patient move the foot toward the opposite leg, pulling against the resistance (Fig. 20.24).

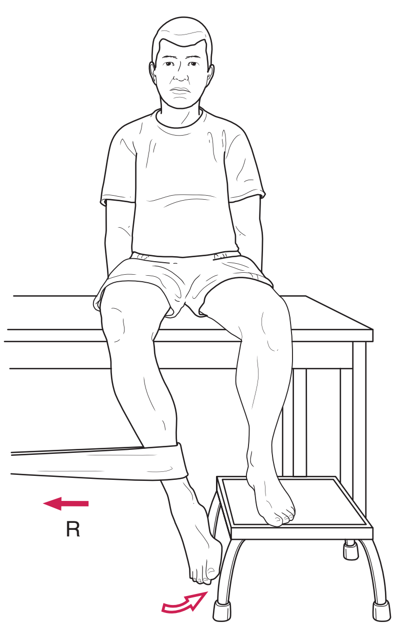

FIGURE 20.24 Strengthening the external rotators in a sitting position with elastic resistance.

NOTE: Do not allow substitution with knee flexion or extension or hip abduction.

To Develop Control and Strength of Hip Flexion (Iliopsoas and Rectus Femoris)

Supine Heel Slides

Patient position and procedure: Begin in hip and knee extension and have the patient flex the hip and knee by sliding the heel toward the buttock.

Standing: Hip and Knee Flexion

Patient position and procedure: Standing in front of a step or stool and holding onto a stable object for balance if necessary. Secure a cuff weight around one or both of the patient's ankles. Have the patient lift the leg (flex the hip and knee) and place the foot on the step and then return the foot to the floor. Repeat with the other leg for bilateral strengthening.

- To progress, increase the resistance and/or the height of the step.
- Variations include having the patient perform alternating hip/knee flexion (high-step marching) or climbing a flight of stairs.

Standing: Straight-Leg Hip Flexion

Patient position and procedure: Standing and holding on to a stable structure for balance if necessary. Place a cuff weight or secure elastic resistance around the patient's distal leg. Have the patient flex the hip while maintaining the knee in extension.

To Develop Control and Strength of Hip Adduction

Side-Lying Adduction

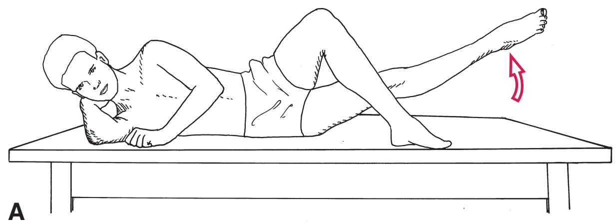
Patient position and procedure: With the bottom leg aligned in the plane of the trunk (hip extension) and the top leg flexed forward with the foot on the floor or with the thigh resting on a pillow, have the patient lift the bottom leg upward into adduction. Weights can be added to the ankle to progress strengthening (Fig. 20.25 A). A more difficult position is to have the patient hold the top leg in abduction and adduct the bottom leg upward to meet it (Fig. 20.25 B).

Standing Adduction

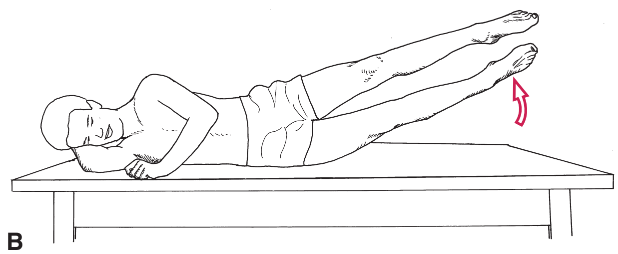
Patient position and procedure: Have the patient adduct the leg across the front of the weight-bearing leg. Add ankle weights to provide resistance, or fasten elastic resistance or a pulley at right angles to the moving leg.

Closed-Chain (Weight-Bearing) Exercises

Weight-bearing exercises in the lower extremity involve all of the joints in the chain and are therefore not limited to hip muscles. Most activities bring into play antagonistic, two-joint muscles in which each muscle is being lengthened across one joint while it is shortening across another, thus maintaining an optimal length-tension relationship. In addition to causing motion, a prime function of the muscles in weight bearing is



A



B

FIGURE 20.25 Training and strengthening the hip adductors. **(A)** The top leg is stabilized by flexing the hip and resting the foot on the mat while the bottom leg is adducted against gravity. **(B)** The top leg is isometrically held in abduction while the bottom leg is adducted against gravity.

to control the forces of gravity and momentum for balance and stability. Therefore, the exercises for the hip described in this section include balance and stabilization training as well as strengthening and functional exercises. More advanced balance and functional exercises are described in Chapter 23.

A number of EMG studies have analyzed lower extremity exercises often used to strengthen hip musculature in both nonweight-bearing and weight-bearing positions. Two such studies, primarily of weight-bearing exercises, are summarized in Box 20.12.[6,38]

Exercises performed in weight-bearing postures described in the following section are closely related and are progressed concurrently as the patient is able. If the patient does not tolerate or is not permitted to be full weight bearing, begin exercises with upper extremity assistance, such as parallel bars, or utilize a therapeutic pool if one is available, and the patient has no open wounds (see Chapter 9).

Closed-Chain Isometric Exercises

Alternating Isometrics and Rhythmic Stabilization

Patient position and procedure: Standing; begin with bilateral standing, progress the patient to unilateral standing. Alternating isometrics and rhythmic stabilization develop postural adjustments to applied forces.

- Apply manual resistance against the pelvis in alternating directions and ask the patient to hold (with isometric contractions). There should be little or no movement.
- Vary the force and direction of resistance; also vary where the force is applied by shifting the resistance from the pelvis to the shoulders and eventually against outstretched arms (see Fig. 22.15).
- At first, use verbal cueing. Then, as the patient learns control, apply the varying forces without warning.

BOX 20.12 EMG Analysis of Selected Weight-Bearing Exercises used to Strengthen Lower Extremity Musculature*

Gluteus maximus: > 40% MVC (strong contraction)

- Single-limb wall slide,[6] single-limb squat, and single-limb deadlift[38]
- Single-limb mini-squat[6]
- Step ups (forward, lateral, retro)[6]
- Lunges (transverse, forward, sideways)[38]

Gluteus maximus: < 40% MVC

- Side-lying hip abduction, clam with 60° hip flexion[38]
- Transverse hop, forward hop, and clam with 30° hip flexion[38]

Gluteus medius: > 40% MVC (strong contraction)

- Side-lying hip abduction[38]
- Single-limb wall slide[6]
- Lateral band walk, single-limb deadlift, sideways hop[38]
- Forward step up[6]
- Sideways hop, transverse hop, transverse lunge, forward hop, forward lunge, clam with 30° hip flexion[38]

Gluteus medius: < 40% MVC

- Sideways lunges and clam exercise (in the side-lying position) with 60° hip flexion[38]

Biceps femoris: < 40% MVC

- Single leg wall squat, mini squat, and forward step up[6]
- Retro step up and lateral step up were 10% and 9% MVC respectively[6]

*One exercise (the clam exercise) was performed in a nonweight-bearing position. The exercises are listed from most effective to least effective for activating the muscle noted based on comparisons with maximum voluntary contractions (MVC) of the gluteus maximus, gluteus medius, and biceps femoris to help the clinician make choices for effective rehabilitation of these muscles.

Stabilization in Single-Leg Stance

Patient position and procedure: Standing on the involved leg with elastic resistance placed around the thigh of the opposite extremity and secured to a stable upright structure. If the knee is stable, the resistance can be applied around the ankle. Have the patient maintain alignment and stability of the trunk and the weight-bearing extremity while moving the opposite extremity forward, backward, and to the side.

- To resist *hip flexion of the moving thigh*, have the patient face away from where the resistance is secured. This requires stabilization by the posterior muscles on the stance side.
- To resist *extension of the moving thigh*, have the patient face toward where the resistance is secured (Fig. 20.26 A). This requires stabilization by the anterior muscles on the stance side.
- To resist *abduction* and *adduction*, have the patient face so the band is directed toward one side and then the other (Fig. 20.26 B).

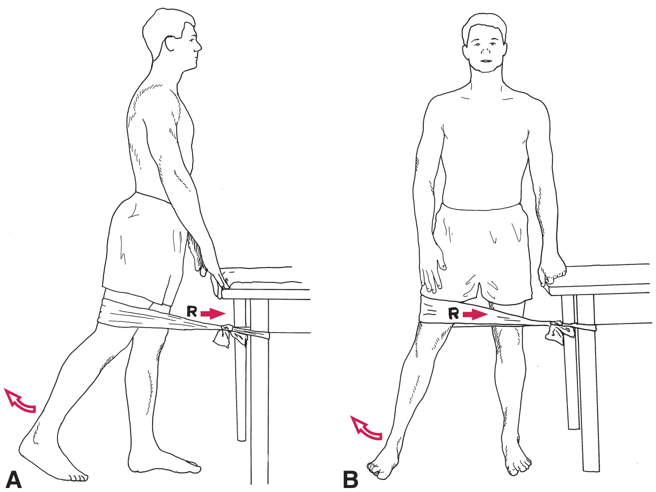


FIGURE 20.26 Closed-chain stabilization and strengthening exercises with elastic resistance around the opposite leg. **(A)** Resisting extension on the right requires stabilization of the anterior muscles of the left side. **(B)** Resisting abduction on the right requires stabilization by the left frontal plane muscles. To increase difficulty, the resistance is moved distally onto the leg.

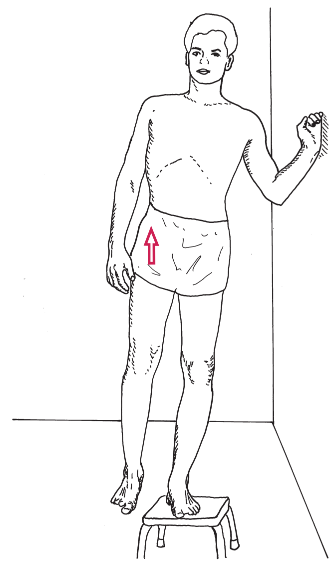

FIGURE 20.27 Training the hip abductor and hiker muscles for frontal plane strengthening and stability.

NOTE: Although the nonweight-bearing extremity is moving against resistance, the emphasis of the exercise is to develop stability and strengthen the weight-bearing side. Therefore, fatigue is determined when the patient can no longer hold the weight-bearing extremity or pelvis stable.

These stabilization exercises can be used for balance training by having the patient vary the speed of the moving leg.

Closed-Chain Dynamic Exercises

Hip Hiking/Pelvic Drop

Patient position and procedure: Standing with one leg on a 2- to 4-inch block and using a wall or stable surface for balance if necessary. Alternately lower and elevate the pelvis on the side of the unsupported leg (Fig. 20.27). This develops control of the abductors of the stance leg and hip hikers on the unsupported side.

FOCUS ON EVIDENCE

In an EMG study by Bolgla and Uhl,[19] a series of 16 healthy subjects performed six different abductor exercises using a constant weight. The authors documented significantly greater maximum voluntary contraction of the gluteus medius in the stance leg (weight-bearing leg) during the pelvic drop exercise than during other hip abduction exercises. In addition, standing hip abduction showed significantly greater hip abductor activity on the weight-bearing side than on the moving (open-chain) side; the activity on the weight-bearing side had a comparable maximum voluntary contraction as side-lying hip abduction.

Bridging

Patient position and procedure: Begin in the hook-lying position. Have the patient press the upper back and feet into the mat, elevate the pelvis, and extend the hips. This strengthens the hip extensors in coordination with the trunk stabilizers (Fig. 20.28).

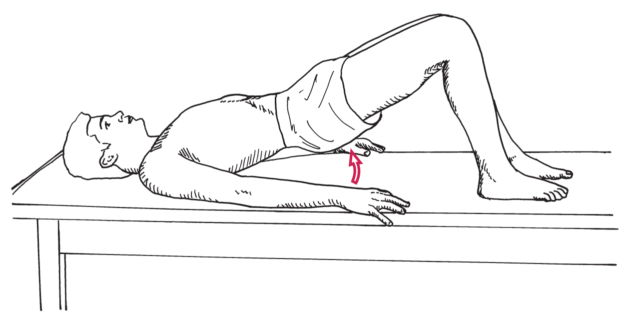

FIGURE 20.28 Training and strengthening the hip extensor muscles using bridging exercises. Resistance can be added against the pelvis.

- *Progressions:* Apply resistance against the anterior pelvis manually or by strapping a weighted belt around the pelvis. Have the patient hold the bridge position and alternately extend the knees. To challenge proprioception and balance, perform bridging exercises using a large gym ball positioned either under the back with feet on the floor or under the feet while lying on the floor.
- *Variation:* Apply elastic resistance around the thighs. While maintaining the bridge position, have the patient abduct and externally rotate the thighs to coordinate strengthening of the gluteus maximus, medius, and external rotators.

Wall Slides

Patient position and procedure: Standing and resting the back against a wall with feet forward and a shoulder-width apart. Have the patient slide the back down the wall by flexing the hips and knees, then slide up the wall by extending the hips and knees (Fig. 20.29 A). This strengthens the hip and knee extensors eccentrically and concentrically. If sliding the back directly against the wall causes excessive friction, place a towel behind the patient's back.

- *Progressions:* Place a large exercise ball behind the back. This requires additional control, because the surface is less stable (Fig. 20.29 B). Add arm motions and weights to develop coordination and increase strength. To develop isometric strength, have the patient hold the flexed position and superimpose arm motions with weights.

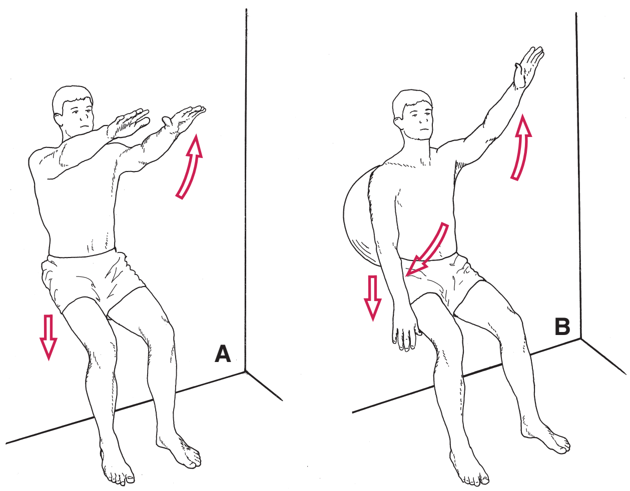

FIGURE 20.29 Wall slides/partial squats to develop eccentric control of body weight. **(A)** The back sliding down a wall, superimposing bilateral arm motion for added resistance. **(B)** The back rolling a gym ball down the wall, superimposing antagonistic arm motion to develop coordination.

Partial Squats/Mini-Squats VIDEO 20.1

Patient position and procedure: In bilateral stance, have the patient lower the body by flexing the hips and knees as if sitting on a chair. Add resistance by having the patient hold weights in the hands, or use elastic resistance secured under the feet (see Fig. 21.27). Progress to safe lifting techniques that involve squatting.

NOTE: To protect the ACL, limit knee flexion range from 0° to 60°. Have the patient lower the hips as if preparing to sit on a chair, so the knees do not move anterior to the toes. To reduce patellofemoral compression, instruct the patient to squat only through pain-free ranges and avoid deep knee bends.

- *Variations:* Apply elastic resistance around the thighs. While abducting and externally rotating the thighs against the resistance, have the patient perform partial squats (Fig. 20.30) or side-step in one direction, then the other (hips slightly flexed) to coordinate strengthening of the gluteus maximus, medius, and external rotators.

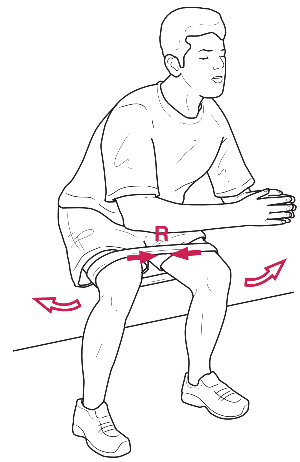

FIGURE 20.30 Elastic resistance around thighs is used to activate the hip external rotators and abductors while performing partial squats to develop strength of the hip and knee extensors.

Single-Limb Deadlift VIDEO 20.1

Patient position and procedure: In unilateral stance with the weight-bearing hip and knee in 30° flexion. Have the patient bend forward at the hips and reach for the toes of the stance leg with the contralateral hand while extending the hip and knee of the nonweight-bearing leg behind (Fig. 20.31). Then return to the upright starting position. This strengthens the hip extensors of the weight-bearing extremity eccentrically and concentrically.

FIGURE 20.31 Single-limb deadlift to strengthen the hip extensors and develop control in the knee.

Step-Ups and Step-Downs

Patient position and procedure: Begin with a low step, 2 to 3 inches in height; increase the height as the patient is able. Have the patient step up and down, forward, laterally, or backward.

- Be sure the patient places the entire foot on the step and lifts and lowers the body with smooth motion. When

stepping up, be certain the patient avoids a lurching motion of the trunk or pushing off with the trailing extremity.

- Make sure the patient keeps the trunk upright and the knee aligned vertically over the foot to prevent hip adduction and internal rotation and subsequent valgus collapse. If valgus positioning occurs, reinforce activation of the gluteus medius with manual resistance applied to the lateral thigh of the stepping leg (see Fig. 21.28 A).
- *Progression:* In addition to increasing the step height, add resistance with a weight belt, elastic resistance around the waist (see Fig. 21.28 B), weights in the hands, or a weight around the ankle of the nonweight-bearing leg.

Partial and Full Lunges

Patient position and procedure: After assuming a forward stride position, have the patient flex the hip and knee of the forward extremity and then return upright. Repeat with the same leg or alternate legs. Begin by flexing the knee within a small range, progressing to 90° knee flexion. Instruct the patient to keep the knee in alignment with the forward foot and not bend the knee forward of the foot.

- Use a cane or rod for balance, or hold on to a stable surface for support (parallel bars, treatment table, countertop) if the patient has difficulty controlling the movement (Fig. 20.32).

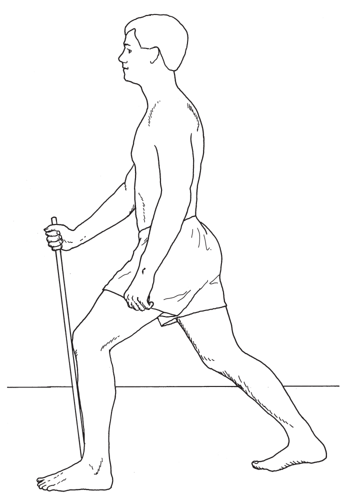

FIGURE 20.32 Partial lunge with cane assistance to develop balance and control for lowering body weight.

- It is important to keep the toes pointing forward, bend the knee in the same plane as the feet, and keep the back upright.
- *Progressions:* Hold weights in the hands for additional resistance, take a longer stride, or lunge forward onto a small step. Integrate a function into this exercise by lunging and picking up objects from the floor.

NOTE: A patient with an ACL-deficient knee or a surgically repaired ACL should not flex the knee forward beyond the toes when performing lunges, because this increases the shear force and stress to the ACL. An individual with patellofemoral pain syndrome typically experiences increased pain under these circumstances, because the compressive force from the body weight is greater when it is kept posterior to the knee. Adapt the position of the knee based on the patient's symptoms and presenting pathology.

Functional Progression for the Hip

For a patient to return to full function, the level of challenge from the exercise program must meet the demands that will be imposed during ADL, IADL, work, or sports-related tasks. An outcome may be simply learning how to ambulate forward, backward, and around obstacles safely, or it may involve developing a high level of strength, endurance, coordination, balance, and skill.

The progression of exercises in a rehabilitation program typically begins with isolated activation, control, endurance, and strengthening of the impaired muscles and progresses to a variety of open- and closed-chain exercises in combined movement patterns that simulate functional activities to further improve strength, power, and muscular endurance. Balance, coordination, skill, and aerobic conditioning also are integrated into the exercise program as the weight-bearing tolerance improves.

Key components of functional exercise progressions for the hip include the entire lower extremity as well as the trunk and upper extremities. Suggestions are summarized in Box 20.13. Details of progressions of exercises for advanced training are described in Chapter 23. Also, refer to Chapter 16 for progressions of spinal exercises and safe body mechanics, Chapter 7 for principles of aerobic exercise, and Chapter 8 for principles of balance training.

BOX 20.13 Summary of Functional Progressions for the Hip

For each activity, adapt the exercise to challenge the patient, but avoid unsafe stresses to the tissues.

- *Balance activities*. Initiate balance activities at the level of weight bearing allowed and progress from bilateral to unilateral activities. Add sagittal and frontal plane arm movements; progress to transverse and diagonal planes. Advance balance/perturbation training activities from stable to unstable surfaces.
- *Ambulation activities*. Increase challenges for ambulation, such as having the patient walk on uneven surfaces, turn, maneuver backward, and walk up and down ramps first under supervision and then unassisted. As soon as the patient is able, have him or her practice rising up and sitting down from chairs of various heights and climbing and descending flights of stairs. Add resistance and speed as tolerated.

Continued

BOX 20.13 Summary of Functional Progressions for the Hip—cont'd

- *Safe body mechanics*. Incorporate exercises that prepare the patient for use of safe body mechanics, such as repetitive squats and lunges. Progress the exercises by having the patient lift and carry or push and pull various loads as part of the exercise routine. Utilize safe patterns of motion that replicate functional requirements.
- *Aerobic training.* Cardiopulmonary endurance exercises that replicate functional demands are introduced early in the rehabilitation program and progressed as the patient tolerates.
- *Agility drills*. Use agility drills such as maneuvering around and stepping over obstacles. Incorporate running, jumping, hopping, skipping, and side-shuffle drills.
- *Advanced strength training.* Incorporate maximum eccentric loading into a weight training progression. Any of the previously described exercises can be adapted, but it is critical to assist the patient through the concentric phase of the exercise and guard him or her through the eccentric phase as the resistance is greater than what the muscle can control concentrically. Also include isokinetic training, particularly at medium and fast speeds (velocity spectrum training), if equipment is available.
- *Plyometric training*. If the patient is returning to activities that require strength and power, incorporate plyometric drills. For example, have the patient jump from a box or step; flex the hips, knees, and ankles to absorb the impact of landing; and immediately jump back up to the box or step.

Independent Learning Activities

Critical Thinking and Discussion

1. Describe the function of the primary muscle groups of the hip joint in open- and closed-chain situations. Include their role in stabilizing the pelvis during single-leg stance and the effects on the spine when the pelvis is moved by the hip musculature.
2. Describe the role of the hip during the gait cycle. Include muscle activity, motion needed, and pathological gait patterns when there is muscle weakness or restricted motion.
3. Analyze the type of gait deviations a patient might exhibit after internal fixation of a fracture of the proximal femur, total hip arthroplasty, or hemiarthroplasty of the hip.
4. After total hip arthroplasty or internal fixation of a hip fracture, what are the signs that dislocation of the hip or loss of fracture stabilization has occurred?

Laboratory Practice

1. Identify and practice the techniques you would use to treat a mobility impairment if the results of your examination included decreased joint play versus restricted flexibility in the hip musculature. Include exercises that could be used in a home exercise program.
2. Demonstrate a progression of exercises to develop control and strength in the gluteus medius muscle after total hip replacement.
3. Develop an exercise routine and progression for an individual with hip muscle weakness who wants to return to work that requires walking, lifting objects that weigh up to 45 lb, and climbing ladders with 45-lb weights.

Case Studies

1. Mr. C., 57 years of age, is a mail carrier; he has walked his mail route for 32 years and is proud "that he has no heart problems." Over the past year, he has noticed that his hip hurts after sitting for more than 1 hour and that there is a marked increase in pain when first getting up out of a chair and walking. He also has noticed that there is increased discomfort in his hip and knees near the end of each workday. The medical diagnosis is osteoarthritis. Strength testing reveals generally 4/5 on manual muscle tests except the gluteus medius, which is 3+/5. There is mild tightness in the hip flexors, including the rectus femoris and tensor fasciae latae. Mr C. wants to avoid being a "candidate for total hip replacement surgery."
   - Explain why the patient's job would perpetuate these symptoms.
   - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals.
   - What can the patient do to protect his hip joints?
2. Ms. J., a 31-year-old mother, recreational tennis player, and bowler, is recovering from multiple femoral fractures she sustained in an automobile accident 3 months ago. There is radiological healing of all the fracture sites, and she is now allowed full weight bearing and no restrictions in activities. She has significant hip mobility impairments from joint restrictions and muscle weakness.
   - What joint ranges and muscle strength levels are needed for her to return to her functional activities?
   - Outline a plan to manage the symptoms; identify measurable goals and interventions you would use to reach the goals. Using the taxonomy or motor skills described in Chapter 1, develop a series of progressively more challenging motor tasks under varying environmental conditions.
3. Mr. C. is a 32-year-old firefighter who strained his hamstrings at the ischial tuberosity while pulling a 250-lb individual out of a burning building. His injury was

sustained 4 days ago. Currently, he is experiencing considerable pain, especially when rising from or lowering himself into a chair and climbing or descending stairs, and is unable to sit on hard surfaces (because of pressure as well as flexing the hip).. Hip flexion is limited to 90° and straight-leg raising to 45°. He tolerates minimal resistance to hip extension or knee flexion. This individual must be able to climb a ladder while wearing his gear (40 lb) and air pack (40 lb) and carrying a 20-lb hand tool; in addition, he must be able to carry a 175-lb individual across his shoulder, drag a heavy body across the floor, climb five flights of stairs while wearing full gear, and run a half mile in 5 minutes to be able to return to work.

- Explain why this patient has impaired function in biomechanical terms.
- Establish goals that reflect treatment of the impairments and desired functional outcomes.
- Design a program of intervention at each stage of tissue healing.
- Design a series of exercises that can be used to prepare Mr. C. for return to function once the muscle has healed.

4. A 78-year-old woman who lives at home with her husband has been referred to you for home-based physical therapy. Ten days ago she underwent cemented THA with a posterolateral approach for late-stage posttraumatic arthritis associated with injuries sustained in a horseback riding accident 30 years ago. She has been home from the hospital for 5 days. She is ambulating with a walker on level surfaces, and weight bearing is tolerated. The patient's long-term goals are to be able to participate in a community-based fitness program for older adults and resume travel with her husband.
   - Continue progressing her exercise program that was initiated in the hospital.
   - Review the precautions she must take for the next 6 to 12 weeks during ADL.
   - Make suggestions on how she or her husband might adapt the home environment to help her adhere to the precautions.
   - To help her meet her long-term goals, design a sequence of progressively more demanding functional activities, integrating the taxonomy of motor tasks (addressed in Chapter 1) and the principles of aerobic conditioning (discussed in Chapter 5).

CHAPTER

21

The Knee

LYNN COLBY, PT, MS ■ CAROLYN KISNER, PT, MS

■ JOHN DEWITT, PT, DPT, SCS, ATC

The knee joint is designed for mobility and stability; it functionally lengthens and shortens the lower extremity to raise and lower the body or to move the foot in space. Along with the hip and ankle, it supports the body when standing, and it is a primary functional unit in walking, climbing, running, and sitting activities.

As in the other regional chapters of the text, this chapter is divided into three primary sections. Highlights of the anatomy and function of the knee complex are reviewed in the first section of the chapter, followed by material on the management of knee disorders and surgeries. The third section includes exercise interventions for the knee region. Chapters 10 through 13 present general information on principles of management. The reader should be familiar with the material in these chapters as well as have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve knee function in patients with impairments due to injury or pathology or following surgery.

Structure and Function of the Knee

The bones of the knee joint consist of the distal femur with its two condyles, the proximal tibia with its two tibial plateaus, and the large sesamoid bone in the quadriceps tendon, the patella. It is a complex joint both anatomically and biomechanically (Fig. 21.1).[105] The proximal tibiofibular joint is anatomically close to the knee but is enclosed in a separate joint capsule and functions with the ankle. Therefore, the proximal tibiofibular joint is discussed in Chapter 22.

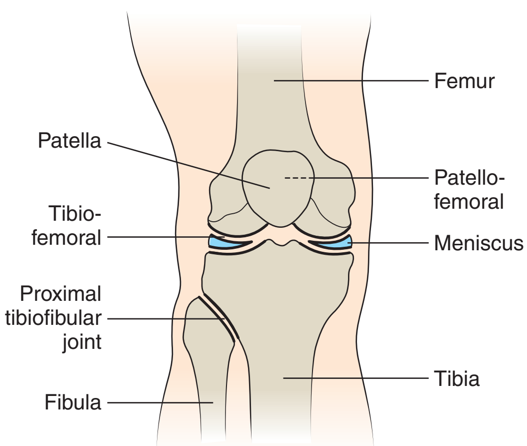

FIGURE 21.1 Bones and joints of the knee and leg.

Joints of the Knee Complex

A lax joint capsule encloses two articulations: the tibiofemoral and the patellofemoral joints. Recesses from the capsule form the suprapatellar, subpopliteal, and gastrocnemius bursae. Folds or thickenings in the synovium persist from embryologic tissue in as many as 60% of individuals and may become symptomatic with microtrauma or macrotrauma.[23,131]

Tibiofemoral Joint

Characteristics. The knee joint is a biaxial, modified hinge joint with two interposed menisci supported by ligaments and muscles. Anteroposterior stability is provided by the cruciate ligaments; mediolateral stability is provided by the medial (tibial) and lateral (fibular) collateral ligaments, respectively (Fig. 21.2).[37,105]

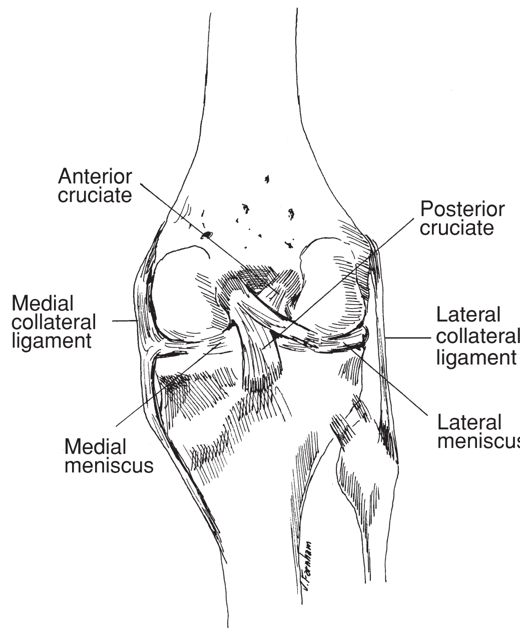

FIGURE 21.2 The medial meniscus is attached to the medial collateral, anterior cruciate, and posterior cruciate ligaments. The lateral meniscus is also attached to the posterior cruciate ligament (the joint capsule has been removed for visualization). *(From Hartigan.[105] In Levangie and Norkin, p. 404, with permission.)*

- The convex boney partner is composed of two asymmetrical condyles on the distal end of the femur. The medial condyle is longer than the lateral condyle, which contributes to the locking mechanism at the knee.
- The concave boney partner is composed of two tibial plateaus on the proximal tibia with their respective fibrocartilaginous menisci. The medial plateau is larger than the lateral plateau.
- The menisci improve the congruency of the articulating surfaces. They are connected to the tibial condyles and capsule by the coronary ligaments, to each other by the transverse ligament, and to the patella via the patellomeniscal ligaments.[105] Anterior and posterior meniscofemoral ligaments also may be present connecting the lateral meniscus to the femur.[102] The medial meniscus is firmly attached to

the joint capsule as well as to the medial collateral ligament, anterior and posterior cruciate ligaments, and semimembranosus muscle. The lateral meniscus attaches to the posterior cruciate ligament and the tendon of the popliteus muscle through capsular connections.[105] Because of the relatively secure attachment of the medial meniscus compared to the lateral meniscus (see Fig. 21.2), it has a greater chance of sustaining a tear when there is a lateral blow to the knee.

Arthrokinematics. Joint mechanics are affected by open- and closed-chain positions of the extremity and are summarized in Box 21.1. Rotation occurs as the knee flexes and extends.

- With motions of the tibia while in a nonweight-bearing, open kinematic chain, the concave plateaus slide in the same direction as the bone motion. Terminal extension results in the tibia rotating externally on the femur; with flexion, the tibia rotates internally.
- With motions of the femur on a fixated tibia while in a weight-bearing, closed kinematic chain, the convex condyles slide in the direction opposite to the bone motion.

Screw-home mechanism. The rotation that occurs between the femoral condyles and the tibia during the final degrees of extension is called the locking, or screw-home, mechanism. When the tibia is fixed with the foot weight bearing on the ground, terminal extension results in the femur rotating internally (the medial condyle slides farther posteriorly than the lateral condyle). Concurrently, the hip moves into extension. Tautness in the iliofemoral ligament, which occurs with hip extension, reinforces the medial rotation of the femur. As the knee is unlocked, the femur rotates laterally. Unlocking of the knee occurs indirectly with hip flexion and directly from action of the popliteus muscle. An individual who lacks full hip extension (hip flexion contracture) cannot stand upright and lock the knee, thus lacking this passive stabilizing function.

BOX 21.1 Summary of Arthrokinematics of the Knee Joint

Physiological Motion	Roll	Slide
Tibial motion—open-chain		
Flexion	Posterior and medial rotation	Posterior
Extension	Anterior and lateral rotation	Anterior
Femoral motion—closed chain		
Flexion	Posterior and lateral rotation	Anterior
Extension	Anterior and medial rotation	Posterior

Patellofemoral Joint

Characteristics. The patella is a sesamoid bone in the quadriceps tendon. It articulates with the intercondylar (trochlear) groove on the anterior aspect of the distal portion of the femur. Its articulating surface is covered with smooth hyaline cartilage. The patella is embedded in the anterior portion of the joint capsule and is connected to the tibia by the ligamentum patellae. Many bursae surround the patella.[105]

Mechanics. As the knee flexes, the patella enters the intercondylar groove with its inferior margin making first contact and then slides caudally along the groove. With extension, the patella slides superiorly. If patellar movement is restricted, it interferes with the range of knee flexion and may contribute to an extensor lag with active knee extension.[283]

Patellar Function

The primary function of the patella is to increase the moment arm of the quadriceps muscle in its function to extend the knee. It also redirects the forces exerted by the quadriceps.

Patellar Alignment

The alignment of the patella in the frontal plane is influenced by the line of pull of the quadriceps muscle group and by its attachment to the tibial tubercle via the patellar tendon. The result of these two forces is a bowstring effect on the patella, causing it to track laterally. One method of describing the bowstring effect is to measure the Q-angle. The *Q-angle* is the angle formed by two intersecting lines: one from the anterior superior iliac spine to the midpatella, the other from the tibial tubercle through the midpatella (Fig. 21.3).[105,173] A normal Q-angle, which tends to be greater in women than men, is 10° to 15°.

Forces Maintaining Alignment

In addition to the boney restraints of the trochlear groove (femoral sulcus), the patella is stabilized by passive and dynamic (muscular) restraints. The superficial portion of the extensor retinaculum, to which the vastus medialis and vastus lateralis muscles have an attachment, provides dynamic stability in the transverse plane. The medial and lateral patellofemoral ligaments, which attach to the adductor tubercle medially and iliotibial band laterally provide passive restraints to the patella in the transverse plane.[105] Longitudinally, the medial and lateral patellotibial ligaments and patellar tendon fixate the patella inferiorly against the active pull of the quadriceps muscle superiorly (Fig. 21.4).

Patellar Malalignment and Tracking Problems

Malalignment and tracking problems of the patella may be caused by several factors that may or may not be interrelated.[97]

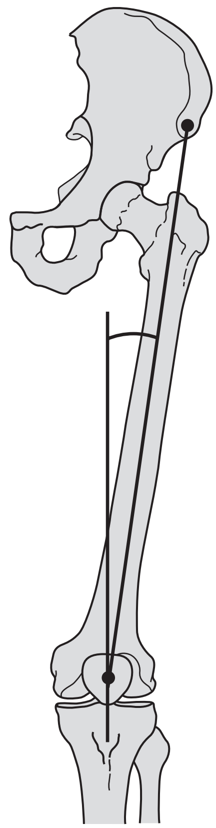

FIGURE 21.3 The Q-angle is the angle formed by the intersection of a line drawn from the center of the patella to the anterosuperior iliac spine and a line drawn from the center of the patella to the tibial tuberosity. These two lines represent the bowstring effect on the patella from the pull of the quadriceps femoris muscle and the patellar tendon. An increased Q-angle is a factor contributing to excessive lateral tracking of the patella. *(From McKinnis,[173] p. 332, with permission.)*

Increased Q-angle. With an increased Q-angle, there may be increased pressure of the lateral facet against the lateral femoral condyle when the knee flexes during weight bearing. Structurally, an increased Q-angle occurs with a wide pelvis, femoral anteversion, coxa vara, genu valgum, and laterally displaced tibial tuberosity. Lower extremity motions in the transverse plane that may increase the Q-angle are external tibial rotation, internal femoral rotation, and a pronated subtalar joint. Dynamic knee valgus (see Fig. 21.9), where the knee joint center moves medially relative to the foot during weight-bearing activities, also increases the Q-angle.[227,228]

FOCUS ON EVIDENCE

A recent weight-bearing MRI study[270] that compared femoral rotation, lateral patellar displacement, lateral patellar tilt, and patellar rotation in females with patellofemoral pain (n=15) to pain-free individuals (n=15) at 45°, 30°, 15°, and 0° knee flexion, showed a significant group-by-angle interaction for femoral medial rotation (p=0.037), lateral patellar displacement (p=0.011), and patellar tilt (p=0.03) in the subjects with patellofemoral pain than those in the control group. The largest difference among groups was at 0° knee flexion for each of these three measures. There was no significant change in patellar rotation.

Muscle and fascial tightness. A tight iliotibial (IT) band and lateral retinaculum prevent medial gliding of the patella. Tight ankle plantarflexors result in pronation of the foot when the ankle dorsiflexes, causing medial torsion of the tibia and functional lateral displacement of the tibial tuberosity in relationship to the patella.[159] Tight rectus femoris and hamstring muscles may affect the mechanics of the knee, leading to compensations.[166]

Hip muscle weakness. Weakness of the hip abductors and external rotators may result in adduction of the femur and valgus at the knee and contribute to increased medial rotation of the femur observed under loaded weight bearing in subjects with patellofemoral pain syndrome.[121,189]

Lax medial capsular retinaculum or an insufficient VMO muscle. The vastus medialis obliquus (VMO) muscle may be weak from disuse or inhibited because of joint swelling or pain, leading to poor medial stability.[272] Poor timing of its contraction, which alters the ratio of firing between the VMO and vastus lateralis (VL) muscle, may lead to an imbalance of forces.[245,292] It has been suggested that weakness or poor timing of VMO contractions increases the lateral drifting of the patella. However, a recent systematic review and meta-analysis indicated that, although there is a trend demonstrating delayed onset of VMO relative to VL contractions in subjects with patellofemoral pain, evidence supporting this idea is difficult to access due to unexplained heterogeneity in the studies reviewed.[42]

Patellar Compression

Patellar contact. The posterior surface of the patella has several facets. It is not completely congruent as it articulates with the trochlear groove on the femur. When the knee is in complete extension (0°), the patella is superior to the trochlear groove. By 15° of flexion, the inferior border of the patella begins to articulate with the superior aspect of the groove. As the knee flexes, the patella slides distally in the groove, and more surface area comes in contact. Beyond 60° there is controversy as to whether the contact area continues to increase, levels off, or decreases.[96,97] In addition, as the knee flexes past 90°, the quadriceps tendon comes in contact with the trochlear groove as the patella slides inferiorly.

Compression forces. In full extension, because there is minimal to no contact of the patella with the trochlear groove, there is no compression of the articular surfaces. Furthermore, because the femur and tibia are almost parallel, the line of pull of the quadriceps muscle and patellar tendon causes a very small resultant compressive load. The resultant force of the quadriceps and patellar tendon forces rises as the knee flexes, but there is also greater surface area of the patella in

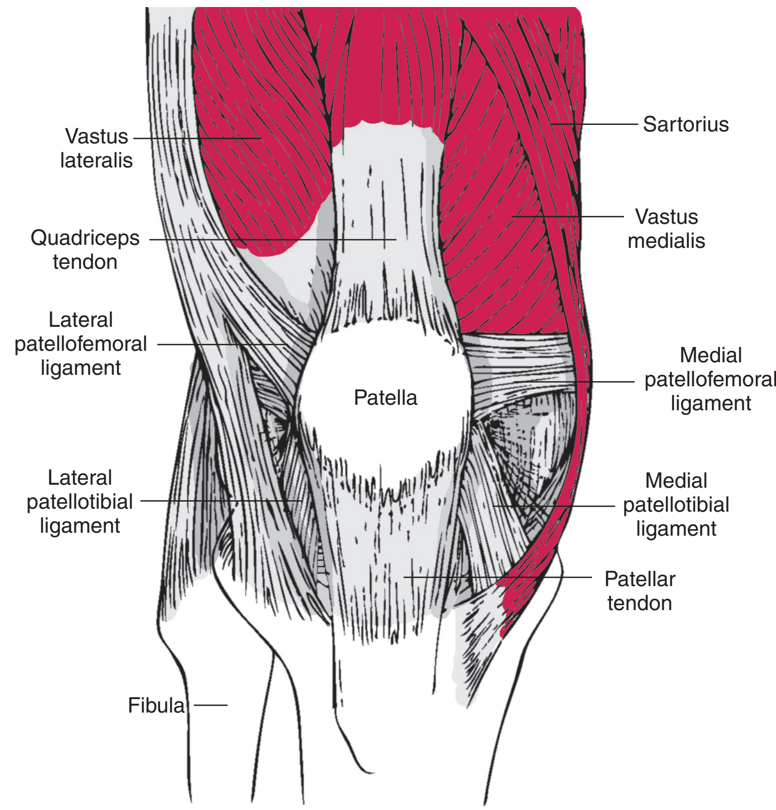

FIGURE 21.4 The extensor retinaculum is reinforced medially by the transversely oriented medial patellofemoral ligament and the longitudinally oriented medial patellotibial ligament. The lateral patellofemoral ligament and lateral patellotibial ligament help resist an excessive medial glide of the patella. *(From Hartigan.[105] In Levangie and Norkin, p. 407, with permission.)*

contact with the groove to dissipate this force. The joint reaction force on the articular surface rises rapidly between 30° and 60°. There is controversy as to the extent of joint reaction forces in greater degrees of flexion.

- During squatting, the joint reaction force continues to rise until 90° and then levels off or decreases because the quadriceps tendon begins making contact with the trochlear groove and therefore dissipates some of the force.[96]
- In an open-chain, nonweight-bearing exercise with a free weight on the distal leg, the greatest joint reaction force in the patellofemoral articulation occurs at around 30° of flexion.[96] This is more likely due to the changing moment arm of the weight rather than the resultant force of the quadriceps and patellar tendons. In an open-chain with variable resistance, the peak stress is at 60° and peak compression is at 75°.[67]
- An increased Q-angle causes increased lateral facet pressure as the knee flexes.[228]

Muscle Function

Knee Extensor Muscle Function

The quadriceps femoris muscle group is the only muscle crossing anterior to the axis of the knee and is the prime mover for knee extension. Other muscles that can act to extend the knee require the foot to be fixated, creating a closed chain. In this situation, the hamstrings and the soleus muscles can cause or control knee extension by pulling the tibia posteriorly.

Closed-chain function. During standing and the stance phase of gait, the knee is an intermediate joint in a closed chain. The quadriceps muscle controls the amount of flexion at the knee and also causes knee extension through reverse muscle pull on the femur. In the erect posture, when the knee is locked, the quadriceps need not function when the gravity line falls anterior to the axis of motion. In this case, tension in the hamstring and gastrocnemius tendons supports the posterior capsule.

Patella. The patella improves the moment arm of the extensor force by increasing the distance of the quadriceps tendon from the knee joint axis. Its greatest effect on the leverage of the quadriceps is during extension of the knee from 60° to 30° and rapidly diminishes from 15° to 0° of extension.[99,105]

Torque. The peak torque of the quadriceps muscle occurs between 70° and 50°.[34] The physiological advantage of the quadriceps rapidly decreases during the last 15° of knee extension because of its shortened length. This, combined with its decreased moment arm in the last 15°, requires the muscle to significantly increase its contractile force when

large demands are placed on the muscle during terminal extension.[99]

- During standing, assistance for extension comes from the hamstring and soleus muscles as well as from the mechanical locking mechanism of the knee. In addition, the anterior cruciate ligament and the pull of the hamstring muscle group counter the anterior translation force of the quadriceps muscle.[76,164]
- During open-chain knee extension exercises in the sitting or supine position, when the resistive force is maximum in terminal extension because of the moment arm of the resistance, a relatively strong contraction of the quadriceps muscle is required to overcome the physiological and mechanical disadvantages of the muscle to complete the final 15° of motion.[99] However, it is worth mentioning that the compressive loads on the patella also decrease in terminal extension because of its superior location with respect to the trochlear groove and the resultant force of the line of pull of the quadriceps and patellar tendon.
- The therapist needs to be aware of the effect of the resistance and where in the range of motion the muscle is being challenged. During open-chain, nonweight-bearing exercises with fixed resistance, when the resistance torque challenges the quadriceps in terminal extension, there is little challenge midrange where the muscle is capable of generating greater tension.

Knee Flexor Muscle Function

The hamstring muscles are the primary knee flexors and also influence rotation of the tibia on the femur. Because the hamstrings are two-joint muscles, they contract more efficiently when they are simultaneously lengthened over the hip (during hip flexion) as they flex the knee. During closed-chain, weight-bearing activities, the hamstring muscles can assist with knee extension by pulling on the tibia.

- The gastrocnemius muscle also can function as a knee flexor, but its prime function at the knee during weight bearing is to support the posterior capsule against hyperextension forces.
- The popliteus muscle supports the posterior capsule and acts to unlock the knee.
- The pes anserinus muscle group (sartorius, gracilis, semitendinosus) provides medial stability to the knee and affects rotation of the tibia in a closed chain.

Dynamic Stability of the Knee

Because of the incongruity of the femoral condyles and tibial plateaus, there is little stability from the boney architecture. The cruciate and collateral ligaments provide significant passive stability in the various ranges of joint motion. Dynamic stability is the ability of a joint to remain stable in the presence of rapidly shifting loads during motion.[118] Dynamic stability involves motor control of the neuromuscular system to coordinate muscle activity around the joint. The complex feedforward and feedback responses mediated by the central nervous system modulate muscle stiffness and are important for providing dynamic knee stability under varying loads and stresses imposed on the joint structures.[304] As summarized in a clinical commentary by Williams,[304] clinical and scientific evidence is accumulating to substantiate exercise programs designed for the purpose of developing dynamic stability of the knee—that is, to improve control of the knee via neuromuscular responses in order to reduce knee ligament stress and the risk of injury during high-intensity activities.

The Knee and Gait

During the normal gait cycle, the knee goes through a range of 60° (0° extension at initial contact or heel strike to 60° at the end of initial swing). There is some medial rotation of the femur as the knee extends at initial contact and just prior to heel-off.[105,207,222]

Muscle Control of the Knee During Gait

Stability during the gait cycle is efficiently controlled by the normal function of the muscles that attach at the knee.[207,222]

Quadriceps. The quadriceps muscle controls the amount of knee flexion during initial contact (loading response) and then extends the knee toward midstance. It again controls the amount of flexion during preswing (heel-off to toe-off) and prevents excessive heel rise during initial swing. With loss of quadriceps function, the patient lurches the trunk anteriorly during initial contact to move the center of gravity anterior to the knee so it is stable or rotates the extremity outward to lock the knee.[276] With fast walking, there may be excessive heel rise during initial swing.

Hamstrings. The hamstring muscles primarily control the forward swing of the leg during terminal swing. Loss of function may result in the knee snapping into extension during this period. The hamstrings also provide posterior support to the knee capsule when the knee is extended during stance. Loss of function results in progressive genu recurvatum.[276]

Soleus. The unijoint ankle plantarflexor muscles (primarily the soleus) help control the amount of knee flexion during preswing by controlling the forward movement of the tibia. Loss of function results in hyperextension of the knee during preswing (also loss of heel rise at the ankle and thus a lag or slight dropping of the pelvis on that side during the preswing phase).

Gastrocnemius. The gastrocnemius muscle provides tension posterior to the knee when it is in extension (end of loading response or foot flat and just prior to preswing or heel-off). Loss of function results in hyperextension of the knee during these periods as well as loss of plantarflexion during preswing or push-off.

Hip and Ankle Impairments

Because the knee is the intermediate joint between the hip and foot, problems in these two areas can interfere with knee function during gait. Examples include the following.

Hip flexion contractures. Inability to extend the hip prevents the knee from extending just before terminal stance (heel-off).

Length/strength imbalances. With asymmetry of length, strength, and neuromuscular control of hip and knee muscles, unbalanced forces may stress various structures of the knee, giving rise to pain during walking or running. For example, a tight tensor fasciae latae or gluteus maximus muscle increases stress on the IT band, which could lead to lateral knee pain. It could also affect tracking of the patella and lead to anterior knee pain. Weak hip external rotators and abductors result in femoral internal rotation, which creates a relative lateral displacement of the patella and subsequent patellofemoral pain.[270] Overuse of the hamstring muscle group increases posterior translation forces on the tibia, requiring compensation in the quadriceps femoris muscle and resulting in anterior knee pain (see Chapter 20 for discussion of muscle imbalances in hip).

Foot impairments. The position and function of the foot and ankle affect the stresses transmitted to the knee. For example, with pes planus or pes valgus, there is medial rotation of the tibia and an increased bowstring effect on the patella, increasing the lateral tracking forces.

Referred Pain and Nerve Injuries

For a detailed description of referred pain patterns and peripheral nerve injuries in the knee region, see Chapter 13.

Major Nerves Subject to Injury at the Knee

The sciatic nerve divides into the tibial and common peroneal nerves just proximal to the popliteal fossa. These nerves are relatively well protected deep in the fossa.

- The *common fibular (peroneal) nerve* (L2–L4) becomes superficial where it winds around the fibula just below the fibular head, a common site for injury. Symptoms of sensory loss and muscle weakness are distal to that site.
- The *saphenous nerve* (L2–L4) is a sensory nerve that innervates the skin along the medial side of the knee and leg. It may be injured with trauma or surgery in that region, resulting in chronic pain syndromes.

Common Sources of Referred Pain

Nerve roots and tissues derived from spinal segments L3 refer to the anterior aspect, and those from S1 and S2 refer to the posterior aspect of the knee.[50] The hip joint, which is primarily innervated by L3, may refer symptoms to the anterior thigh and knee. Therapeutic exercise for the knee is beneficial only for preventing disuse of the part. Primary treatment must be directed to the source of the nerve irritation.

Management of Knee Disorders and Surgeries

To make sound clinical decisions when treating patients with knee disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting structural and functional impairments, activity limitations (functional limitations), and possible participation restrictions (disabilities). In this section, common pathologies and surgical procedures are presented and related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[3] (Table 21.1). Conservative and postoperative management of these conditions is described in this section.

Joint Hypomobility: Nonoperative Management

Common Joint Pathologies and Associated Impairments

OA and rheumatoid arthritis (RA), as well as acute joint trauma, can affect the knee articulations. In addition, decreased flexibility and adhesions develop in the joints and surrounding tissues any time the knee joint is immobilized for a period of time such as following an injury, surgery, or fracture in the related bones. Reflex inhibition and resulting weakness of the quadriceps femoris muscle occurs because of joint distention.[272] The etiology of arthritic and joint symptoms and general management guidelines are described in Chapter 11; this section applies that information to management of the knee joint.

Osteoarthritis (Degenerative Joint Disease)

OA, often referred to as degenerative joint disease (DJD), is the most common disease affecting weight-bearing joints. Articular cartilage destruction typically is more apparent on the medial than the lateral aspect of the knee (Fig. 21.5).

One-third of individuals older than age 65 have radiographic evidence of OA.[16] Pain, muscle weakness, medial joint laxity, and limitation of joint motion affect function and lead to disability. Deformity such as genu varum commonly develops in the knees. Knee instability (the sensation of knee buckling or shifting) is also frequently reported by individuals with knee OA and significantly contributes to impaired physical function.[78]

TABLE 21.1 Knee Pathologies/Surgical Procedures and Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Pattern and Associated Impairments[3]
■ Abnormal knee posture (related to hip and foot alignment)	■ Pattern 4B—impaired posture
■ Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis) ■ Synovitis ■ Postimmobilization arthritis (stiff knee) ■ Joint instability, ligament tears ■ Meniscus lesions ■ Patellofemoral syndromes (patellar instability, malalignment, plica syndrome, fat pad syndrome, patellar tendonitis, bursitis, chondromalacia) ■ Apophysitis (Osgood-Schlatter disease)	■ Pattern 4D—impaired joint mobility, motor function, muscle performance, and ROM associated with connective tissue dysfunction
■ Acute arthritis ■ Acute tendinitis, bursitis ■ Acute capsulitis ■ Acute patellofemoral pain	■ Pattern 4E—impaired joint mobility, motor function, muscle performance, and ROM associated with localized inflammation
■ Arthroscopic débridement ■ Articular cartilage repair: microfracture, osteochondral autograft transfer, autologous chondrocyte implantation ■ Arthroscopic synovectomy ■ Total knee arthroplasty	■ Pattern 4H—impaired joint mobility, motor function, muscle performance, and ROM associated with joint arthroplasty
■ Lateral retinacular release ■ Extensor mechanism realignment ■ Arthroscopic or open ligament repair/reconstruction ■ Meniscectomy or meniscus repair ■ Repair of ruptured patellar tendon ■ Osteotomy ■ Patellectomy	■ Pattern 4I—impaired joint mobility, motor function, muscle performance, and ROM associated with boney or soft tissue surgery
■ Common peroneal, saphenous nerve injury in the knee region	■ Pattern 5F—impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

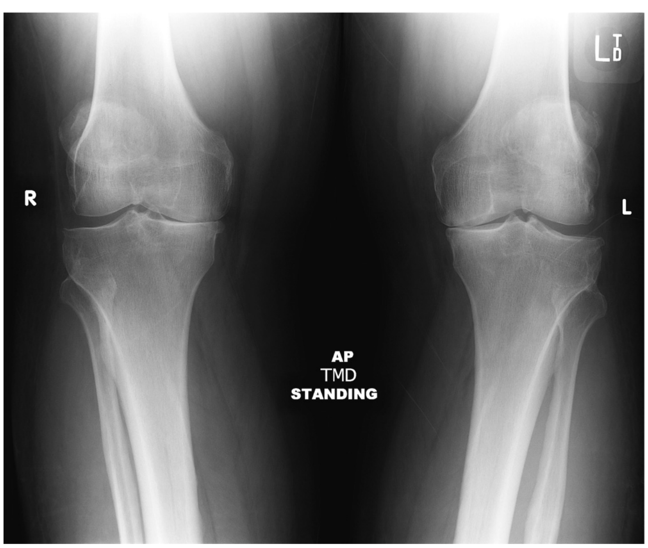

FIGURE 21.5 Advanced bilateral, medial compartment degenerative joint disease in the knees of a 52-year-old computer programmer/analyst who subsequently underwent right total knee arthroplasty.

FOCUS ON EVIDENCE

An investigation of 52 patients with medial knee OA by Schmitt and associates[246] found that self-reported knee instability contributed to limited function during daily living. However, the findings of the study showed no direct relationship between the severity of reported knee instability and the amount of medial joint laxity, varus alignment of the knee, or quadriceps muscle strength (maximum voluntary isometric contraction.

Factors such as excess weight, joint trauma, developmental deformities, weakness of the quadriceps muscle, and abnormal tibial rotation are identified as risk factors for developing OA of the knee.[16]

Posttraumatic arthritis of the knee occurs in response to any injury that affects the joint structures, particularly following acute ligament and meniscal tears. Joint swelling (effusion) may be immediate, indicating bleeding within the joint, or progressive (more than 4 hours to develop), indicating serous

effusion. Acute symptoms include pain, limited motion, and muscle guarding. Trauma, including repetitive microtrauma, is a common cause of degenerative changes in the knee joint.

Rheumatoid Arthritis

Early-stage rheumatoid arthritis (RA) usually manifests first in the hands and feet. With progression of the disease process, the knees also may become involved. The joints become warm and swollen, and limited motion develops. In addition, a genu valgum deformity commonly develops during the advanced stages of this disease.

Postimmobilization Hypomobility

When the knee has been immobilized for several weeks or longer, such as during healing of a fracture or after surgery, the capsule, muscles, and soft tissue develop contractures, and motion becomes restricted. Adhesions may restrict caudal gliding of the patella, which limits knee flexion, and may cause pain as the patella is compressed against the femur. An extensor lag may occur with active knee extension if the patella does not glide proximally when the quadriceps muscle contracts.[274] This usually occurs after operative repairs of some knee ligaments, when the knee is immobilized in flexion for a prolonged period.

Common Structural and Functional Impairments

- With joint involvement, the pattern of restriction at the knee is usually more loss of flexion than extension.
- When there is effusion (swelling within the joint), the joint assumes a position near 25° of flexion, the position at which there is the greatest capsular distensibility. Little motion is possible because of the swelling.
- Symptoms of joint involvement, such as distention, stiffness, pain, and reflex quadriceps inhibition, may cause extensor (quadriceps) lag in which the active range of knee extension is less than the passive range available.[274]
- Impaired balance responses also have been reported in patients with arthritis.[295]

Common Activity Limitations and Participation Restrictions (Functional Limitations and Disabilities)

- With acute symptoms and in advanced stages of degeneration, there is pain during motion, weight bearing, and gait that may interfere with work or routine household and community activities.
- There is limitation of, or difficulty controlling, weight-bearing activities that involve knee flexion, such as sitting down and rising from a chair or a commode, descending or ascending stairs, stooping, or squatting.[75]
- With end-stage arthritis, physical activity is markedly curtailed with less participation in leisure activities (e.g., walking, gardening, swimming, athletic activities) and household activities (e.g., dusting, washing floors, cleaning, shopping).[285]

Joint Hypomobility: Management—Protection Phase

See Chapter 11 for general guidelines for the management of acute joint lesions and specific guidelines for OA and RA.

Control Pain and Protect the Joint

Patient education. It is important to teach the patient methods to protect the joint including bed positioning, use of splints in order to avoid deforming contractures, range-of-motion (ROM) and muscle-setting exercises to maintain mobility and promote blood flow, and safe functional activities that reduce stresses on the knee.

Functional adaptations. Instruct the patient to minimize stair-climbing, use elevated seats on commodes, and avoid deep-seated or low chairs in order to minimize stressful knee flexion ranges while bearing weight. If necessary during an acute flare of arthritis, have the patient use crutches, canes, or a walker to distribute forces through the upper extremities while walking.

Maintain Soft Tissue and Joint Mobility

Passive, active-assistive, or active ROM. Use ROM techniques within the limits of pain and available motion. The patient may be able to perform active ROM in the gravity-eliminated, side-lying position, or self-assisted ROM.

Grade I or II joint distraction and anterior/posterior glides. Apply gentle joint techniques, if tolerated, with the joint in or near resting position (25° flexion). These techniques are used to inhibit pain as well as maintain joint mobility. Stretching is contraindicated at this stage.

Maintain Muscle Function and Prevent Patellar Adhesions

Setting exercises. Perform pain-free quadriceps ("quad sets") and hamstring muscle-setting exercises with the knee in various pain-free positions, quad sets with leg raises, and submaximal closed-chain muscle setting exercises. Muscle-setting exercises are described in detail in the last section of this chapter. Quad sets may help maintain mobility of the patella when the tibiofemoral joint is immobilized and therefore are routinely taught following surgery or when the joint is immobilized.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

As joint effusion decreases and joint tissues are able to tolerate increased stresses, the goals of treatment change to deal with the impairments that interfere with functional activities. The patient is progressed through controlled motion exercises and activities that focus on safely returning to desired functional outcomes.

Educate the Patient

- Inform the patient about his or her condition, what to expect regarding recovery, and how to protect the joints.
- Teach the patient safe exercises to do at home, how to progress them, and how to modify them if symptoms are exacerbated by the disease or from overuse. Exercises that include specifically designed strengthening, stretching, ROM, and use of a stationary bicycle have been shown to improve functional outcomes in patients with OA in a home exercise program.[58] It is important to emphasize that maintaining strength in the supporting muscles helps protect and stabilize the joint and that balance exercises help reduce the incidence of falls.
- Instruct the patient to perform active ROM and muscle-setting techniques frequently during the day, especially prior to bearing weight, in order to reduce the painful symptoms that occur with initial weight bearing.[75]
- The patient with OA or RA should be cautioned to alternate activity with rest.

FOCUS ON EVIDENCE

In a randomized, controlled study[58] of 134 patients with OA of the knees, a clinic treatment group (n=66) underwent treatment that consisted of supervised exercise, manual therapy, and home exercises for 4 weeks. A home exercise group (n=68) performed home exercises only (instructions and a follow-up examination were provided for the same exercises as the clinic treatment group). Outcomes that were measured consisted of the distance walked in 6 minutes and the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). Both groups improved in the outcome measures at 4 weeks; the clinic treatment group improved 52% on the WOMAC, whereas the home exercise group improved 26%. Both groups improved 10% on the 6-minute walk distances. At 1 year, there was no difference between the groups, and both groups demonstrated improvement over baseline measurements. However, it was noted that the clinic treatment group was less likely to be taking medication for the arthritis and was more satisfied with the outcome of their rehabilitation. The lack of long-term maintenance highlights the importance of patient education and adherence to a prescriptive long-term home exercise program.

Decrease Pain from Mechanical Stress

Continue use of assistive devices for ambulation, if necessary. The patient may progress to using less assistance or may ambulate for periods without assistance. Continue use of elevated seats on commodes and chairs, if needed, to reduce the mechanical stresses imposed when attempting to stand.[75]

Increase Joint Play and Range of Motion

PRECAUTION: Do not increase ROM unless the patient has sufficient strength to control the motion already available. A mobile weight-bearing joint with inadequate muscle control causes impaired stability and makes lower extremity weight-bearing function difficult.

Joint mobilization. When there is loss of joint play and decreased mobility, joint mobilization techniques should be used. Apply grade III or IV sustained or oscillatory techniques to the tibiofemoral and patellofemoral articulations with the joint positioned at the end of its available range before applying the mobilization technique. (See Figures 5.49 through 5.54 and their descriptions in Chapter 5.) As ROM increases, it is important to emphasize the rotational accessory motions that accompany flexion and extension.[129]

- To increase *flexion*, position the tibia in medial rotation and apply the posterior glide against the anterior aspect of the medial tibial plateau.
- To increase *extension*, position the tibia in lateral rotation and apply the anterior glide against the posterior aspect of the lateral tibial plateau.
- Medial and lateral gliding of the tibia on the femur may also be done to regain mobility for flexion and extension.

Stretching techniques. Passive and PNF stretching techniques are used to increase extensibility of the muscles and extracapsular noncontractile soft tissues that restrict knee motion. Specific techniques are described in the last section of this chapter.

PRECAUTIONS: Techniques that force the knee into flexion by using the tibia as a lever or by using strong quadriceps contractions (during a hold-relax maneuver) may exacerbate joint symptoms.

Incorporate the following to minimize joint trauma from stretching.

- Mobilize the patellofemoral and tibiofemoral joints before stretching in order to improve gliding of the joint surfaces during the stretch maneuvers.
- Apply soft tissue or friction massage to loosen adhesions or contractures prior to stretching. Include deep massage around the border of the patella.
- Modify the intensity of contraction when applying PNF stretching techniques to range-limiting muscles in order to decrease the effects of joint compression. If the hold-relax technique aggravates anterior knee pain when attempting to increase knee flexion, use the agonist contraction technique to the hamstring muscles to minimize compression from a strong quadriceps muscle contraction.
- Use low-intensity, long-duration stretches within the patient's tolerance.

Mobilization with movement. Mobilization with movement (MWM) may be applied to increase ROM and/or decrease the pain associated with movement by improving joint tracking. Mulligan[190] states that MWM is more effective with loss of flexion than extension. The principles of MWM are described in Chapter 5.

MWM: Lateral or Medial Glides

Patient position and procedure: Supine for extension or prone for flexion. Apply a pain-free medial or lateral glide to the tibial plateau manually or through the use of a mobilization belt. The direction of glide is often in the direction of the pain (i.e., lateral knee pain responds best to a lateral glide of the tibia and medial knee pain to a medial glide).[190]

- While sustaining the mobilization, ask the patient to move to the end of the available pain-free range of flexion or extension.
- Add pain-free overpressure to achieve the benefit of end-range loading.

MWM: Internal Tibial Rotation for Flexion—Manual Technique

Patient position and procedure: Supine with the knee flexed to the end of its available pain-free range. Apply internal rotation mobilization to the tibia with manual pressure from one hand on the anteromedial tibial plateau simultaneously with pressure from the other hand on the posterolateral tibial plateau, posterior to the fibular head.

- Sustain the internal rotation mobilization, and ask the patient to flex the knee through the use of a mobilization belt looped around the foot. Hold the position at the end of the available pain-free range for several seconds (Fig. 21.6).

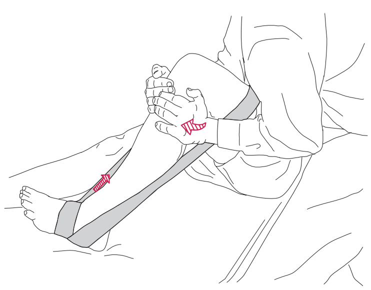

FIGURE 21.6 MWM with internal tibial rotation to increase knee flexion.

MWM: Internal Rotation for Flexion—Self-Treatment

Patient position and procedure: Standing with the foot of the involved leg on a chair and knee flexed. Position the foot such that the tibia is internally rotated. Have the patient apply internal rotation pressure against the anteromedial and posterolateral tibial plateaus and shift the weight forward to flex the knee to the end of the available pain-free range (Fig. 21.7).

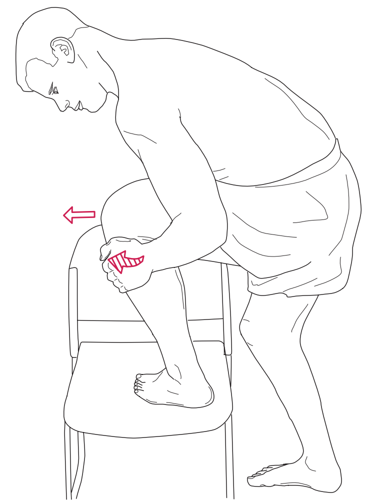

FIGURE 21.7 Self-treatment using MWM with internal tibial rotation to increase knee flexion.

Improve Muscle Performance in Supporting Muscles

Exercises identified in this section are described in detail in the last section of this chapter.

Progressive strengthening. Begin with multiple-angle isometrics to both knee flexors and extensors and active ROM exercises in open- and closed-chain positions using a moderate progression of repetitions and resistance in arcs of pain-free motion. Exercise intensity should be within the tolerance of the joint and not exacerbate symptoms.

- When performing open-chain exercises, patients experience less pain with faster speeds and lighter resistance than when doing the exercises slowly with heavy resistance.
- Resistance through the midrange (45° to 90°) tends to exacerbate patellofemoral pain because of the compressive forces on the patella. Apply resistance in arcs of motion that are pain-free on either side of the symptomatic range. This could be done using manual or mechanical resistance in the pain-free ranges.
- Strengthen both hip and ankle musculature using open- and closed-chain exercises in order to balance forces throughout the lower extremities and progress the patient toward functional independence. (See Chapters 20 and 22 for hip and ankle exercises.)

Muscular endurance training. Increase repetitions at each resistance level before increasing resistance.

Functional training. Climbing steps, sitting down and rising up from chairs and commodes, and using safe body mechanics to lift objects from the floor are often compromised in individuals with knee arthritis. It is imperative to strengthen the knee musculature using modifications of

functional activities, progressing the difficulty as strength improves.

- ***Step-up and step-down exercises (forward, backward, lateral).*** Begin with a low step height, and progress to the step height the patient requires for home and community mobility. Progress to functional activities, such as climbing stairs or ladders, depending on the desired outcomes.
- ***Wall slides and minisquats to 90°, if tolerated.*** Stay within a range that does not exacerbate symptoms or cause crepitation. Practice sitting down and sit-to-stand with arm assistance to and from various chair heights. Determine if chair adaptation is needed for safe function. Correct lower extremity alignment and posterior weight shift are imperative to activate and strengthen the gluteus maximus for total lower extremity control.
- ***Partial lunges.*** This activity is progressed to include lunging to pick up small objects from the floor. Lunges are an effective way to teach body mechanics for an individual with unilateral knee impairment. Concentrate on trunk control during the motion. Have the patient activate the lumbopelvic musculature to stabilize the pelvis during the lunge activity.
- ***Balance activities.*** Balance activities are initiated at the level the patient can control. Detailed suggestions are outlined in Chapters 8 and 23.
- ***Ambulation.*** Decrease use of assistive devices as quadriceps strength improves to a manual muscle test level of 4/5 and as gait is normalized and symmetrical. Practice walking on a variety of terrains and up and down ramps, and reverse directions, first with assistance and then independently.

Improve Cardiopulmonary Endurance

Select and adapt activities to minimize irritating stresses on the knee.

- ***Swimming, water aerobics, and aquatic exercises*** provide an environment for improving muscular and cardiopulmonary function with minimal joint trauma.
- ***Bicycling*** is a low-impact form of exercise. Adjust the seat height so the knee goes into complete extension (but not hyperextension) when the pedal is down. On a stationary bike, use low resistance.
- ***High impact activities—with caution.*** For some patients, progression to running or jumping rope and other high-impact, faster-paced, or more intense activities can be undertaken so long as the joint remains asymptomatic. If joint deformity is present and proper biomechanics cannot be restored, the patient probably cannot progress to these activities.

Outcomes

Two systematic reviews of studies designed to examine evidence of the effects of exercise in the management of hip and knee OA describe support for aerobic exercise and strengthening exercises to reduce pain and disability.[239,240] The consensus of expert opinion cited by Roddy[239] is that: (1) there are few contraindications; and (2) exercise is relatively safe in patients with OA, but it should be individualized and patient-centered with consideration for age, comorbidity, and general mobility. Similarly the Cochrane Database of Systematic Reviews,[81] the Philadelphia Panel Evidence-Based Clinical Practice Guidelines,[223] and more recently a summary of systematic reviews of studies on physical therapy interventions for patients with knee OA[123] indicated that there is evidence to support strengthening, stretching, and functional exercises as interventions for the management of knee pain as the result of OA and to improve physical function.

In another study that followed 285 patients with knee OA for 3 years, investigators found that factors that protected the individuals from poor functional outcomes included strength and activity level, as well as factors such as mental health, self-efficacy, and social support.[255]

An outcome review[57] summarized that moderate- or high-intensity exercises for patients with RA have minimal effect on the disease activity but that there is insufficient radiological evidence on the effect on large joints. The review also indicated that long-term moderate- or high-intensity exercises that are individualized to protect radiologically damaged joints improve aerobic capacity, muscle strength, functional ability, and psychological well-being of patients with RA. A 24-month follow-up study by the same researchers revealed a better attainment of muscle strength in participants who continued with the exercise program than those who did not.[56]

Finally, a recent systematic review by the Osteoarthritis Research Society International recommended a referral to a physical therapy as a nonpharmacological intervention to improve functional capacity of patients with symptomatic OA underscoring the important role of physical therapy for regaining function.[313]

Joint Surgery and Postoperative Management

A range of surgical options for management of arthritis of the knee is available when joint pain and synovitis cannot be controlled with conservative therapy and appropriate medical management or when destruction of articular surfaces, deformity, or restriction of motion have progressed to the point that functional abilities are significantly impaired.

The surgical procedure selected depends on the patient's signs and symptoms, activity level and age, type of disease, severity of articular damage or joint deformity, and involvement of other joints. *Arthroscopic débridement* and *lavage* are used to remove loose bodies that may be causing swelling and intermittent locking of the knee.[17,251] A number of procedures to repair damaged articular cartilage have been developed. *Abrasion arthroplasty*, a procedure designed to smooth worn articular surfaces and stimulate growth of replacement cartilage has met with only limited success.[17,251] More recently

developed procedures used to repair small, localized articular cartilage defects of the knee, such as *microfracture*,[92,253] *osteochondral autograft transplantation (mosaicplasty)*,[12,103,137] and *autologous chondrocyte implantation*,[45,93,298] appear to hold promise.

Synovectomy was the procedure of choice in the past for a young patient with unremitting joint effusion, synovial proliferation, and/or pain as the result of RA or juvenile RA (JRA) but with minimal destruction of articular surfaces.[35,218,251] However, it is now used infrequently. *Osteotomy* of the distal femur or proximal tibia (an extraarticular procedure) redistributes weight-bearing forces between the tibia and femur in an attempt to reduce joint pain during weight-bearing activities and delay the need for arthroplasty of the knee.[17,35,251] In the past, high tibial osteotomy was considered a surgical option for the active patient younger than age 50 to 55 years without active systemic disease and significant limitation of motion or joint deformity. However, because arthroplasty is now performed in younger patients than was the case a decade or two ago, osteotomy is an infrequently selected surgical option.[39]

When erosion of articular surfaces becomes severe and pain is unremitting, *total knee arthroplasty (total knee replacement)* is the surgical procedure of choice to reduce pain, correct deformity, and improve functional movement.[119,160,249] Only in highly selective situations is *arthrodesis* (fusion) of the knee used as a salvage procedure to provide a patient with a stable and pain-free knee.

Regardless of the type of surgery selected, the goals of surgery and postoperative management are to: (1) reduce pain; (2) correct deformity or instability; and (3) restore lower extremity function. Carefully progressed postoperative rehabilitation is essential for optimal functional outcomes.

Repair of Articular Cartilage Defects

Injuries of the ligaments or menisci of the knee and acute or chronic patellofemoral dysfunction often are associated with damage to an articular surface of the knee. Surgical management of chondral defects has proved challenging because of the limited capacity of articular cartilage to heal.[45,144] However, several surgical procedures introduced during the 1990s are available for repairing small lesions in the symptomatic knee when nonoperative management or arthroscopic débridement and lavage have been unsuccessful.

Procedures include microfracture,[92,144,253,275] osteochondral autograft transplantation/mosaicplasty,[12,18,103,137] and autologous chondrocyte implantation.[93,144,298] These procedures are designed to stimulate growth of hyaline cartilage for repair of focal defects of articular cartilage and for preventing progressive deterioration of joint cartilage leading to osteoarthritis.[45,144]

Descriptions of procedures specific to the knee are presented in this section. Regardless of the cartilage procedure selected, each requires the patient's ability and willingness to adhere to a lengthy rehabilitation process.

Indications for Surgery

The primary indication for repair of an articular cartilage defect is a symptomatic knee caused by a small to relatively large focal lesion of the tibiofemoral or patellofemoral joint. Sites typically involved are the weight-bearing portions of the medial or lateral femoral condyles, the trochlear groove, and the articulating facets of the patella.

Selection criteria when choosing the procedure include the size of the chondral lesion (in general, defects greater than 1 to 2 cm^2 but no more than 4 cm^2 are considered suitable for repair), the depth of the lesion, the location of the lesion, the elapsed time since the occurrence of the defect, and the patient's age and intended activity level. Most patients who undergo articular cartilage repair are young and active.[45,144]

CLINICAL TIP

A system for classification of cartilage lesions developed by the International Cartilage Repair Society is based on a five-point grading scale. Lesions range from grade 0 (normal cartilage without notable defects) to grade 4 (severely abnormal, full-thickness osteochondral defects).[31]

Procedures

Microfracture. Microfracture is indicated for repair of very small defects, usually of the medial or lateral femoral condyle or the posterior aspect of the patella. The procedure is performed arthroscopically and involves the use of a nonmotorized awl to systematically penetrate the subchondral bone and expose the bone marrow. The procedure is designed to stimulate a marrow-based repair response leading to local ingrowth of cartilaginous repair tissue (fibrocartilage) to repair the lesion.[45,92,144,253,275]

Osteochondral autograft transplantation/mosaicplasty. For focal lesions involving chondral or subchondral tissue of the weight-bearing surfaces of the knee, osteochondral graft transplantation may be selected. It is an arthroscopic or mini open procedure involving transplantation of intact articular cartilage along with some underlying bone, resulting in a bone-to-bone graft.[12,18,103,137] Rather than using a single piece of tissue and creating a similar size osteochondral defect at the donor site, mosaicplasty is used in which multiple, small-diameter osteochondral plugs are harvested and press-fit into the chondral defect.[12,18,103,137]

Donor sites typically are nonweight-bearing, nonarticulating portions of the supracondylar ridge of the lateral femoral articulating surfaces or elsewhere in the knee.[12]

Autologous chondrocyte implantation. This procedure, also referred to as chondrocyte transplantation, is used for full-thickness chondral and osteochondral defects (2 to 4 cm^2) of the femoral condyles or patella.[45,93,298] The procedure occurs in two stages. First, healthy articular cartilage is harvested arthroscopically from the patient. Then chondrocytes are

extracted from the articular cartilage, cultured for several weeks, and processed in a laboratory to increase the volume of healthy tissue. The second phase is the implantation phase, which currently requires an arthrotomy (open procedure). After the chondral defect sites have been débrided, they are covered with a periosteal patch, typically harvested from the proximal medial tibia and secured with fibrin glue. Then millions of autologous chondrocytes are injected under the patch and into the articular defect.

Patient positioning during the first 4 hours after surgery is critical. Patients are positioned so the effect of gravity distributes the chondrocytes evenly along the base of the defect.[232] For example, after a patellofemoral repair, the patient is placed in the prone position.

Maturation of the implanted chondrocytes is a lengthy process. It may take as long 6 months for the graft site to become firm and as long as 9 months for the graft to become as durable as the healthy tissue surrounding the graft.[93]

Osteochondral allograft transplantation. For defects larger than 4 cm^2, the only option for repair—although used infrequently—is an osteochondral allograft of intact articular cartilage from a cadaveric donor. However, only fresh, intact grafts, which are in limited supply and can be stored only a few days, can be used. A frozen allograft cannot be used because freezing the graft material kills the articular chondrocytes, leading to graft failure.[45,144]

Other procedures. If coexisting ligament or meniscus pathology or tibiofemoral or patellofemoral malalignment are identified prior to or concomitant with surgical repair, reconstruction or realignment must be carried out for the articular cartilage repair to be successful. The most common procedures are ACL reconstruction and meniscus repair for tibiofemoral articular defects and lateral retinacular release for patellar defects.[12,93]

Postoperative Management

A cautiously progressed and closely monitored rehabilitation program after articular cartilage repair procedures is critical for a successful outcome. The components and progression of a rehabilitation program, including exercise, ambulation, and functional activities, must be graded to protect the repair or graft and prevent further articular damage while applying controlled stresses to stimulate the healing process.

The progression of postoperative exercises and functional activities after microfracture, osteochondral autologous transplantation, and autologous chondrocyte implantation has many common elements, yet they vary to some degree. Detailed postoperative protocols, as well as comprehensive clinical practice guideline for each of these procedures, have been published in the literature.[12,93,137,148,232] In addition to the type of repair employed, the rehabilitation progression is based on the size, depth, and location of the articular defect, the need for concomitant surgical procedures, and patient-related factors such as age, body mass index, health history, and preoperative activity level.

The goals during rehabilitation after articular cartilage repair are similar to those found for most knee rehabilitation programs presented in this chapter. Protected weight bearing over an extended period of time and early motion are essential after articular cartilage repair to promote maturation and maintain the health of the repaired or implanted cartilage. Special considerations for exercise and weight bearing associated with the various articular cartilage procedures are summarized in Box 21.2.[12,93,137,148,232,298]

BOX 21.2 Special Considerations and Precautions for Rehabilitation after Articular Cartilage Repair*

- The larger the lesion, the slower/more cautious the progression of rehabilitation.
- Early but controlled ROM is advocated to facilitate the healing process and begins immediately or within a day or two after surgery (CPM, passive or assisted exercise).
- Controlled (protected) weight bearing initiated as early as possible is beneficial to the healing process, but adherence to weight-bearing restrictions is critical.
- Duration and degree of weight-bearing restrictions vary with the size of the defect and type and location of the repair.*
  - Longer period of protected weight bearing for osteochondral transplantation/mosaicplasty and autologous chondrocyte implantation than after microfracture
  - Longer period of protected weight bearing for a femoral condyle repair (up to 8 to 12 weeks) than for a patellar defect (up to 4 weeks)
  - Full weight bearing is delayed for as long as 8 to 12 weeks
- Protective bracing may be used postoperatively.
  - Typically locked in extension, except during exercise
  - Worn during weight-bearing activities 4 to 6 weeks
  - Worn during sleep for as many as 4 weeks
  - An unloading brace may be used after repair of a femoral condyle defect to shift the weight away from the repair during the period of protected weight bearing
- Return to functional activity.[148]
  - Generally, low-impact sports, such as swimming, skating, rollerblading, and cycling, are permitted at about 6 months
  - High-impact sports, such as jogging, running, and aerobics are permitted at:
    - 8–9 months for small lesions
    - 9–12 months for larger lesions
  - Higher-impact sports, such as tennis, basketball, football, and baseball, are permitted at 12–18 months.

*Considerations and precautions vary with the size, depth, and location of the articular defect, type of surgical repair and concomitant procedures, and patient-related factors (age, body mass index, health history, preoperative activity level).

Total Knee Arthroplasty

Total knee arthroplasty (TKA), also called total knee replacement, is a widely performed procedure for advanced arthritis of the knee primarily in older patients (≥70 years of age) with osteoarthritis. However, during the decade between 1990 and 2000, the proportion of younger patients undergoing TKA increased significantly. During this period the proportion of knee replacements performed in the 40- to 49-year-old age group increased by 95.2% and in the 50- to 59-year-old age group by 53.7%. This indicates the criteria for TKA, traditionally reserved for the patient older than 65 years of age, have broadened.[122]

The primary goals of TKA are to relieve pain and improve a patient's physical function and quality of life.[184,249]

Indications for Surgery

The following are common indications for TKA.[119,160,249]

- Severe joint pain with weight bearing or motion that compromises functional abilities
- Extensive destruction of articular cartilage of the knee secondary to advanced arthritis
- Marked deformity of the knee such as genu varum or valgum
- Gross instability or limitation of motion
- Failure of nonoperative management or a previous surgical procedure

BOX 21.3 Total Knee Arthroplasty: Design, Surgical Approach, Fixation

Number of Compartments Replaced
- Unicompartmental: only medial or lateral joint surfaces replaced
- Bicompartmental: entire femoral and tibial surfaces replaced
- Tricompartmental: femoral, tibial, and patellar surfaces replaced

Implant Design
- Degree of constraint
  - Unconstrained: no inherent stability in the implant design; used primarily with unicompartmental arthroplasty
  - Semiconstrained: provides some degree of stability with little compromise of mobility; most common design used for total knee arthroplasty
  - Fully constrained: significant congruency of components; most inherent stability but considerable limitation of motion
- Fixed-bearing or mobile-bearing design
- Cruciate-retaining or cruciate-excising/substituting

Surgical Approach
- Standard/traditional or minimally invasive
- Quadriceps-splitting or quadriceps-sparing

Implant Fixation
- Cemented
- Uncemented
- Hybrid

Procedure

Background

Prosthetic replacement of one or more surfaces of the knee joint began to develop during the 1960s. To address problems with early designs, semiconstrained, two-component designs evolved. For the patient with severe anterior knee pain resulting from advanced patellofemoral deterioration, a three-component, total condylar design that included resurfacing the patellofemoral joint was developed. For advanced arthritis of just the medial or lateral aspect of the knee, the unicompartmental (unicondylar) knee arthroplasty (UKA) was developed as an alternative to TKA.[192,212,243,284]

A therapist's knowledge of the different types of TKA and UKA used today enhances communication between the therapist and surgeon and provides a foundation for decisions made during rehabilitation.

Types of knee arthroplasty. Contemporary knee replacement procedures can be divided into several categories based on component design, surgical approach, and type of fixation (Box 21.3).[120,160,189,192,249,284] One category is based on the number of components implanted or articulating surfaces replaced. Another is based on the degree of constraint (i.e., the amount of inherent congruency/stability in the design). Most TKA procedures today involve a two-component (bicompartmental), semiconstrained prosthetic system to replace the proximal tibia and distal femur (Fig. 21.8). These systems typically are composed of a modular or nonmodular femoral component with a metal articulating surface and a single all-polyethylene or metal-backed modular or nonmodular tibial component with a polyethylene articulating surface.[120,160,249]

Occasionally, a tricompartmental design, which also resurfaces the posterior aspect of the patella with a polyethylene component, is selected if the patellofemoral joint is symptomatic.[119,160,249] For the younger patient (< 55 years of age) with advanced disease of only the medial or lateral aspect of the knee joint, a unicompartmental design often is selected to replace just one tibial and one femoral condyle.[192,212,243,249,284]

Intact medial and lateral collateral ligaments are necessary prerequisites for semiconstrained and unconstrained TKA.[119,160,249] Fully constrained designs, now used infrequently, are reserved for the low-demand patient who has marked instability of the knee, extensive bone loss, or severe deformity or who has had previous TKA revisions.[119,160] Contemporary fully constrained designs are not hinged but have inherent medial-lateral (ML) and anterior-posterior (AP) stability and some degree of rotation of the tibia on the femur to lessen the problem of progressive loosening of the prosthetic components over time.[119,160]

TKA designs also are classified as mobile-bearing or fixed-bearing. The most recent development in the evolution of TKA is the introduction of the mobile-bearing, bicompartmental prosthetic knee. A mobile-bearing knee has a rotating

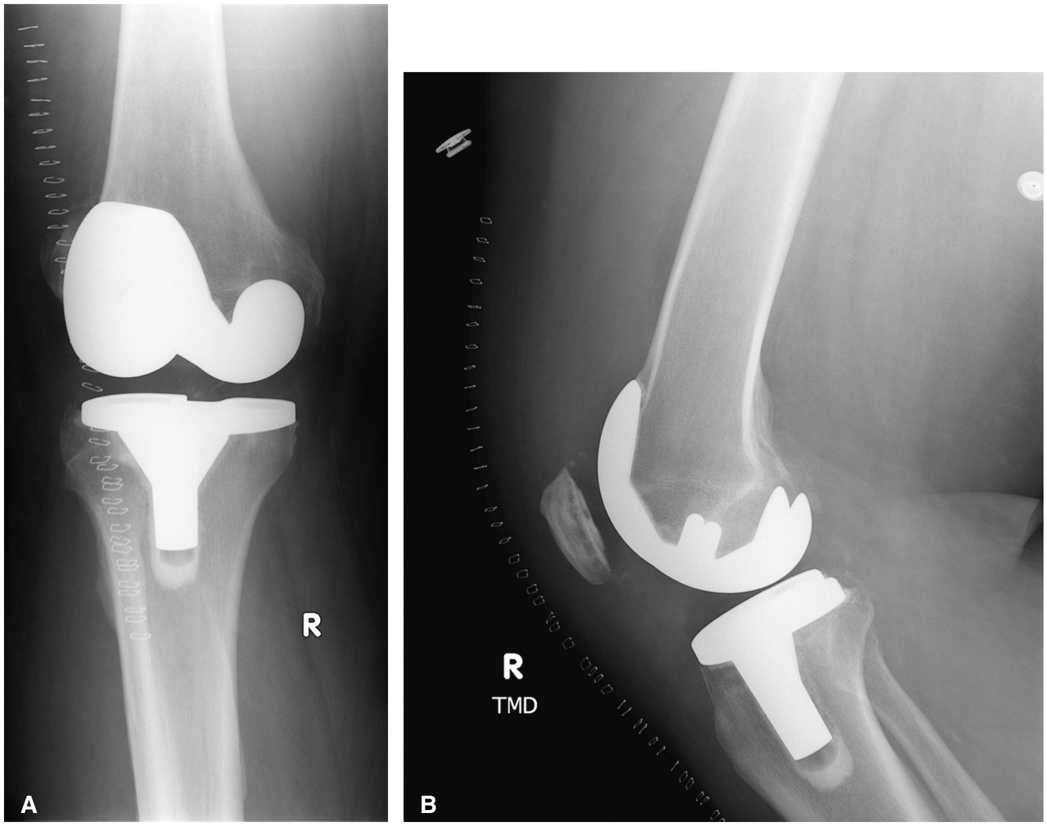

FIGURE 21.8 Posterior cruciate-retaining total knee arthroplasty of the right knee with cemented fixation. **(A)** Anteroposterior view. **(B)** Lateral view. Preoperative ROM is 0° to 125°; ROM 1 month after surgery is 0° to 120°.

platform inserted between the femoral and tibial components whose top surface is congruent with the femoral implant (round-on-round articulation) but whose undersurface is flat for rotation and sliding of the tibial component (flat-on-flat articulation).[38,189,249] A fixed-bearing knee does not have such an insert.[60,249] The purpose of the mobile-bearing insert is to decrease long-term wear of the polyethylene tibial component. A mobile-bearing knee design is recommended most often for the active patient, younger than 55 to 65 years of age.[249]

Another way to classify TKA design is based on the status of the posterior cruciate ligament (PCL). Designs are described as cruciate-retaining or cruciate-excising/substituting.[119,160,208,211,249] Although the ACL is routinely excised during knee replacement—except with UKA—the PCL can be preserved or sacrificed. If the PCL is intact to provide posterior stability to the knee, one of several cruciate-retaining designs that require less congruency and allow some degree of AP glide can be used. If the PCL is irreparably deficient, a cruciate-excising/substituting prosthesis is selected. This type of design has inherent posterior stability from the congruency of the components, a posterior prominence in the tibial component, or a cam-post mechanism built into the design. Cruciate-retaining and cruciate-excising designs can have a fixed-bearing or mobile-bearing design.[249]

Surgical approach. TKA and UKA procedures are also described in terms of the surgical approach employed.[26,41,192,249] Since the inception of knee arthroplasty, an open approach requiring a relatively long anterior incision traditionally has been employed to provide sufficient exposure of the knee joint during the procedure. A recent advance is the development of *minimally invasive* knee arthroplasty.[26,192] As with traditional joint arthroplasty, minimally invasive arthroplasty is an open procedure. However, minimally invasive TKA involves a smaller incision and less soft tissue disruption to reduce postoperative pain and increase the rate of postoperative recovery. Standard (traditional) and minimally invasive surgical approaches are described later in this section.

Fixation. The method of fixation—cemented, uncemented, or "hybrid"—is another way to classify TKA procedures—that is, implants are held in place with acrylic cement, bone ingrowth (uncemented), or a combination of these two methods.[160,210,231,297] Initially, almost all total knee replacements relied on cemented fixation. In fact, cemented fixation revolutionized knee arthroplasty.[119,231] However, a long-term complication associated with early designs of cemented prostheses was biomechanical loosening, primarily of the tibial component at the bone-cement interface. Young, active patients were believed to be at highest risk for component loosening.[297]

To address the problem of loosening, cementless (biological) fixation relying on rapid growth of bone into the surfaces of a porous-coated or beaded prosthesis was introduced and recommended primarily for the young, active

patient.[119,160,210,249,297] In addition, the use of a hydroxyapatite coating on the prosthesis has been advocated to enhance the ingrowth of bone.[251] However, long-term follow-up demonstrated that although the femoral component reliably achieved fixation to bone tibial component, loosening occurred at an even higher rate with all-cementless fixation compared with cemented fixation.[210,297] This finding gave rise to the "hybrid" TKA, which combines cemented fixation of the tibial component and cementless fixation of the femoral component.

Currently, all-cemented fixation is used most often and all-cementless used least often. A surgeon's decision whether to employ hybrid fixation is based on the patient's age, bone quality, and expected activity level and the tightness of fit of the femoral component achieved during surgery.[249] Design modifications to augment fixation of the tibial component (e.g., with pegs or screws) continue, although the long-term value of these design changes has yet to be determined.[119,311]

In summary, research continues on the biomechanics of knee arthroplasty, modifications of designs, development of better methods of fixation and new materials with better wear qualities, as well as improved surgical techniques and use of sophisticated instrumentation for alignment and placement of prosthetic components. Ongoing developments in all of these areas will continue to contribute to the success of current-day and improvement of future TKA procedures.[249,311]

Operative Overview

One of several variations of standard or minimally invasive approaches with an incision along the midline or anteromedial aspect of the knee can be used. Key features of these two types of approaches are compared in Table 21.2.[26,41,192,249] A quadriceps-splitting or a quadriceps-sparing approach is used to reach the capsule for an arthrotomy. The knee is flexed; and osteophytes, menisci, and the ACL are resected. If a posterior cruciate-substituting prosthesis is to be implanted, the PCL is also excised.

A series of surgical techniques are performed prior to inserting the implants.[120,249] Contemporary TKA employs computer-assisted, image-guided surgery to ensure precise placement and alignment of the components. Small portions of the distal femur and proximal tibia are removed and prepared for the implants. If a patellar implant is indicated, the patellar surface also is prepared and the prosthesis inserted. After trial components are inserted, soft tissue tension, collateral ligament balance, ROM, and patellar tracking are assessed. The lateral retinaculum may be released to improve patellar tracking.[138,249] Permanent components are inserted, and the capsule and other soft tissues are repaired. The area is thoroughly irrigated, and the wound is closed with the knee positioned in extension and a small suction drain in place. A sterile dressing is placed over the incision, and the area is covered from foot to thigh with a compression wrap.

Complications

Overall, the incidence of complications after TKA is low. Intraoperative complications during knee arthroplasty, such as an intercondylar fracture or damage to a peripheral nerve (e.g., the peroneal nerve), are uncommon. Because minimally invasive TKA is considered more technically challenging than conventional TKA, early reports suggest that the rate of intraoperative complications, such as fracture or malpositioning of an implant, is higher with a minimally invasive than a standard approach.[26] An increased incidence of intraoperative technical errors, which can affect outcomes, is associated with patient obesity.[124]

Early and late postoperative complications include infection, joint instability, polyethylene wear, and component loosening. As with arthroplasty of other joints, there is a risk of wound-healing problems and deep vein thrombosis (DVT) during the first few months after surgery. Although the incidence of deep periprosthetic infection is low, it is the most common reason for early failure and the need for revision arthroplasty. In contrast, polyethylene wear of the patellar and tibial components is the most common late complication requiring revision.[52,191] The incidence of biomechanical loosening has been reduced significantly with the newer prosthetic designs and improved surgical techniques.[191,250] If mechanical loosening develops over time, it occurs most often at the tibial component and more often with cementless or hybrid TKAs than fully cemented replacements.[210]

Other postoperative complications that can compromise a patient's functional recovery include limited knee flexion, joint instability leading to subluxation,[52,249] and patellar

TABLE 21.2 Features of Standard and Minimally Invasive Surgical Approaches for Total Knee Arthroplasty

Standard Traditional Approach	Minimally Invasive Approach
▪ Anteromedial parapatellar vertical or curved incision from the distal aspect of the femoral shaft, running medial of the patella to just medial of the tibial tubercle, ranging from 8–12 cm[26] or 13–15 cm[249] in length ▪ Necessary soft tissue releases prior to eversion of the patella ▪ Anterior capsule release ▪ Dislocation of the tibiofemoral joint prior to bone cuts and implantation of components	▪ Reduced length of anteromedial skin incision 6–9 cm in length[26] ▪ No patellar eversion ▪ Anterior capsule release ▪ No tibiofemoral dislocation ▪ In situ bone cuts ▪ In situ implantation of components

instability or tracking problems leading to impaired function of the extensor mechanism (most often an extensor lag).[138,249] Additionally, obesity has been shown to limit outcomes in a patient's mobility after TKA compared to nonobese patients.[124]

Postoperative Management

Goals and interventions during progressive phases of postoperative rehabilitation after TKA are summarized in Table 21.3. Guidelines are similar for management after UKA. Interventions also may include preoperative patient education on an individual or group basis.[251] Following surgery, patients routinely receive gait training and exercise instruction while hospitalized and in a subacute rehabilitation facility. Many patients also receive home-based or outpatient therapy after discharge from inpatient care.

A patient is advanced from one phase of rehabilitation to the next based on an evaluation of their signs and symptoms and responses to selected interventions rather than solely at designated time periods. Accordingly, the timelines noted in Table 21.3 and described in the following sections are intended to serve only as general guidelines.

NOTE: The postoperative guidelines in Table 21.3 and the following sections reflect recommendations for patients who have undergone *primary* TKA in which a *standard* surgical approach was used. The suggested timelines for the progression of exercises and weight bearing tend to be more rapid after UKA than TKA and minimally invasive compared with traditional

TABLE 21.3 Total Knee Arthroplasty: Interventions for Each Phase of Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phases: Weeks 4–8	Minimum Protection/Return to Function Phases: Beyond Week 8
Patient presentation			
	▪ Patient enters rehabilitation 1–2 days postoperatively ▪ Postoperative compression dressing ▪ Postop pain controlled ▪ ROM 10°–60° ▪ Weight bearing as tolerated with cemented prosthesis, delayed with uncemented or hybrid	▪ Minimum pain ▪ Full weight bearing except with uncemented or hybrid ▪ ROM 0°–90° ▪ Joint effusion controlled ▪ Impaired balance and functional mobility ▪ Diminished muscle function and cardiopulmonary endurance	▪ Muscle function: 70% of noninvolved extremity ▪ No symptoms of pain or swelling during previous phase ▪ Impaired balance and functional mobility
Key examination procedures			
	▪ Pain (0–10 scale) ▪ Monitor for hemarthrosis ▪ ROM ▪ Patellar mobility ▪ Muscle control ▪ Soft tissue palpation	▪ Pain assessment ▪ Joint effusion—girth ▪ ROM ▪ Patellar mobility ▪ Gait analysis	▪ Pain assessment ▪ Muscular strength testing ▪ Patellar alignment/stability ▪ Gait analysis ▪ Functional status
Goals			
	▪ Control postoperative swelling ▪ Minimize pain ▪ ROM 0°–90° ▪ 3/5 to 4/5 strength of quadriceps ▪ Ambulate with or without assistive device ▪ Establish home exercise program	▪ Reduce swelling ▪ ROM 0°–110° or greater ▪ Full weight bearing ▪ 4/5 to 5/5 strength ▪ Unrestricted ADL function ▪ Improved balance, neuromuscular control, and functional mobility ▪ Adherence to home exercise program	▪ Develop maintenance program, and educate patient on importance of adherence including methods of joint protection ▪ Community ambulation ▪ Improve cardiopulmonary endurance/aerobic fitness

TABLE 21.3 Total Knee Arthroplasty: Interventions for Each Phase of Rehabilitation—cont'd

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phases: Weeks 4–8	Minimum Protection/Return to Function Phases: Beyond Week 8
Interventions			
	▪ Pain modulation modalities ▪ Compression wrap to control effusion ▪ Ankle pumps to minimize risk of DVT ▪ A-AROM and AROM ▪ Muscle setting quadriceps, hamstrings, and adductors (may augment with E-stim) ▪ Patellar mobilization (grades I and II) ▪ Gait training ▪ Flexibility program hamstrings, calf, IT band ▪ Trunk/pelvis stabilization exercises	▪ Patellar mobilization ▪ LE stretching program ▪ Closed-chain strengthening ▪ Limited range PRE ▪ Tibiofemoral joint mobilization, if appropriate and needed ▪ Proprioceptive training ▪ Stabilization and balance exercises ▪ Protected aerobic exercise—swimming, cycling or walking	▪ Continue as previous phase; advance as appropriate ▪ Progression of balance and advanced functional activities ▪ Implement exercise specific to identified deficits and expected functional tasks

arthroplasty but slower after complex revision arthroplasty versus primary arthroplasty.

Immobilization and Early Motion

Typically, after primary TKA, the knee is immobilized in a bulky compression dressing for a day, or sometimes continuous passive motion (CPM) is initiated in the recovery room or within a day after surgery. After complicated revision arthroplasty, an extended period of immobilization may be required. The position of immobilization after primary TKA is usually extension.[249] Although uncommon, an alternative approach is to immobilize the knee in a 90° flexion splint immediately after surgery and for brief intervals during the next day or two to achieve knee flexion as soon as possible while maintaining knee extension with exercises.[112]

During the initial postoperative period, it may be advisable to have a patient wear a posterior extension splint during ambulation until quadriceps control is reestablished. An extension splint also is indicated at night for a patient who is having difficulty achieving full knee extension after surgery or who had a significant preoperative knee flexion contracture.[39,249]

In the past, CPM was used routinely during a patient's hospital stay after TKA.[95] At that time, a number of studies describing the benefits of CPM, such as decreased need for postoperative pain medication, decreased incidence of deep vein thrombosis, and increased or more rapid recovery of ROM, were reported in the literature.[126,151,171] However, in some of the investigations that reported greater ROM with CPM, the knees of patients in the control groups, who did not undergo CPM, were immobilized for several days to a week after surgery.[126,171]

Customary practice for the past two decades has been to initiate early postoperative exercise except in some instances of complex revision arthroplasty.[66]

FOCUS ON EVIDENCE

To evaluate postoperative CPM in the context of current practice, several randomized, controlled studies have been conducted comparing the effects of early postoperative exercise with and without the use of CPM after TKA.[14,43,55,152] The results of these studies have demonstrated that although the addition of CPM in the recovery room or within a day after surgery increased the rate of return of knee flexion during the early postoperative period in one study,[43] it provided no significant long-term benefits as to gains in ROM and functional mobility.

Although CPM continues to be used at the surgeon's discretion, the literature currently reflects that it is either no longer recommended after primary TKA[55,210] or, if used, is recommended as an adjunct to—not a replacement for—a postoperative exercise program.[14,43,55,152,249]

Weight-Bearing Considerations

The extent to which weight bearing is allowable after primary TKA depends on the type of prosthesis implanted, the type of fixation used, the patient's age, size, and bone quality, and

whether a knee immobilizer is worn during ambulation or transfers. With *cemented fixation*, weight bearing typically is permitted as tolerated immediately after surgery using crutches or a walker. During the first few days after surgery, use of a knee immobilizer may be required. The patient progresses to full weight bearing over a 6-week period.[231]

With *biological/cementless fixation*, recommendations for weight bearing vary from permitting only touch-down weight bearing for 4 to 8 weeks while using crutches or a walker[210] to weight bearing as tolerated within a few days after surgery while using crutches or a walker.[39,249,251]

Cane use is indicated during progression from partial to full weight bearing. Ambulation without an assistive device, particularly during outdoor walking, is not advisable until the patient has attained full or nearly full, active knee extension and adequate strength of the quadriceps and hip musculature to control the operated lower extremity.[39,160,210,251]

Exercise Progression

Goals and exercises for progressive phases of postoperative rehabilitation after current-day TKA, noted in Table 21.3, are discussed in the following sections.[10,39,66,175,180,225,251,312] Precautions for exercise during rehabilitation are summarized in Box 21.4.

Many of the exercises described for the early phase of rehabilitation were reported in a consensus document developed by physical therapists on the management of patients during the period of hospitalization after TKA.[66] Prior to discharge from inpatient rehabilitation, a home exercise program serves as the foundation for the remainder of the rehabilitation process, with some patients also undergoing home-based or outpatient rehabilitation for a limited number of visits.

BOX 21.4 Exercise Precautions Following TKA

- Monitor the integrity of the surgical incision during knee flexion exercises. Watch for signs of excessive tension on the wound, such as drainage or skin blanching.
- Postpone SLRs in side-lying positions for 2 weeks after cemented arthroplasty and for 4 to 6 weeks after cementless/hybrid arthroplasty to avoid varus and valgus stresses to the operated knee.
- Confer with the surgeon to determine when it is permissible to initiate exercises against low-intensity resistance. It may be as early as 2 weeks or as late as 3 months postoperatively.[23a]
- If a posterior cruciate-sacrificing (posterior-stabilized) prosthesis was implanted, avoid hamstring strengthening in a sitting position to reduce the risk of posterior dislocation of the knee.[39]
- Tibiofemoral joint mobilization techniques to increase knee flexion or extension may or may not be appropriate, depending on the design of the prosthetic components. It is advisable to discuss the use of these techniques with the surgeon before initiating them.
- Postpone unsupported or unassisted weight-bearing activities until strength in the quadriceps and hamstrings is sufficient to stabilize the knee.

Exercise: Maximum Protection Phase

The focus of management during the first phase of rehabilitation and the acute/inflammatory and early subacute stage of tissue healing, which extends for about 4 weeks, is to control pain and swelling (with cold and compression), achieve independent ambulation and transfers while using a walker or crutches, prevent early postoperative medical complications, such as pneumonia and deep vein thrombosis, and minimize the adverse effects of postoperative immobilization. The goal is to attain 90° of knee flexion and full knee extension by the end of this first phase of rehabilitation. However, full knee extension may not be possible until joint swelling has subsided.

It is well established that pain and joint swelling limit the function of the quadriceps muscle. In addition, there is a high correlation between quadriceps muscle weakness and impaired functional abilities during the initial period of recovery after TKA.[182] Regaining quadriceps muscle strength, particularly in terminal extension, as early as possible after TKA is essential for functional control of the knee during ambulation and negotiating stairs. In addition to early postoperative exercise, neuromuscular electrical stimulation or biofeedback may be recommended as it has been shown to be safe when initiated as early as 2 days following surgery.[8,180]

FOCUS ON EVIDENCE

A study by Mizner and co-investigators[183] measured the voluntary activation and force-producing capacity of the quadriceps femoris muscle group in 52 patients (mean age, 64.9 years; range 49 to 78 years) 3 to 4 weeks after unilateral, cemented primary TKA for OA and in 52 healthy individuals (mean age, 72.2 years; range, 64 to 85 years) without knee pathology. All patients in the TKA group had participated in a standard exercise program following surgery. Force production (maximum voluntary isometric contraction) and volitional activation of the quadriceps muscle group of the operated limb were, respectively, 64% and 26% less in the TKA group than in the healthy group. There was a weak relationship ($r^2=0.17$) between these results and postoperative knee pain. There were no significant differences in quadriceps muscle force production and volitional activation of the noninvolved knees in the TKA group compared with the healthy group. Based on the results of their study, the investigators recommended the use of neuromuscular electrical muscle stimulation or biofeedback as an adjunct to an individualized postoperative exercise program to augment quadriceps muscle force production after TKA.

Results of a prospective, randomized, controlled study conducted by Avramidis and colleagues[8] support the use of neuromuscular electrical stimulation in addition to a postoperative exercise program after TKA. Thirty patients scheduled to undergo primary TKA were randomly assigned to two groups (15 patients per group). Postoperatively, patients in

both groups underwent an individualized program of exercise and gait training. In addition, the treatment group received electrical stimulation to the vastus medialis muscle 4 hours a day for 6 weeks beginning on postoperative day two. Patients in the electrical stimulation group demonstrated a significantly faster walking speed than those in the control group at 6 weeks and 12 weeks postoperatively.

Goals and interventions. The following goals and exercise interventions are included in the initial phase of rehabilitation after TKA.[10,39,66,175,180,251,312]

- ***Prevent vascular and pulmonary complications.***
  - Ankle pumping exercises with the leg elevated immediately after surgery to prevent venous stasis and reduce the risk of a DVT or pulmonary embolism
  - Deep breathing exercises
- ***Control pain and swelling.***
  - Cold, compression, and elevation
- ***Minimize reflex inhibition or loss of strength of knee and hip musculature.***
  - Muscle-setting exercises of the quadriceps (preferably coupled with neuromuscular electrical stimulation), hamstrings, and hip extensors and abductors
  - Active-assisted and active straight leg raise (SLR) exercises in supine and prone positions the first day or two after surgery, postponing SLRs in side-lying positions for as long as 2 weeks after cemented TKA and for as long as 4 to 6 weeks after cementless/hybrid replacement to avoid varus or valgus stresses to the operated knee
  - Active-assisted ROM (A-AROM) progressing to active ROM (AROM) of the knee while seated and standing for antigravity knee extension and flexion, respectively.
  - As weight bearing on the operated lower extremity permits, terminal knee extension in standing, wall slides in a standing position, minisquats, and partial lunges to develop control of the knee extensors and reduce the risk of an extensor lag
- ***Maintain or improve strength of the contralateral lower extremity.***
  - PRE of nonoperated lower extremity, particularly the quadriceps and hip extensors and abductors[312]
- ***Regain knee ROM.***
  - Heel-slides in a supine position or while seated with the foot on the floor to increase knee flexion
  - Neuromuscular facilitation and inhibition technique, such as the agonist-contraction technique (described in Chapter 4), to decrease muscle guarding, particularly in the quadriceps, and increase knee flexion
  - Gravity-assisted knee flexion by having the patient sit and dangle the lower leg over the side of a bed
  - Gravity-assisted or self-assisted knee extension in the supine or long-sitting position by periodically placing a rolled towel under the heel and leaving the knee unsupported or in a seated position with the heel on the floor and pressing downward just above the knee with both hands
  - Gentle inferior and superior patellar gliding techniques to prevent restricted mobility

PRECAUTION: Avoid placing a pillow under the knee while lying supine or while seated with the operated leg elevated to reduce the risk of developing a knee flexion contracture.

- ***Improve trunk stability and balance.***
  - Trunk stabilization exercises
  - Balance activities in sitting and weight shifting in bilateral stance while adhering to weight-bearing restrictions
- ***Reestablish functional mobility***.
  - Gait training adhering to weight-bearing restrictions with use of appropriate assistive device
  - Functional training (bed mobility, sit-to stand transfers, basic ADL)

Criteria to progress. The criteria to progress to the intermediate phase of rehabilitation include the following.

- Minimal swelling and pain
- Well-healed incision with no signs of infection
- Independent basic ADL and ambulation with appropriate assistive device
- AROM approaching full or nearly full, active knee extension and 90° knee flexion

Exercise: Moderate Protection/Controlled Motion Phase

The emphasis of the intermediate phase of rehabilitation, which begins at about 4 weeks and extends to 8 to 12 weeks postoperatively, is to achieve approximately 110° knee flexion and active knee extension to 0° and gradually to regain lower extremity strength and muscular endurance, balance, cardiopulmonary endurance, and additional functional mobility.

By 4 to 6 weeks postoperatively, if nearly full knee extension has been achieved and the strength of the quadriceps is sufficient, most patients transition to using a cane during ambulation activities. This makes it possible to focus on normalizing the patient's gait, sit-to-stand, and stair ascent and descent patterns and improving the speed and duration of walking. In general, most improvements in a patient's functional abilities and quality of life tends to occur by 3 months postoperatively.[127]

Goals and interventions. The goals and exercise interventions for the intermediate phase of rehabilitation are the following.[10,39,66,175,182,225,251,312]

- ***Increase strength and endurance of knee and hip musculature***.
  - Multiple-angle isometrics and low-intensity dynamic resistance exercises of the quadriceps, hamstrings, and hip musculature (extensors, abductors, external rotators) against a light grade of elastic resistance or a cuff weight around the ankle
  - Resisted SLRs in various positions to increase the strength of hip and knee musculature

- As weight bearing allows, continue or begin closed-chain exercises including resisted terminal knee extension in standing, standing wall slides, minisquats, partial lunges, and the sit-to-stand task emphasizing proper lower extremity alignment. Include scooting forward and backward on a wheeled stool to improve functional control of the knee.
- Add forward and backward, progressing to lateral step-ups and step-downs (initially using a low step and increasing the height of the step). Reinforce proper lower extremity alignment. To progress, perform step-ups against elastic resistance.
- Stationary cycling with the seat positioned as high as possible to emphasize knee extension
- Include strengthening exercises for the nonoperated lower extremity

- ***Continue to increase knee ROM.***
  - Low-intensity self-stretching using a prolonged stretch or hold-relax technique to increase knee flexion and extension if limitation persists. Flexibility of the hip flexors, hamstrings, and calf muscles also may need to be increased for standing and ambulation activities.
  - Stationary cycling with seat lowered to increase knee flexion
  - Grade III inferior or superior patellar mobilization techniques to increase knee flexion or extension, respectively, if insufficient patellar mobility is restricting ROM
- ***Improve standing balance and trunk stability.***
  - Trunk stabilization exercises
  - Proprioceptive and balance training progressing from bilateral to unilateral stance on stable surface, then to balance activities on an unstable surface
  - Functional reaching activities while standing or stooping
  - Tandem walking, grapevine walking initially in parallel bars for safety (See Chapter 23 for additional activities.)

PRECAUTION: A progression of balance activities for patients with TKA is typically safe to begin about 8 weeks postoperatively but must be based on the ability to control the knee during stance, weight-bearing restrictions, and the absence of pain.[225]

- ***Continue to improve functional mobility.***
  - Symmetrical heel-toe walking, ambulation on a variety of surfaces and inclines, kneeling and getting up to a standing position, and ascending and descending stairs
  - Functional exercises: backward walking, side-stepping, marching, stepping over small objects

FOCUS ON EVIDENCE

Following TKA or UKA, patients often report difficulty kneeling or the inability to kneel even a year after surgery. Although many functional activities, such as housework and gardening, involve kneeling, patient education about this skill often is not included in postoperative rehabilitation. Jenkins and associates[125] conducted a single-blind, prospective, randomized, controlled study to investigate the impact of kneeling instruction following partial knee replacement. All patients participated in postoperative rehabilitation, but at 6 weeks after surgery, only half received a single physical therapy intervention of advice and instruction on kneeling. At 1 year following surgery, patient-reported kneeling ability was significantly better in the group who received kneeling advice and instruction than in the group that did not. As such, the investigators suggested that kneeling advice and instruction should be included in postoperative rehabilitation after partial knee replacement. Although the findings of this study may have implications for patients who have undergone TKA, the investigators pointed out that the results of the study can be applied to patients following only partial knee replacement.

- ***Improve cardiopulmonary endurance.***
  - Aerobic conditioning on a stationary cycle or upper body ergometer, emphasizing increased duration

Criteria to progress. The following criteria typically must be met to progress to the final phase of rehabilitation following TKA.

- AROM: full knee extension (no extensor lag), 110° knee flexion
- Quadriceps/hamstring and hip muscle strength: at least 70% (or 4/5 muscle testing grade) compared to uninvolved leg
- Minimal to no pain during exercises and ambulation with or without a cane

Exercise: Minimum Protection/Return to Function Phase

Beginning at approximately 8 to 12 weeks and beyond after surgery, the emphasis of the final phase of rehabilitation is on task-specific strengthening exercises, proprioceptive and balance training, advanced functional training (see Chapter 23), and continued cardiopulmonary conditioning so that the patient develops the strength, power, balance, and endurance needed to return to a full level of functional activities in the community. (Refer to Table 21.3 for a summary of goals and interventions during the final phase of rehabilitation.)

Despite persistent strength and power deficits, altered movement patterns and insufficient speed and endurance during functional activities, patients often are discharged from supervised therapy 2 to 3 months postoperatively after attaining functional ROM of the knee and the ability to ambulate independently with an assistive device. However, deficits in physical function have been shown to persist for an average of 10 months[291] to a year or more after surgery.[182]

It is likely that some patients, especially those living in the community, could benefit from an intensive exercise program during the late phases of rehabilitation to perform demanding physical activities more efficiently, such as ascending and descending stairs and returning to selected recreational activities.

FOCUS ON EVIDENCE

Moffet and associates[184] conducted a single-blind, randomized, controlled study to determine the effectiveness of an intensive, supervised functional training program initiated 2 months after primary TKA for OA. Patients in the experimental group (n=38) participated in facility-based, twice-weekly, 60- to 90-minute exercise sessions consisting of hip and knee strengthening exercises, task-specific functional exercises, and aerobic conditioning. These exercises were preceded by a warm-up and followed by a cool-down period. The full cohort of exercises was phased in gradually during the first 2 weeks of the program. Patients also received a home program to be followed on the days they did not participate in the supervised program. Patients in the control group (n=39) participated in a home exercise program for 6 weeks with periodic home visits by a therapist. No exercise-related adverse events occurred during the study.

Patients were evaluated by means of the 6-minute walk test and two functional outcome and quality-of-life (QOL) measures prior to beginning the exercise program (baseline measurement at 2 months after surgery), at the conclusion of the 6-week exercise program, and at 6 and 12 months postoperatively. The two groups were comparable at baseline. At the conclusion of the intervention and at the 6- and 12-month follow-ups, patients in the intensive exercise group walked significantly longer distances (walked at a faster speed) during the 6-minute walk test than did those in the control group. Functional abilities and QOL measures also were significantly better for the intensive exercise group than the control group immediately after the 6-week program and at 6 months postoperatively. At 1 year after surgery there were no significant differences in function or QOL measures between the two groups.

The investigators concluded that an intensive, functionally oriented exercise program initiated 2 months after primary TKA was safe and effective for improving physical function and quality of life.

With the trend toward an increasing number of young (< 60 years of age) and active patients undergoing TKA,[122] patient education is essential to help patients understand the detrimental effects of repetitive, high-impact activities (work-related, fitness-related, recreational) on the prosthetic implants and to learn how to select activities that promote fitness but are least likely to reduce the longevity of the prosthetic knee.[106,139,169] Accordingly, patients are advised to participate in low-impact physical activities after TKA to reduce the risk of component wear and mechanical loosening over time and the premature need for revision arthroplasty.

For the patient who wishes to participate in athletic activities after TKA, there are a number of considerations. Factors that influence participation include the level of demand (intensity and load) of an athletic activity, a patient's body weight, overall level of fitness, and preoperative experience with the activity and the technical quality of the knee replacement and related soft tissue balancing or reconstruction.[106,139]

Physical activities for fitness and recreation that are highly recommended, recommended with caution, or not recommended after TKA are noted in Box 21.5.[106,139,169]

Outcomes

Although the ideal knee replacement that replicates the normal biomechanics of the native knee joint has yet to be developed, knee arthroplasty has been shown to be a successful procedure for patients with advanced joint disease. Extensive research has been published in the orthopedic literature on patient-related outcomes and the survivorship associated with a wide variety of prosthetic designs, surgical techniques, methods of fixation, and types of materials.[119,120,154,249,311] Because of the variability of procedures and the fact that outcomes are often based on nonrandomized, retrospective

BOX 21.5 Recommendations for Participation in Physical Activities Following TKA

Highly Recommended*

- Stationary cycling
- Swimming, water aerobics
- Walking
- Golf (preferably with golf cart)
- Ballroom or square dancing
- Table tennis

Recommended If Experienced Before TKA**

- Road cycling
- Speed/power walking
- Low-impact aerobics
- Cross-country skiing (machine or outdoor)
- Table tennis
- Doubles tennis
- Rowing
- Bowling, canoeing

Not Recommended***

- Jogging, running
- Basketball
- Volleyball
- Singles tennis
- Baseball, softball
- High-impact aerobics
- Stair-climbing machine
- Handball, racquetball, squash
- Football, soccer
- Gymnastics, tumbling
- Water-skiing

*Low impact, low-load; appropriate at moderate- or high-intensity on a regular basis for aerobic fitness.
**Moderate impact; appropriate on a recreational basis if performed at low or moderate intensity.
***High impact, high-load; peak load occurs during knee flexion.

studies, it has been difficult to draw general conclusions.[250] However, a recent large-scale (2,352 patients), multicenter, randomized study comparing patient-related outcomes following three variations of total knee component designs demonstrated no significant differences in clinical, functional, and quality of life improvements in the randomized groups at 2 years following surgery.[127]

Patient-related outcomes after knee arthroplasty that have the most influence on patient satisfaction are relief of pain and an improved ability to perform necessary and desired functional activities for an extended number of years. Approximately 90% of patients who undergo primary TKA can expect 10 to 20 years of satisfactory function before revision arthroplasty may need to be considered.[249] For example, Dixon and colleagues[60] reported a 92.6% survival rate of modular, fixed-bearing TKA in patients followed for a minimum of 15 years.

Parameters typically measured by means of self-report and performance-based instruments to determine the success of knee replacement surgery are the level of pain, overall QOL, knee ROM, strength of the knee musculature, and a patient's ability to perform functional activities safely and with ease. An understanding of evidence-based outcomes following TKA can assist a therapist in developing realistic goals with a patient and better determining a patient's prognosis.

Pain relief. Almost all patients who undergo knee arthroplasty report a significant reduction of pain during knee motion and weight bearing, with most patients reporting good to excellent pain relief.[86,249,250,293]

ROM. Improvements in knee ROM are not as predictable as relief of pain. Stiffness often persists after the initial recovery from surgery has occurred.[86] However, it also has been reported that ROM may continue to improve as many as 12 to 24 months postoperatively.[265] Factors that influence postoperative ROM include preoperative ROM, the underlying disease, obesity, postoperative pain, and whether a primary or a revision arthroplasty was performed. Complications such as component malpositioning, inadequate soft tissue balancing or reconstruction, infection, and mechanical loosening of an implant can adversely affect postoperative ROM.[215,262]

Patients with restricted ROM preoperatively often continue to have limited knee flexion, extension, or both postoperatively despite an aggressive postoperative exercise program.[262,265] In fact, the most important predictor of long-term postoperative knee ROM is preoperative ROM.[145,248,262] For example, in a study of 358 patients who underwent primary TKA for OA, total ROM of the knee was 110° preoperatively and 113° postoperatively due to a reduction in the average knee flexion contracture from 12° to 9°.[248] The results of several other studies found that despite patients' participation in an outpatient or home-based postoperative rehabilitation program, there was no significant change in preoperative versus postoperative knee ROM at 6 months[10,182] or at 12 months after surgery.[230]

Differences in prosthetic design, such as mobile-bearing versus fixed-bearing[38,249] or PCL-retaining versus PCL-substituting (posterior stabilized) designs,[208,211,249] and in the method of fixation[210,249] do not appear to affect ROM outcomes after primary TKA. A comparison of five designs of posterior cruciate-substituting implants, for example, showed no significant differences in the extent of improvement of knee ROM among designs.[248]

Limited knee ROM has a substantial impact on postoperative function, particularly if knee flexion is less than 90° and knee extension is limited by more than 10° to 15°.[249] With less than 90° to 100° of knee flexion, it is difficult to negotiate stairs, and having less than 105° makes it difficult to stand up from a standard height chair without using arm support.[249] In a retrospective study of more than 5,000 total knee arthroplasties, Ritter and associates[237] determined that an even greater degree of knee flexion was necessary for optimal postoperative function. Results of their study indicated that functional outcomes were highest when at least 128° of knee flexion was achieved following surgery but were substantially compromised if < 118° was achieved. In contrast, lack of full knee extension because of contracture or an extensor lag is thought to be a source of a patient's perception of knee pain or instability during ambulation activities, particularly when ascending and descending stairs.[138,249]

Strength and endurance. It takes a minimum of 3 to 6 months after surgery for a patient to regain strength in the quadriceps and hamstrings of the operated knee to a preoperative level.[138,182,265] Quadriceps weakness tends to persist longer after knee arthroplasty than does knee flexor weakness.[265] Furthermore, quadriceps weakness of the contralateral (nonoperated) side is a predictor of impaired functional outcomes at 1 and 2 years following unilateral TKA.[312]

Studies of patients after unilateral TKA with a conventional surgical approach have demonstrated that quadriceps strength in the operated leg correlates highly with performance on tests of functional abilities during the first 6 months after surgery.[182] For example, a study by Farquhar and associates[70] demonstrated that at 3 months post-TKA, patients had quadriceps weakness and an altered sit-to-stand movement pattern reflected by the use of increased hip flexion and greater reliance on hip extensor strength, thus reducing the demand on the knee extensors when rising from a chair. Of additional interest was the finding that at 1 year after surgery, despite improved symmetry of quadriceps strength, the altered sit-to-stand pattern persisted, perhaps as the result of habit.[70]

Quadriceps strength is also significantly less than in similarly aged healthy individuals 6 months to a year after surgery[72,86,182,293] and the noninvolved leg 1 to 2 years postoperatively.[242,263] It has been suggested that eversion of the patella during a conventional surgical approach may contribute to impaired function of the quadriceps mechanism after surgery.[154,263]

Given the number of studies that have identified significant quadriceps weakness after TKA and the high correlation

between quadriceps strength and functional performance, there is substantial evidence to support the importance of quadriceps-strengthening exercises in postoperative rehabilitation programs to optimize function after TKA.

Physical function and activity level. The greatest and most rapid improvements in physical performance following TKA occur during the first 12 weeks with an additional but small amount of improvement occurring beyond 12 weeks.[132] Relief of pain appears to significantly improve a patient's QOL and ability to perform functional activities. However, just 1 month after TKA, functional performance is dramatically worse than the preoperative level of function, despite a patient's participation in a rehabilitation program the day after surgery.[10]

A systematic review of the literature by Ethgen and colleagues[69] revealed that a patient's postoperative level of function and QOL, as measured by self-report questionnaires, typically begins to surpass the preoperative level at approximately 3 months, with most improvement in function occurring by 6 months. However, results of some studies have shown that additional improvements may occur for a year or more postoperatively.[265,293]

Overall, when comparing preoperative with postoperative function, patients with high preoperative scores on functional measures achieved a higher level of function postoperatively than patients with low preoperative functional scores.[80]

A survey by Weiss and colleagues[296] of 176 patients (mean age, 70.5 years) 1 year or more after TKA identified patients' level of participation in activities of graduated difficulty and determined which activities were most important to patients. The survey also identified activities that were difficult after TKA. The results of the survey indicated that in addition to basic activities of daily living (ADL)—walking, stair-climbing, personal care—patients performed a wide range of therapeutic and recreational activities after TKA. The activities in which the highest percentage of patients participated were stretching exercises (73%), leg-strengthening exercises (70%), gardening (57%), and stationary cycling (51%). These same activities were rated as important by patients. Functions that were the most difficult and most often caused knee pain were squatting (75%) and kneeling (70%).

Bradbury and colleagues[28] studied the pre- and postoperative sports participation of 160 patients who had undergone TKA 5 years earlier. Preoperatively, there were no significant differences in knee ROM, walking abilities, and radiographs in the patients who did and did not participate in sports activities. Postoperatively, the investigators found that 51 (65%) of the 79 patients (mean age, 73 years at the 5-year follow-up) who had regularly (at least twice a week) participated in sports activities during the year prior to surgery were participating in some type of sport at the 5-year follow-up. Patients were more likely to return to low-impact rather than high-impact activities. Of the patients who did not regularly participate in a sport before surgery, none took up a sport postoperatively.

Despite an overall positive impact of TKA on physical function, long-term studies indicate that functional abilities typically remain below norms for age-matched, healthy populations.[10,72,80,] A follow-up study of 276 community-dwelling patients 6 months after primary TKA revealed that overall physical function improved significantly for all patients, although 60% reported moderate to extreme difficulty descending stairs and 64% continued to have a similar degree of difficulty with heavy household tasks.[128]

Results of another study indicated that 1 year after TKA, despite a relative absence of pain and some improvement in functional abilities, significant deficits in strength and function were apparent when compared with the abilities of age-matched, healthy individuals.[293] The post-TKA patients had less strength of the knee musculature, slower walking and stair-climbing speeds, and a higher perceived level of exertion during activities than healthy individuals. The authors pointed out that the post-TKA patients as a group were heavier than the control group and suggested that general physical deconditioning may have contributed to the postoperative group's functional limitations. This study emphasized the need for inclusion of a low-impact aerobic conditioning program during rehabilitation after TKA.

Patellofemoral Dysfunction: Nonoperative Management

Related Patellofemoral Pathologies

Historically, the differential diagnosis of patellofemoral (PF) pathologies has been plagued with confusion, largely related to the use of broadly inclusive terminology such as chondromalacia patellae and patellofemoral pain syndrome (PFPS). In an attempt to more clearly identify the anatomical structures involved and the biomechanical changes leading to dysfunction, several classification systems have been proposed. These classifications include guidelines for intervention based on impairments and activity limitations.[115,302]

PF Instability

Instability includes subluxation or dislocation of a single or recurrent episode. There may be an abnormal Q-angle, dysplastic trochlea (shallow groove or flat lateral femoral condyle), patella alta, tight lateral retinaculum, and inadequate medial stabilizers (vastus medialis oblique muscle [VMO] and medial patellofemoral ligament [MPFL]). There may be associated fractures. Usually the instability is in a lateral direction. The dislocation may derive from direct trauma to the patella or from a forceful quadriceps contraction while the foot is planted and the femur is externally rotating while the knee is flexed. Recurrent dislocation is usually an indication for surgery to redirect the forces through the patella.

PF Pain with Malalignment or Biomechanical Dysfunction

Patellofemoral pain reportedly due to malalignment or biomechanical dysfunction includes impairments that cause an

increased functional Q-angle such as femoral anteversion, external tibial torsion, genu valgum, or foot hyperpronation. There may be a tight lateral retinaculum, weak VMO muscle, neuromuscular deficits in the hip musculature, incompetent MPFL, patella alta, patella baja, generalized laxity, or dysplastic femoral trochlea. There is usually abnormal patellar tracking, and there may be discordant firing of the quadriceps muscle.[115]

CLINICAL TIP

Although it is widely reported that PF malalignment is seen in patients with PFPS and may be a precursor of or may contribute to symptoms, the evidence to support the existence of abnormal alignment in PFPS is lacking. Specifically, because there is little evidence to support the validity and reliability of various testing procedures currently used to measure patellar position and tracking, whether performed in weight-bearing or nonweight-bearing positions, only assumptions can be made as to the presence of malalignment in PFPS.[306]

PF Pain Without Malalignment

Patellofemoral pain without malalignment includes many subcategories of lesions that cause anterior knee pain.

Soft tissue lesions. Soft tissue lesions include plica syndrome, fat pad syndrome, tendonitis, IT band friction syndrome, and bursitis.

- *Plica syndrome* describes a condition related to irritation of remnants of embryological synovial tissue around the patella. With chronic irritation, the tissue becomes an inelastic, fibrotic band that is tender during palpation. When acute, the tissue is painful during palpation. The band is usually palpable medial to the patella, although there are variations in its location.[23,131]
- *Fat pad syndrome* involves irritation of the infrapatellar fat pad from trauma or overuse.
- *Tendonitis* of the patellar or quadriceps tendons, sometimes called *jumper's knee*, typically occurs from overuse as the result of repetitive jumping. Tenderness occurs along the attachment of the tendon to the patella. Symptoms may be exacerbated secondary to tightness quadriceps.[294]
- *IT band friction* syndrome is irritation of the IT band as it passes over the lateral femoral condyle. Contributing factors could be tight tensor fasciae latae or gluteus maximus (see discussion in Chapter 20). Because the IT band attaches to the patella and lateral retinaculum, it may cause anterior knee pain.
- *Prepatellar bursitis*, also known as housemaid's knee, is the result of prolonged kneeling or recurrent minor trauma to the anterior knee. When inflamed, there may be restricted motion due to swelling and pain caused by direct pressure or pressure from the patellar tendon.

Tight medial and lateral retinacula or patellar pressure syndrome. There is increased contact pressure of the patella in the trochlear groove.

Osteochondritis dissecans of the patella or femoral trochlea. Osteochondral lesions result in pain on the retro surface of the patella that is worse during squatting, stooping, ambulating, and descending steps. The knee may give way or lock. There may be loose bodies within the joint.

Traumatic patellar chondromalacia. With chondromalacia, there is softening and fissuring of the cartilaginous surface of the patella, which is diagnosed with arthroscopy or arthrography.[115] It may eventually predispose the joint to degenerative arthritis or basal degeneration of the middle and deep zones of the cartilage.[94] Causes of degeneration may include trauma, surgery, prolonged or repeated stress, or lack of normal stress such as during periods of immobilization.[209]

PF osteoarthritis. Osteoarthritis may be idiopathic or posttraumatic and is diagnosed by radiographic changes consistent with degeneration.

Apophysitis. Osgood-Schlatter disease (traction apophysitis of the tibial tuberosity) and Sinding-Larsen Johansson syndrome (traction apophysitis on the inferior pole of the patella) occur during adolescence as a result of overuse during rapid growth. They are self-limiting conditions.

Symptomatic bipartite patella. Most bipartite patellae (due to patellar ossification variants) are asymptomatic, but trauma may disrupt the chondro-osseous junction leading to symptoms.[115]

Trauma. Trauma includes tendon rupture, fracture, contusion, and articular cartilage damage that results in inflammation, swelling, limited motion, and pain with dysfunction whenever contracting the quadriceps, such as during stair climbing, squatting, and resisted knee extension.

Etiology of Symptoms

The cause of anterior knee pain may be direct trauma, overuse, faulty patellar tracking from malalignment due to anatomical variations or soft tissue length and strength imbalances in the hip, knee, or ankle/foot; degeneration; or a combination of these factors.[33,61,166,227,228,245,260,292,294,308] An attempt should be made to determine the causative factors based on the patient's history and a comprehensive and sequential examination.

Consensus on Factors Leading to PF Symptoms

A consensus statement summarizing input from leaders and researchers studying PF pain categorized factors leading to PFPS into local, distal, and proximal influences. The following are examples of these factors.[54]

Local factors. Local factors include structures around the joint itself, such as infrapatellar fat pad, ligaments, quadriceps tendon, medial and lateral retinaculum, and subchondral bone. Symptoms may be provoked by faulty mechanics. Walking and squatting increase PF joint stress.

Distal factors. Factors arising from the foot include an externally rotated foot during relaxed stance, rearfoot eversion at heel strike, delayed or prolonged rearfoot eversion during walking and running, and increased midfoot mobility.

Proximal factors. Factors arising from the hip region include altered hip kinematics of increased hip adduction and internal rotation during specific tasks such as running and single-limb activities of squatting, jumping, and drop landing. These may be associated with hip abductor and eternal rotator muscle weakness.

Common Impairments, Activity Limitations, and Participation Restrictions

Structural and functional impairments. Impairments that may be associated with PF dysfunction include the following.[33,61,142,166,224,227,228,245,260,290,292,294,308]

- Pain in the retropatellar region
- Pain along the patellar tendon or at the subpatellar fat pads due to irritation
- Patellar crepitus; swelling or locking of the knee
- Altered lower extremity alignment (Fig. 21.9), specifically increased hip adduction and internal rotation and dynamic knee valgus (valgus collapse) that occurs during weight-bearing activities, such as ascending and descending stairs, squatting, or landing after a jump[121,172,227,228,229,238,271]
- Weakness of the hip abductor, external rotator, and/or extensor muscles[24,121,172,224,227-228,238,271]
- Weakness, inhibition, or altered recruitment or timing of firing of the VMO muscle[49]
- Decreased flexibility of the tensor fasciae latae, hamstrings, quadriceps, or gastrocnemius and soleus muscles[224,227]
- Overstretched medial retinaculum
- Restricted lateral retinaculum, IT band, or fascial structures around the patella
- Decreased medial gliding or medial tipping of the patella
- Pronated foot

FIGURE 21.9 Excessive hip adduction and internal rotation (valgus collapse at the knee) during descent from a step.

FOCUS ON EVIDENCE

There are a substantial number of studies that have found altered lower extremity kinematics and/or strength and activation deficits of hip musculature in individuals (primarily females) with versus those without PF pain.[24,121,172,224,227-229,238,271] Overall, the findings of most of these studies have revealed greater hip adduction and/or internal rotation during weight-bearing activities that involve knee flexion, such as squatting, ascending or descending stairs, or landing from a jump, in individuals with PF pain compared with noninvolved controls. Decreased strength of hip extensors, external rotators, and/or abductors, typically measured during a maximum voluntary isometric contraction, has also been identified in those with PF pain.

It is important to point out that the results of studies have not been consistent. For example, the association between weakness of specific hip muscles in individuals with PFPS and abnormal lower extremity kinematics is not absolute. McKenzie and colleagues[172] reported diminished strength of hip extensors, abductors, and external rotators, as well as excessive hip adduction and internal rotation during stair descent and ascent. Souza and colleagues[271] also reported that females with PFPS had significantly decreased strength of the hip extensors and abductors and excessive internal rotation but not increased hip adduction during step-down movements, a drop-jump, and running. In contrast, Bolgla and colleagues[24] identified weakness of the hip abductors and external rotators in females with PFPS but no evidence of abnormal hip kinematics during stair descent. The inconsistent findings may be attributed to a number of factors including differences in weight-bearing tasks and measurement techniques.

Although these studies suggest that an interdependence exists between the knee and more proximal regions of the body, specifically the hip, pelvis, and trunk, it is also important to recognize that because of the retrospective nature of

these studies, the findings demonstrate associations—not cause-and-effect relationships—among altered hip mechanics, deficits in hip muscle performance, and signs and symptoms of PF dysfunction.[109,227,229]

Activity limitations and participation restrictions. Limitations and restrictions associated with the impairments include the following.

- Limited performance of basic ADL as the result of pain or poor knee control (valgus collapse)
- Pain-related limitations of functional mobility (e.g., reduced ability to get in or out of a chair or car, ascend and descend stairs, walk, jump, or run) that are necessary to carry out ADL and IADL, work, and community, recreational, or sport activities
- Inability to maintain prolonged flexed knee postures, such as sitting or squatting, as the result of pain and stiffness in the knee

Patellofemoral Symptoms: Management—Protection Phase

When symptoms are acute, treat them as any acute joint problem—with modalities, rest, gentle motion, and muscle-setting exercises in pain-free positions. Pain and joint effusion inhibit the quadriceps,[279] so it is imperative to reduce irritating forces. Splinting the patella with a brace or tape may unload the joint and relieve the irritating stress.

Patellofemoral Symptoms: Management—Controlled Motion and Return to Function Phases

When signs of acute pain and inflammation are no longer present, management is directed toward correcting or modifying the biomechanical factors that may be contributing to the impairment. Because no one factor or combination of factors has been identified as the direct cause or effect of PF pain symptoms, it is imperative to develop interventions that address the scope of impairments identified during the examination.[228] It is also important to integrate the concept of regional interdependence in the application of exercise interventions by addressing proximal weakness and tightness, impaired stability, and distal malalignment that may place excessive stress through the PF joint.[109,227]

Management during the controlled motion and return to function phases of rehabilitation typically emphasizes increasing strength, dynamic control, and pain-free mobility of the knee and hip; modifying abnormal movement strategies that may contribute to impairments; and improving stability of the pelvis and trunk, balance, and functional abilities.

Patient Education

Instructions. Because end-range stress and prolonged postures tend to exacerbate symptoms, instruct the patient to avoid positions and activities that provoke the symptoms.

- Minimize or avoid stair climbing and descending until the hip and knee muscles are strengthened to a level at which they can control knee function without symptoms.
- Do not sit with the knees flexed excessively for prolonged periods. During sitting, periodically perform ROM of the knee to relieve stasis.

Home exercise program. Implement a home exercise program to reinforce supervised training. Prior to discharge, provide instructions for a safe progression of exercises and functional activities.

Increase Flexibility of Restricting Tissues

Identify any structures that could be contributing to faulty mechanics and establish a stretching program. The gastrocnemius, soleus, quadriceps, hamstring, and tensor fasciae latae (TFL) muscles have been identified as specific muscles with reduced flexibility in individuals with patellofemoral dysfunction.[224,227,290] Self-stretching techniques are described in the exercise section of this chapter. Techniques to stretch the two-joint muscles that cross the hip and knee are described in Chapter 20, and those that cross the knee and ankle are described in Chapter 22.

Because restrictions related to insertion of the IT band and the lateral retinaculum may contribute to decreased patellar mobility and faulty patellar tracking in some patients with PFPS, specific techniques to address these impairments are described in this section.

Patellar mobilization: medial glide. Position the patient side-lying. Stabilize the femoral condyles with one hand under the femur, and glide the patella medially with the base of the other hand (Fig. 21.10).[97] There is usually greater mobility with the knee near extension; progress by positioning the knee in greater flexion prior to performing the medial glide.

Medial tipping of the patella. Position the patient supine. Place the thenar eminence at the base of the hand over the

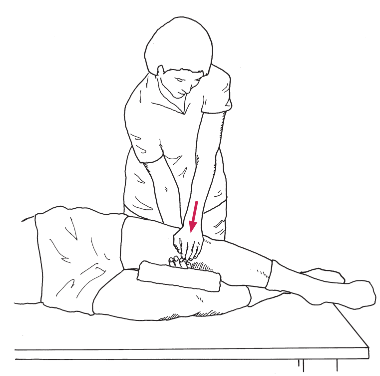

FIGURE 21.10 Medial glide of the patella.

medial aspect of the patella. Apply a posterior force to tip the patella medially. While the patella is held in this position, apply friction massage with the other hand along the lateral border (Fig. 21.11). Teach the patient to self-stretch in this manner.

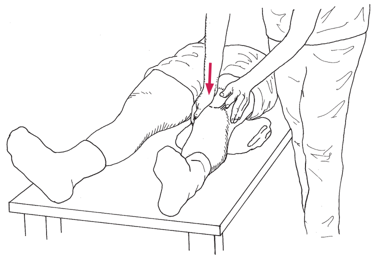

FIGURE 21.11 Medial tipping of the patella with friction massage along the lateral border.

Patellar taping. Although the use of patellar taping to realign the patella and provide a prolonged stretch has been recommended in early resources,[97,166] the primary benefit of taping identified in two systematic reviews of the literature[22,49] is the reduction of anterior knee pain during provoking activities. However, it is not clear whether pain relief is the result of patellar realignment from taping.

FOCUS ON EVIDENCE

A multicenter, single-blind study demonstrated little to no change in patellar alignment as the result of three different patellar taping techniques. A decrease of symptoms in 71 subjects with PFPS did occur, but the reduction of symptoms occurred regardless of the direction in which the tape was applied.[305] The investigators suggested that taping may alter proprioceptive input and increase tolerance to functional training and therefore should be used while the focus of treatment addresses proximal weakness.

Improve Muscle Performance and Neuromuscular Control

Because many possible diagnoses fall under the category of PFPS, various biomechanical influences may be the precipitating or perpetuating cause of the symptoms. Impaired strength, endurance, and control of the knee extensors and hip musculature (extensors, external rotators, and abductors), as well as impaired stability of the trunk and pelvis, must be addressed.[227-229]

However, not all patients with PF symptoms benefit from the same exercises. Consequently, it is imperative that the therapist design a progression of exercises that addresses the specific impairments of each patient. Exercises to improve muscle performance and functional control in associated regions proximal and distal to the knee are described in Chapters 16, 20, and 22, respectively. Additional lower extremity exercises are described in Chapter 23.

VMO Emphasis: A Closer Look

Although it is not possible to isolate contraction of the VMO, it is accepted that the line of pull of this component of the quadriceps muscle influences the tracking of the patella. Consequently, one aspect of management traditionally has been directed toward developing awareness of the VMO contraction during quadriceps muscle activation. Tactile cues over the muscle belly, electrical stimulation, or biofeedback can be implemented to reinforce the VMO contraction during knee extension exercises.

It is now well accepted that exercise programs for patients with PFPS should target regions proximal to the knee.[85,161,195,290] However, substantial attention also has been given to the need for activating the VMO through various weight-bearing and nonweight-bearing exercises and functional activities.[6,49,61,166] As discussed in this section, however, evidence is inconsistent regarding the onset timing and activation of the VMO in individuals with and without PFPS, the role of the VMO/VL ratio, and the effectiveness of various nonweight-bearing and weight-bearing exercises and functional activities to promote VMO activation.[49,116,130,142,165,269,292] Evidence about selected exercises is summarized in the following section, but further investigation is warranted.

Nonweight-Bearing (Open-Chain) Exercises

NOTE: There is controversy regarding compressive forces and stress on the PF joint with open-chain exercises.[67,96] The type of resistance (constant, variable, or isokinetic) places different demands on the quadriceps muscle in terms of maximum effort at various ranges. The resultant force from the quadriceps tendon and patellar tendon and the patellar contact area also vary through the ROM. Therefore, the stress on the articulating surface of the patella varies. There is little or no contact of the patella with the trochlear groove from 0° to 15° of flexion,[67] so pain felt in that range could derive from irritation of the patellar fat pads or synovial tissue. Greatest patellar stress is at 60° and compression loads at 75°, so pain may be provoked in these ranges when maximum torque from the resistance force is applied in these ranges.[67] Where the pathology is located affects where in the range the patient feels pain.[96] It is recommended that when examining the patient, the range where pain is felt be noted and resistance loads that cause pain in that range be avoided.

Quadriceps setting (quad sets) in pain-free positions. Have the patient set the quads with the knee in various positions while focusing on developing tension in the VMO. Because the site of irritation varies among patients with PF dysfunction, identify pain-free positions to ensure nondestructive loading.[67,96]

Quad sets with straight-leg raise. Have the patient perform straight-leg raising (SLR) exercises in supine or long-sitting positions to target quadriceps control. Because many fibers of the VMO originate on the adductor tendons and medial intramuscular septum, it was suggested a number of years ago that simultaneous activation of the hip adductors during contraction of the quadriceps might provide a firm base for the

VMO.[34] As a result, some exercise programs for treatment of PFPS[6,61,166] have recommended combining SLR exercises with isometric hip adduction or external rotation of the femur (so that the adductors contract during the SLR exercises). However, a study using electromyography (EMG) demonstrated that SLR exercises performed in the supine position with simultaneous external rotation of the femur or resisted isometric hip adduction were no more effective in activating the VMO relative to the VL than SLR exercises performed with the femur in neutral rotation.[130]

Progression of resisted isometrics. Initiate multiple-angle isometrics against resistance to knee extension in pain-free positions as tolerated by the patient. During resisted isometrics of the knee extensors, have the patient simultaneously resist medial rotation of the tibia to optimize activation of the VMO.[142]

FOCUS ON EVIDENCE

Because the lower fibers of the VMO attach to the anteromedial aspect of the proximal tibia via the medial extensor aponeurosis, it is thought that the fibers may resist lateral tibial rotation during resisted knee extension. LaPrade and colleagues[142] carried out a study to determine if active medial rotation of the tibia led to preferential recruitment of the VMO over the VL. Investigators also sought to further explore the effect of hip adduction during resisted knee extension.

Study participants with and without PFPS performed five different isometric knee extension exercises in various combinations of hip adduction and medial rotation of the tibia while in a sitting position with the knee flexed. Results of the study showed no significant differences in VMO/VL ratios between the PFPS group and the controls during any of the exercise conditions. Results also demonstrated that the VMO/VL ratio was highest when there was simultaneous resistance to knee extension and medial tibial rotation (initiated in 30° of lateral tibial rotation). However, the ratio was not significantly higher than when resisted knee extension alone was performed. During simultaneous resisted hip adduction and knee extension, VMO and VL recruitment was almost equivalent, indicating no preferential activation of the VMO, and VMO activation also was less than with resisted knee extension alone. This study did not evaluate the effects of exercise on pain or improved function.

Short-arc terminal extension. Begin with the patient supine and knee flexed around 20° (see Fig. 21.23). If tolerated and the motion is not painful, apply light resistance at the ankle. Strengthening in terminal extension trains the muscle to function where it is least efficient because of its shortened position and where there is minimal patellar compression because it is superior to the femoral groove. End-range knee extension is needed when lifting the leg into bed and moving the covers, as well as when lifting the leg into a car.

PRECAUTION: If there is irritation of the synovial lining of the suprapatellar pouch or bursa, terminal knee extension may be painful and should be avoided until the pain subsides.

Weight-Bearing (Closed-Chain) Exercises

A progression of closed-chain/axial-loading exercises, typically performed in weight-bearing positions, should be a major component of an exercise program for PFPS to reduce PF symptoms, increase muscle performance and dynamic control of knee, hip, and trunk, and to improve neuromuscular control/response time and balance.[25,110,161,195,290] As discussed previously, if excessive valgus alignment of the knee occurs during weight-bearing activities involving knee flexion (squats, lunges, stair ascent or descent, or landing from a jump), it may be indicative of weakness of hip abductors, extensors, and/or external rotators. Strengthening these muscle groups in weight-bearing positions and practicing movement strategies in proper alignment should be a priority.[110,161,227,228,290]

PRECAUTION: Because there are higher patellar compressive loads when the knee is flexed beyond 60° during weight bearing, exercises and activities with the knee flexed beyond this angle may provoke symptoms. Use caution when the patient is ready to progress beyond 60°. Have the patient carefully monitor symptoms and stop the exercise if symptoms develop.

CLINICAL TIP

When selecting weight-bearing exercises for patients with PFPS, it is important to know that some activate the VMO to a greater extent than others. An EMG study[9] of five weight-bearing exercises in single-leg stance demonstrated the following from greatest to least VMO recruitment: wall squat (wall slide), forward step-up, minisquat, reverse step-up, and lateral step-up. (Refer to the last section of this chapter and Chapter 23 for detailed descriptions of various weight-bearing exercises.)

- If full weight bearing is painful, begin with partial weight-bearing exercises. Progress exercises in standing as tolerated.
- To improve strength and muscular endurance, have the patient perform multiple repetitions of appropriate exercises until PF symptoms or loss of control just begins to occur. Do not push beyond that point in order to avoid faulty mechanics or loss of control.
- Initiate terminal knee extension against light resistance in standing for end-range knee control (see Fig. 21.26).
- Introduce bilateral progressing to unilateral minisquats, which may be useful for improving patellar tracking, early in the exercise program when weight bearing and partial squatting are tolerated and do not provoke symptoms (see Fig. 21.27). Be sure that the knees remain aligned over the toes during squatting.

- Progress dynamic exercises by adding double-leg, then single-leg standing wall slides, short-step, then long-step lunges, and forward, backward, and lateral step-ups and step-downs to the exercise program. Add elastic resistance for further challenge.

NOTE: Based on a study of adults without PFPS, there is some evidence to suggest that the VMO/VL ratio is higher during single-leg minisquats than a maximum voluntary isometric quadriceps contractions performed in a standing position.[116]

- Select resistance equipment for progressive strengthening and muscular endurance training that incorporates weight bearing, such as the seated leg press, the Total Gym® unit, and the stepping machine.

CLINICAL TIP

When using a seated leg press to strengthen the hip and knee extensors, combining isometric hip adduction with resisted extension provides no additional benefit compared with performing the exercise with the hips in neutral in the frontal plane.[269]

- Combine balance and agility training with strengthening exercises in weight-bearing positions.
- Include plyometric training for individuals wishing to return to high-demand activities if symptoms do not recur (see Chapter 23).

Functional Activities

Practice simulated functional activities and activity-specific drills without provoking symptoms to prepare the patient to return to the desired activities (see Chapter 23). If abnormal lower extremity alignment occurs during weight-bearing activities despite improvements in muscle strength and endurance, integrate movement reeducation into activity-specific drills to reinforce proper movement strategies.

Modify Biomechanical Stresses

Assess lower extremity mechanics, and modify any faulty alignment. If the patient exhibits excessive foot pronation, a foot orthosis, such as a medial wedge, may reduce the stresses at the knee and decrease PF pain.[65,100] However, in adults without PFPS, use of a either a medial or lateral wedge or no wedge has been shown to have no significant impact on activation of the VMO and VL muscles during a single-leg minisquat and a maximum isometric contraction of the quadriceps in a standing position.[116]

Outcomes

Two systematic reviews of the literature focusing on quality randomized, controlled studies for PFPS have revealed that interventions most effective for reducing pain and improving function were quadriceps strengthening, acupuncture, and combinations of interventions that include quadriceps strengthening with patellar taping and use of biofeedback.[22,49] The effectiveness of a patellar brace was neither refuted nor supported, nor was the use of manual therapy techniques, such as stretching and manipulation. A more recent evaluation of the scope and quality of systematic reviews on the effectiveness of treatment of PFPS also supported the findings of the earlier reviews.[13]

No particular exercise approach has been found to be superior to another for reducing symptoms and improving function. Consequently, there is ongoing debate as to whether nonweight-bearing or weight-bearing exercises yield better outcomes. Herrington and Al-Sherhi[110] conducted a study on the effects of nonweight-bearing versus weight-bearing exercises in a group of male participants with patellofemoral pain. Participants were randomly assigned to one of three groups: nonweight-bearing resisted knee extension exercise, weight-bearing resisted knee extension exercise, or no exercise (controls). All participants were instructed to avoid pain-provoking activities during the course of the study. The two exercise groups carried out their programs three times per week for 6 weeks. At the conclusion of the study the two exercise groups showed a significant reduction in pain and improvement in overall function and strength of the knee extensors. However, there were no significant differences between the two exercise groups following the treatment program, indicating that both forms of resistance exercise were equally effective. It should be noted that the control group exhibited a decrease in overall function and no change in pain or knee extension strength throughout the course of the study.

Although there is a substantial body of evidence indicating that decreased strength and flexibility of regions proximal to the knee are associated with PFPS, only a few studies, to date, have evaluated the effectiveness of a treatment program that targets the hip, pelvis, and trunk. Several of these studies evaluated the effect of hip strengthening,[25,161,195] whereas others evaluated the effects of a combined program of strengthening hip musculature and stretching the IT band and hip flexors[290] or stretching the hamstrings, IT band, and plantarflexors.[85]

A summary of two case studies[161] indicated that, after a 14-week program of strength and endurance training of hip, pelvis, and trunk musculature, both patients reported a decrease in pain and exhibited increased hip extensor and abductor strength and improvements in functional abilities. Motion analysis of one patient following treatment showed 12° and 5° decreases respectively of hip internal rotation and adduction of the stance leg during a step-down task.

More recently, Nakagawa and colleagues[195] conducted a randomized, controlled pilot study with 14 patients with PFPS to investigate the effectiveness of a quadriceps strengthening program with and without the addition of strengthening exercises for the hip abductors and external rotators. A home exercise program was carried out five times per week for 6 weeks. Pain, isokinetic eccentric torque of the quadriceps

and hip abductors and external rotators, and EMG analysis of the gluteus medius activation were measured before and after the treatment program. A decrease in pain during dynamic functional activities and increased activation of gluteus medius during a maximum voluntary isometric contraction occurred only in the treatment group (the group that performed the hip strengthening exercises). Eccentric knee extensor torque increased in both groups, but there was no significant difference in eccentric hip muscle torque in either group before or after the exercise program.

Fukuda[85] conducted a randomized, controlled study of 70 sedentary females with anterior knee pain: 22 received knee exercises that emphasized stretching and strengthening the knee musculature, 23 received the same program with the addition of hip strengthening and stretching, and 25 served as controls and did not receive any treatment. Interventions were three times per week for 4 weeks in the clinic only. Measures included a lower extremity functional scale, an anterior knee pain scale, and the single-limb single hop test. All groups were the same at baseline. After intervention both exercise groups showed significant improvement in function and reduced pain compared to the controls. The group that performed the combined hip and knee exercise program showed greater improvement in all measures (compared to the knee exercise group), although the measures were not statistically significant except for the reduction in pain during stair descent.

Systematic reviews and preliminary studies, such as those described in this discussion of outcomes, provide some insight into the effectiveness of various exercises for management of PFPS. However, more rigorously designed studies must be carried out to enable therapists to gear interventions to maximize each patient's outcomes.

Patellar Instability: Surgical and Postoperative Management

Following conservative (nonoperative) management of a primary (first-time) patellar dislocation, the rate of recurrence is between 15% to 44% and is as much as 50% after subsequent episodes.[47] When nonoperative interventions fail in the management of patellar instability, including acute and recurrent dislocation or chronic subluxation and associated pain, crepitus, or degeneration of the articular surfaces of the PF joint, surgery usually is indicated.

Surgical interventions can be used to alter the alignment of the patella, correct imbalances of the static stabilizers (see Fig. 21.4) of the patella and knee, decrease an abnormal Q-angle (see Fig. 21.3 for depiction of Q-angle measurement), improve tracking of the patella, and débride or repair articular surfaces of the PF joint. However, before a surgical procedure is selected, the etiology of symptoms and identification of factors contributing to patellar instability must be determined by a thorough physical examination and radiographic and arthroscopic evaluation.

Overview of Surgical Options

Types of surgical options for lateral patellar instability are noted in Box 21.6.[40,46,47,86–89,114,178,179,194,216,226,233] Numerous variations of operative procedures fall under each of these categories. Some are arthroscopic procedures, whereas others involve an open approach. Often a combination of procedures is necessary.

When soft tissue abnormalities contribute to lateral patellar instability, a proximal realignment procedure, such as repair or reconstruction of the MPFL or VMO imbrication, is often selected. A distal realignment procedure that involves a tibial tubercle osteotomy with patellar tendon transfer is selected when an osseous abnormality is the underlying cause of patellar instability. Repair of chondral lesions associated with acute or recurrent patellar dislocation or trauma may also be necessary.[179] In contrast, TKA or patellectomy (a salvage procedure) is performed only for end-stage PF arthritis and collapse of the joint space.[87,179,216]

BOX 21.6 Surgical Options for Management of Lateral Patellar Instability and Associated Structural Impairments

Soft Tissue and Osseous Procedures for Patellar Instability
- Medial patellofemoral ligament repair or reconstruction with autograft or allograft
- Medial retinacular imbrication (advancement)
- Lateral retinacular release, including release of the lateral patellofemoral and patellotibial ligaments
- Imbrication and medialization of the VMO
- Distal realignment of the extensor mechanism (anteromedialization of the tibial tubercle and insertion of the patellar tendon)
- Trochleoplasty (to improve the size/shape of the trochlear groove) for trochlear dysplasia

Articular Cartilage Procedures
- Arthroscopic débridement
- Repair of patellofemoral articular cartilage lesions (microfracture, osteochondral autograft transfer/mosaicplasty, autologous chondrocyte implantation)
- Abrasion arthroplasty/chondroplasty of the posterior surface of the patella (used less frequently with the advent of surgeries to repair articular cartilage)

Procedures for End-Stage Patellofemoral Arthritis
- TKA or replacement arthroplasty of the posterior surface of the patella
- Patellectomy (salvage procedure)

The two broad categories of surgery for patellofemoral instability—proximal and distal realignment of the extensor mechanism—may be performed with or without a lateral retinacular release (LRR). As an independent procedure, LRR has been shown to be useful for alleviating or reducing patellofemoral pain if the cause of the pain stems from compression of lateral structures of the knee (lateral compression syndrome) as the result of an excessive lateral tilt of the patella (without subluxation) but not for management of lateral patellar instability.[47,79,87,179,226]

FOCUS ON EVIDENCE

The results of several current literature reviews[46,47,233] have demonstrated that the use of LRR *in isolation* for recurrent or acute lateral patellar instability yields poor long-term outcomes (high recurrence rates for dislocation). According to another review,[87] LRR failed to realign the patella more medially. All reviews concluded that LRR in isolation is not effective for treatment of lateral patellar instability.

Operative procedures, other than proximal or distal extensor mechanism realignment, sometimes are used for recurrent patellar instability. Trochleoplasty, which involves deepening of the trochlear sulcus, may be indicated if trochlear dysplasia is contributing to patellar instability.[47] If excessive rotational deformity of the lower extremity is determined to be an underlying cause of severe patellar malalignment and recurrent instability, a recently reported procedure—supratubercle, derotational, high tibial osteotomy—may be indicated as an alternative to proximal or distal realignment procedures.[219]

After either proximal or distal extensor mechanism realignment, a number of factors influence the rate of progression of rehabilitation. They include the type of surgical procedure performed; the patient's age, general health, and severity of patellofemoral symptoms prior to surgery; the presence of other pathologies; the desired functional outcomes; and the patient's adherence to the prescribed home exercise program and motivation to return to functional activities.

Proximal Extensor Mechanism Realignment: Medial Patellofemoral Ligament Repair or Reconstruction and Related Procedures

Repair, realignment, or reconstruction of the static and dynamic medial patellar support structures, such as the MPFL, are surgical options performed with or without LRR for the patient with recurrent lateral patellar instability (dislocation or subluxation) and associated pain and compromised function despite a course of nonoperative treatment.[4,40,47,196] MPFL repair or reconstruction also may be used following an acute, first-time lateral patellar dislocation as the result of trauma. Other proximal realignment procedures include VMO imbrication (advancement) and medial retinacular reefing/tightening. These soft tissue procedures are also appropriate for the skeletally immature patient with patellar instability or may be used in conjunction with distal realignment of the extensor mechanism involving an osteotomy in the skeletally mature patient.[87,114]

Indications for Surgery

Although opinion varies, the following are often cited as indications for MPFL repair or reconstruction or other proximal realignment procedures with or without LRR.[4,40,47,87,88,114,194,196,216,226]

- Deficiency (acute tear, chronic laxity) of the medial patellar support structures, in particular the MPFL, a primary static stabilizer, leading to malalignment and recurrent instability of the patella
- Excessive (or abnormal) lateral tracking of the patella and insufficiency of the VMO, a primary dynamic medial stabilizer of the patella
- Normal boney architecture (normal tibial tubercle-trochlear groove distance) and no evidence of patella alta trochlear dysplasia
- Painful, lateral compressive forces at the patellofemoral joint and persistent lateral tilt of the patella despite a previous LRR
- An appropriate realignment option for the skeletally immature patient with patellar instability[114]

CONTRAINDICATIONS: Proximal realignment procedures are not appropriate for patients with articular degeneration of the medial patella, patella alta, or trochlear dysplasia, because they may exacerbate or have no impact on symptoms.[87,114]

Procedures

Background and Operative Overview

Proximal realignment procedures use an open surgical approach through a medial parapatellar incision preceded by an arthroscopic examination of the knee, LRR, débridement of any loose osteochondral fragments or partial-thickness lesions, and, if necessary, microfracture for full-thickness chondral lesions.[179]

MPFL repair or tightening. An acute lateral patellar dislocation usually results in disruption of the MPFL and is managed with a direct repair.[40,114] Repair is also an option if the ligament is lax as the result of recurrent dislocations. To expose the MPFL, the medial retinaculum must be opened. Depending on the location(s) of the tear, the ligament is reattached to the femoral condyle or patella or to both boney surfaces with suture anchors, or the ligament fragments are repaired with nonabsorbable locking sutures in a pants-over-vest fashion.

MPFL reconstruction. This procedure, which has many variations, is used if the MPFL is incompetent as the result of recurrent lateral dislocation or subluxation or if a previous repair or reefing of the ligament has failed. Reconstruction involves reinforcement of the MPFL with an autogenous hamstring, TFL, or quadriceps tendon graft or allograft.[4,62,196]

Depending on the type of reconstruction and graft selected, the patellar and femoral ends of the graft are secured in drill holes with sutures, suture anchors, or screw fixation. In other procedures drill holes are not required, therefore eliminating the risk of patellar fracture.

VMO imbrication (advancement). This procedure is performed to improve the resting length-tension relationship of the VMO by moving the muscle to a more central and distal location.[87,194,216,226]

Lateral retinacular release and other concomitant procedures. If a lateral patellar tilt is identified, LRR is indicated to reduce the tilt and restore the balance of the patella in the trochlea.[46,87,226,233] LRR is performed arthroscopically through several lateral parapatellar portals. The procedure "releases" the lateral structures supporting the patellofemoral joint, specifically the superficial and deep portions of the lateral retinaculum and the lateral patellofemoral and patellotibial ligaments by means of an incision extending from the superior lateral pole of the patella to just lateral and inferior to the patellar tendon.[179] The location of the incision is such that the superior lateral and inferior lateral geniculate arteries are cut and must be cauterized immediately and tied. However, the release leaves the tendinous portion of the VL muscle intact so as not to compromise the function of the quadriceps. Electrocautery[194] and, most recently, radiofrequency ablation[89] are alternatives to surgically incising the retinaculum. The advantages of these methods for releasing the lateral structures are less bleeding and subsequent hemarthrosis.

In addition to repair or reconstruction of the MPFL, sometimes the medial patellotibial and medial patellomeniscal ligaments must be tightened or repaired.[87,88] A boney distal realignment procedure also may be combined with a medial soft tissue repair or reconstruction.[87,88,194]

Complications

Postoperative complications that can occur with any of the patellofemoral surgeries include a superficial infection, but rarely an intra-articular infection, or a DVT. Patellar adhesions and arthrofibrosis can compromise postoperative ROM. In rare instances, complex regional pain syndrome can develop (see Chapter 13).[48] There are also complications seen in proximal realignment procedures and LRR.[87,156]

Following proximal realignment. Overtightening medial soft tissue structures or "overtensioning" the native MPFL or graft tissue during repair or reconstruction, inaccurate graft placement, and/or excessive imbrication of the VMO can exacerbate pain and increase loads on medial articular surfaces, leading to deterioration.[4,40,47] Significant scarring or overtightening of medial tissues also can cause increased patellar rotation and excessive medial tracking leading to retropatellar erosion or increased risk of *medial* instability of the patella.[40,87] In contrast, inadequate medial tightening or VMO realignment may result in no change in patellar position, tracking, or a patient's symptoms. Although the risk of patellar fracture is low, it is a complication that can occur during MPFL reconstruction procedures that require patellar drill holes for graft placement and fixation.[47]

Entrapment, irritation, or a neuroma of the saphenous nerve as it passes the adductor tubercle and splits at the pes anserine tendon can occur with any procedure involving structures on the medial side of the knee.[87]

Following LRR. Several complications may occur with LRR.[22,89,156,] Because of the location of the geniculate artery, hemarthrosis can occur if it is not adequately cauterized during surgery. Thermal injury to overlying skin can occur with radiofrequency ablation or electrocautery.[89] Another complication, postoperative medial patellar subluxation, can develop as the result of the lateral release extending too far proximally, causing weakness of the VL muscle. In rare instances following VMO advancement, rupture of the quadriceps tendon occurs.

Postoperative Management

Postoperative rehabilitation after MPFL repair or reconstruction or other proximal realignment procedures follows a course summarized in Table 21.4.[4,40,88,156,196] The patient is progressed through each phase of rehabilitation based on signs and symptoms and the attainment of phase-specific goals.[204]

TABLE 21.4 MPFL Repair or Reconstruction: Intervention for Each Phase of Postoperative Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phase: Weeks 4–8	Minimum Protection Phase: Weeks 8–12 and Beyond
Patient presentation			
	▪ Rehab begins within 1–2 days after surgery ▪ Postoperative pain ▪ ROM limited ▪ Weight bearing as tolerated in locked extension orthosis	▪ Minimum pain ▪ Joint effusion controlled ▪ Full weight bearing with orthosis locked until full, active knee extension achieved ▪ Functional ROM of knee ▪ Able to perform SLR (no extensor lag) by 6 weeks	▪ No pain, swelling, or tenderness ▪ No signs or symptoms of patellar subluxation, during the previous phase ▪ Muscle function: at least 75% (4/5 MMT) of noninvolved extremity ▪ Unrestricted ADL and IADL

Continued

TABLE 21.4 MPFL Repair or Reconstruction: Intervention for Each Phase of Postoperative Rehabilitation—cont'd

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–4	Moderate Protection Phase: Weeks 4–8	Minimum Protection Phase: Weeks 8–12 and Beyond
Key examination procedures			
	▪ Pain (0–10 scale) ▪ Monitor for hemarthrosis ▪ ROM ▪ Muscle control—ability to perform quad set ▪ MMT: hip muscle strength ▪ Soft tissue palpation	▪ Pain assessment ▪ Joint effusion—girth ▪ ROM ▪ Muscle control ▪ Gait analysis	▪ Pain assessment ▪ Muscle strength ▪ Neuromuscular balance ▪ Patellar alignment and stability ▪ Functional status
Goals			
	▪ Control postoperative ▪ swelling ▪ Minimize pain ▪ Knee ROM: 0°–90° (end of week 4) ▪ 3/5 muscle strength ▪ Ambulate full weight bearing on operated side without assistive device but in locked brace ▪ Establish home exercise program	▪ Control swelling ▪ Knee ROM: 0°–120° (end of week 6) ▪ 0°–135° (end of week 8) ▪ 4/5 to 5/5 strength ▪ Improve neuromuscular control ▪ Normalize the gait pattern ▪ Adherence to home program	▪ Functional knee ROM ▪ 75% muscle strength compared to nonoperated lower extremity ▪ Gradual return to ADL and IADL ▪ Educate patient on resuming activity slowly, monitoring signs and symptoms ▪ Develop maintenance program, and educate patient on importance of adherence
Interventions			
	▪ Compression wrap to control effusion ▪ Pain modulation modalities ▪ Gait training with crutches in locked brace, weight bearing as tolerated ▪ Ankle pumps ▪ Knee: A-AROM→ AROM in range-limiting brace ▪ Superior and inferior patellar mobilization (grades I and II) ▪ Setting exercises: quadriceps, hamstrings, and gluteal muscles (may augment with pain-free NMES over VMO) ▪ Four-position SLRs in locked brace for hip strength ▪ Flexibility program hamstring, calf, IT band	▪ LE flexibility program ▪ Continued open-chain (SLR without lag) and closed-chain strengthening ▪ Limited-range PRE ▪ Proprioceptive training ▪ Stabilization and balance exercises ▪ Gait training ▪ Low-intensity stationary cycling in range-limiting brace for aerobic conditioning	▪ Continue stretching for LE flexibility ▪ Progress PRE for strengthening ▪ Advanced closed-chain exercise ▪ Aerobic conditioning program: cycling, swimming, or walking program ▪ Walk-jog progression at week 10 ▪ Agility drills by week 10–12 ▪ Implement drills specific to occupation or sport ▪ Consider bracing for high-demand activity occupation ▪ Task specific training. Simulated functional tasks based on signs and symptoms

Immobilization and Weight-Bearing Considerations

A compression dressing is applied following surgery, and the knee is immobilized in a range-limiting, hinged orthosis locked in extension or in a posterior splint to prevent excessive knee flexion and protect the repaired or reconstructed soft tissues. Some surgeons allow removal of the immobilizer for early ROM in a protected range or while wearing the range-limiting orthosis within a few days after surgery,[4,40,156,196] whereas others advocate continuous immobilization for a week postoperatively.[114,226]

During ambulation with crutches in the early postoperative period, the knee orthosis is locked in extension. From 25% weight bearing to weight bearing as tolerated is permitted on the operated extremity. Full weight bearing with the immobilizer locked is permitted by about 4 weeks after surgery.[196] Full weight bearing with the orthosis unlocked and without an assistive device is permitted only when the patient can control the knee and has achieved full, pain-free passive and active knee extension (no evidence of an extensor lag/quadriceps lag).[156,226]

Exercise Progression

Exercise goals following MPFL repair or reconstruction or VMO imbrication are directed toward restoring and improving the function of the entire lower extremity and trunk, not just the knee.[79,156,161,228] As with nonoperative management of patellofemoral dysfunction, many of the exercises traditionally selected for a patient's rehabilitation have focused on regaining pain-free knee ROM, maintaining patellar mobility, and recruiting the quadriceps mechanism as a unit and the VMO in particular. These interventions are designed to prevent or remediate patellar restrictions and an extensor lag.[61,130,156,274,283]

A more recent but equally important postoperative focus for exercise interventions is remediating strength deficits in the trunk, pelvis, and hip abductor, external rotator, and extensor muscles and improving flexibility of the hip and ankle musculature.[121,161,224,227,228]

Exercise goals, a progression of exercise interventions, and criteria to progress from one phase of rehabilitation to the next after MPFL repair or reconstruction or other proximal realignment procedures are summarized in the following sections.[88,156,196] Exercise precautions after proximal and distal extensor realignment procedures are noted in Box 21.7.[114,156,196]

Exercise: Maximum Protection Phase

Goals and interventions. During the first 4 weeks after surgery, the repaired or reconstructed medial patellar tissues are in the acute and subacute stages of healing and vulnerable to excessive stresses. The goals and interventions during this period are directed toward achieving independent ambulation with crutches; controlling pain and swelling; preventing complications, such as a DVT or adhesions; and beginning to regain quadriceps control and ROM of the knee while protecting the reconstructed soft tissues (see Table 21.5).

- ***Achieve independent ambulation.*** Gait training with crutches for protected weight bearing and knee orthosis locked in extension
- ***Control pain and swelling.*** Apply cold and compression regularly throughout the day.
- ***Patient education.*** Review weight-bearing and exercise precautions with the patient to protect the repaired ligament or graft tissue while it is most vulnerable to excessive stresses (see Box 21.7). Establish and teach a home exercise program.
- ***Restore ROM.*** Perform knee flexion/extension exercises (PROM→A-AROM and AROM) in the range-limiting orthosis within a day or two after surgery. Depending on the type of repair or reconstruction performed, the goal is to attain full passive and active knee extension and *at least* 90° flexion by the end of week 4.[88,156,196] Stretch hip and ankle musculature, if restricted.

BOX 21.7 Exercise Precautions After Proximal or Distal Realignment of the Extensor Mechanism

- Initiate PROM or A-AROM→AROM exercises in a hinged, range-limiting orthosis to prevent excessive knee flexion or a valgus stress to the knee.
- Progress knee flexion gradually so as not to disrupt sutures after MPFL repair or reconstruction, advancement of the VMO, or tibial tubercle osteotomy with medial transfer of the patellar tendon.
- When assisting with supine-lying hip and knee flexion/extension ROM, stand on the contralateral side of the operated extremity to avoid placing a valgus stress on the knee and stretching repaired medial structures.
- Perform SLR on the operated side with the orthosis locked in extension.
- Begin weight-bearing exercises, such as weight shifting, in bilateral stance with the knee orthosis locked in extension.
- Begin bilateral closed-chain exercises, such as minisquats, in the unlocked, range-limiting knee orthosis when 50% weight bearing on the operated side is permissible.
- Continue to keep the orthosis locked in extension during closed-chain exercises or ambulation in full weight bearing until quadriceps control has been established (full, active knee extension/no extensor lag).
- Postpone unilateral weight-bearing exercises that involve full weight on the operated side and without the orthosis:
  - For at least 4 to 6 weeks after soft tissue reconstruction
  - For at least 8 weeks or until radiographic healing has occurred after a distal realignment involving a tibial tubercle osteotomy
- Do not perform a maximum voluntary contraction (MVC) of the quadriceps for at least 12 weeks after VMO advancement or tibial tubercle osteotomy.

- ***Maintain patellar mobility.*** Apply gentle (grades I and II) patellar mobilization (superior and inferior) to reduce pain and prevent adhesions.
- ***Reestablish neuromuscular control and improve muscle performance.*** Begin gentle quadriceps setting for knee control and active superior patellar gliding with emphasis on VMO activation augmented with pain-free neuromuscular electrical muscle stimulation or biofeedback. While wearing the orthosis locked in extension, initiate SLRs in supine, prone, and side-lying positions for hip control. With the orthosis unlocked, begin partial-range heel-slides in the supine position and bilateral minisquats and heel raises when 50% pain-free weight bearing on the operated side is possible.

Criteria to progress. Criteria to progress to the intermediate phase of rehabilitation include[156,196]:

- Minimal pain and swelling.
- Incision healing well; no signs of infection.
- Full, active knee extension (no evidence of extensor lag) and at least 90° of knee flexion.

Exercise: Moderate Protection/Controlled Motion Phase

Goals and interventions. During the intermediate phase of rehabilitation (from approximately 4 to 8 weeks postoperatively), soft tissues are in the repair and remodeling stage of healing. Full weight bearing without an assistive device but with the orthosis locked typically is permitted by 4 to 6 weeks after surgery. The patient should be able to achieve functional knee ROM by the end of this phase of rehabilitation.

As symptoms subside and quadriceps strength improves, the focus of this phase of rehabilitation is to establish a normal gait pattern with the orthosis unlocked, continue to increase knee ROM, and increase flexibility of hip and ankle structures if restricted. It is equally important to develop strength and endurance of hip and trunk musculature, improve neuromuscular control/response time and balance, regain cardiopulmonary endurance, and progress and reinforce the home exercise program.

- ***Normalize the gait pattern.*** If full weight bearing is pain-free and quadriceps control is sufficient (no extensor lag), practice walking with crutches or a cane with the orthosis unlocked.
- ***Restore ROM and joint mobility.*** Begin low-intensity, prolonged stretching and grade III joint mobilization to increase ROM of restricted areas. Achieve 0° to 120° knee ROM by the end of week 6 and 0° to 135° by the end of week 8.[4,88,156] Also stretch tight musculature. Specifically evaluate the gastrocnemius, soleus, hamstring muscles, and IT band, because they have been shown to be tight in patients with PF dysfunction.[224]
- ***Improve muscle performance.*** Progress pain-free, closed-chain (bilateral minisquats, seated leg press) and open-chain resistance training to increase strength and muscular endurance of the entire lower extremity. Place emphasis on strengthening the knee extensors and hip extensors, abductors, and external rotators. (Suggestions for a progression of nonweight-bearing and weight-bearing exercises are noted in the previous section on nonoperative management and described in the final section of this chapter and Chapter 20).

PRECAUTION: Be certain to have the patient perform resisted exercises only in pain-free ranges and in positions consistent with weight-bearing precautions. During weight-bearing exercises, reinforce proper lower extremity alignment to avoid knee valgus during flexion.

- ***Improve neuromuscular control and response time, proprioception, and balance.*** While wearing the orthosis locked in extension, begin neuromuscular/proprioceptive training and stabilization and balance activities on a stable surface and then on unstable surfaces (minitrampoline, BOSU®, or wobble board). Place emphasis on maintaining proper lower extremity alignment. Progress from bilateral to unilateral stance and from uniplanar to multiplanar movements. As knee control improves, unlock the orthosis during training.
- ***Improve cardiopulmonary endurance.*** Begin a stationary cycling program while wearing the range-limiting orthosis. Begin with a high seat adjustment and low tension. If wound healing is adequate, begin pool walking and marching or jogging in a pool.

Criteria to progress. The following criteria should be achieved to advance to the final phase of rehabilitation.[156]

- No swelling or extensor lag
- Knee ROM: 0° to 135°
- Sufficient strength of knee and hip musculature (at least 75% compared to nonoperated side) to initiate lower extremity functional activities

Exercise: Minimum Protection/Return to Function Phase

Goals and interventions. During the final phase of rehabilitation, which extends from 8 to 12 weeks and beyond, the patient gradually participates in more demanding functional activities without recurrence of pain, patellar instability, or joint effusion. By 12 weeks postoperatively, the patient should be able to begin land-based jogging and, by 16 to 20 weeks, return to a full level of activity without symptoms. Modification of some activities, however, may be necessary.[4]

Emphasize activity-specific training, always maintaining proper lower extremity alignment. Efforts should be made to modify the patient's lifestyle to avoid symptom-provoking activities, at least on a temporary basis. Develop and implement a self-managed program to continue to improve and maintain strength, flexibility, and balance, and devise a plan for adherence.

NOTE: Continued use of patellar taping or a patellar tracking orthosis during exercise may be useful during the progression of exercises and transition to high-demand functional activities.

Refer to the exercise progression previously discussed for advanced nonoperative management and selected exercises described in the final sections of this chapter and Chapter 20. More advanced exercises, including plyometric training and agility drills, are described in Chapter 23.

Outcomes

Outcomes reported after repair or reconstruction of the MPFL (the most common proximal realignment procedures for acute and chronic patellar instability) vary considerably among studies because of the many variations of procedures—some performed in isolation and others combined with lateral release or distal realignment. Following a first-time lateral dislocation, the results of a randomized, controlled trial demonstrated that nonoperative management and repair of medial structures results in similar rates of subsequent patellar dislocation, suggesting there is no advantage of undergoing surgery for an acute (first-time) dislocation prior to a course of nonoperative exercises.[214]

Camp and colleagues[40] carried out a retrospective review of 27 patients (29 knees) who underwent MPFL repair at an average of 19 years of age for recurrent patellar instability. The success rate for the prevention of recurrence of patellar dislocation for an average of 4 years following MPFL repair was 72% (21 of 29 knees), which the investigators considered a relatively high rate of recurrence. The patients who reported a postoperative dislocation subsequently underwent additional procedures, including MPFL reconstruction and/or distal realignment (tibial tubercle osteotomy).

In contrast, MPFL reconstruction procedures have resulted in high patient satisfaction and low redislocation rates. For example, in a retrospective case series, Drez and co-investigators[62] reported the use of MPFL reconstruction with a soft tissue graft (and no distal realignment) in 15 patients with recurrent lateral instability after first-time patellar dislocation. At a mean follow-up of 31.5 months (minimum of 2 years), 93% of patients had excellent results (10 patients) or good results (3 patients) on an objective functional outcome and patient satisfaction scale. Only one of the 15 patients reported one episode of subluxation during the follow-up period.

There is general agreement that LRR performed in isolation is not an effective procedure for management of acute or chronic patellar instability.[46,47,226,233] The poor results can be attributed to the inability of LRR to align the patella in a more medial position.[87]

Poor outcomes, overall, following the many proximal realignment procedures described in the literature appear to be due more to retropatellar pain than to recurrent instability.[114] Patients with generalized joint hypomobility or uncorrected trochlear dysplasia tend to have a high rate of redislocation and typically require a distal realignment procedure.[88]

Distal Realignment Procedures: Patellar Tendon with Tibial Tubercle Transfer and Related Procedures

For a patient with recurrent subluxation/dislocation of the patella with or without degeneration of the lateral and distal articular surfaces of the patella, a procedure involving distal realignment of the extensor mechanism may be the surgical intervention of choice. A medial transfer and possibly anteriorization of the tibial tubercle decreases laterally directed forces on the patella to improve patellar tracking and shifts contact stresses in a medial and proximal direction away from chondral lesions of the distal and lateral articular surface of the patella.[47,86]

Distal realignment procedures may be used in isolation or coupled with LRR or a proximal soft tissue procedure, such as MPFL repair or reconstruction or medial capsular reefing.[47,88,194]

Indications for Surgery

The following are indications for distal realignment procedures.[47,86,87,179,194,216,226]

- Recurrent episodes of lateral patellar instability (dislocation/subluxation) and a sense of the knee "giving way" because of patellar malalignment due to lateralization of the tibial tubercle and patellar tendon insertion
- Painful lateral tracking of the patella with no instability
- Anterior knee pain associated with patellar maltracking and patellofemoral arthrosis (chondral or osteochondral defects) of the lateral and distal retropatellar surfaces
- Abnormally increased Q-angle
- Excessive tibial tubercle-trochlear groove distance (> 15 mm)

CONTRAINDICATION: Boney procedures are not recommended for the skeletally immature patient whose tibial tubercle growth plate is open. Recurvatum of the knee can develop with premature closure of this epiphyseal plate.[86,114]

Procedures

Background and Operative Overview

The purpose of distal realignment procedures is to reduce patellar instability and anterior knee pain by reducing laterally directed forces on the patella and improving patellar tracking.[47,86,87,216,226] Distal realignment procedures are performed using an open surgical approach. However, arthroscopic examination of the knee joint, débridement of the articular surface of the patella, and sometimes an LRR precede the distal realignment procedure.

A number of surgical techniques for distal realignment have been reported.

Tibial tubercle transfer (Elmslie-Trillat procedure). An osteotomy of the tibial tubercle is performed; the boney prominence is then transferred medially and secured with screw fixation.[47,86,88]

Anteriorization (elevation) of the tibial tubercle. Typically combined with a medial tibial tubercle transfer, this procedure involves displacing the tubercle anteriorly by means of a bone graft.[226] This serves to reduce shear forces on the patella and offloads the articular surfaces of the distal patella.[47,86,226]

Distal medialization of the patellar tendon. This procedure involves only a soft tissues transfer for the skeletally immature patient.

Complications

Uncommon but serious complications associated with distal realignment procedures include tibial fracture during placement of fixation screws, neurovascular injury during surgery, inadequate skin closure or sloughing over the osteotomy site, soft tissue infection or osteomyelitis, and nonunion of the transposed bone.[86,226] Redislocation can occur laterally because of undercorrection or medially with overcorrection, particularly in patients who return to high-demand activities.[86,194]

Pain at the anterior tibial tubercle from the fixation screws is not unusual. Therefore, screws are removed routinely 6 to 12 months after surgery.[86] As with all patellofemoral surgeries, patellar adhesions can occur, restricting knee motion. Because distal realignment shifts retropatellar loads medially and proximally, excessive medialization of the tibial tubercle and patellar tendon (> 15 mm past the original insertion site) can cause excessive contact pressure on the medial patellar facet and medial compartment, contributing to arthrosis of these areas over time.[47]

Postoperative Management

Immobilization and Weight-bearing Considerations

Depending on the type of fixation used, rehabilitation after distal realignment involving boney procedures must progress even more gradually than rehabilitation following proximal realignment of soft tissues to allow time for boney healing. Ambulation with crutches while wearing a knee orthosis locked in extension is permissible the day after surgery. Weight bearing is limited to touch-down/toe-touch for the first 4 weeks or until radiographic verification of bone callus formation at the osteotomy site has occurred.[86,156] Weight bearing is progressed gradually, with full weight bearing permissible without the immobilizer at 8 weeks if quadriceps control is sufficient.[156]

Exercise Progression

ROM also is progressed more gradually than after soft tissue procedures. (Refer to exercise precautions noted in Box 21.7.) A range-limiting orthosis is worn that allows motion from only 0° to 30°[156] or 0° to 60°[88] of flexion during the first week to 90° of flexion by the end of week 4 to 135° by the end of week 8.[156] Closed-chain exercises are initiated in the range-limiting knee orthosis as increased weight bearing is permitted. Otherwise, exercises are similar to those for nonoperative management, LRR, and proximal realignment procedures. The return to full activity generally takes about 5 to 6 months and is based on bone healing and lower extremity strength.

Outcomes

Successful outcomes after distal realignment surgeries for recurrent patellar instability and/or painful patellar maltracking without instability, often associated with chondral lesions, are contingent on correctly determining the underlying causes of the patient's symptoms. Patients without degeneration of the retropatellar surface or those with lateral and distal lesions tend to have better results than those with medial articular lesions or advanced PF arthritis.[47,179]

Outcomes following medial tibial tubercle transfer have been shown to be better for patients with painful lateral tracking of the patella but no patellar instability than for patients with at least a 1-year history of recurrent instability.[136] However, the investigators advocated tibial tubercle transfer for painful maltracking and recurrent instability because improvement occurred in both groups of patients.

Often distal realignment procedures are coupled with a proximal repair and/or lateral release to correct malalignment and relieve symptoms. Results of studies of combined procedures reflect good to excellent outcomes for most patients measured by one or more objective assessment tools. For example, Garth and colleagues[88] studied a group of young adults (mean age, 18 years) with recurrent patellar instability despite a course of conservative management after sustaining an acute, traumatic, lateral dislocation of the patella. After undergoing distal realignment coupled with MPFL repair and advancement of the patellomeniscal ligament, 90% (18 of 20) patients reported good to excellent results in knee function and patient satisfaction and no recurrence of instability at a minimum follow-up of 24 months. The results of another study[194] in which three procedures were performed (lateral release, repair of medial supporting structures, and distal realignment) revealed that 32 of 42 knees (76%) in 37 patients had good or excellent outcomes at follow-up (mean, 44 months; minimum, 25 months; range, 25 to 85 months). At the time of follow-up, redislocation had occurred in four knees (9.5%).

Ligament Injuries: Nonoperative Management

Mechanisms of Injury

Ligament injuries occur most frequently in individuals between 20 and 40 years of age as the result of sport injuries (e.g., skiing, soccer, football) but can occur in individuals of all ages. The anterior cruciate ligament (ACL) is the most commonly injured ligament. Often, more than one ligament is damaged as the result of a single injury. Sprain and strain injuries of the knee are classified as knee instability and movement coordination impairments.[149]

Anterior Cruciate Ligament

ACL injuries can occur from both contact and noncontact mechanisms (Fig. 21.12). The most common contact mechanism is a blow to the lateral side of the knee resulting in a

valgus force to the knee. This mechanism can result in injury not only to the ACL but also to the medial collateral ligament (MCL) and the medial meniscus. This injury is termed the "unholy triad" or "terrible triad" injury because of the frequency with which these three structures are injured from a common blow (Fig. 21.13).

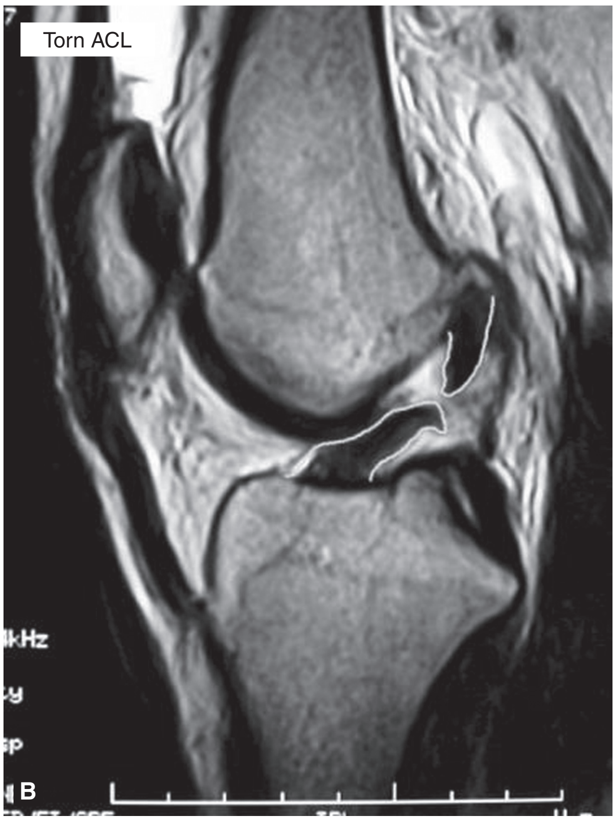

FIGURE 21.12 Sagittal MRI demonstrating a complete midstructure tear of the anterior cruciate ligament (outlined). *(From McKinnis[173] Fig. 13.48 B, p. 396, with permission.)*

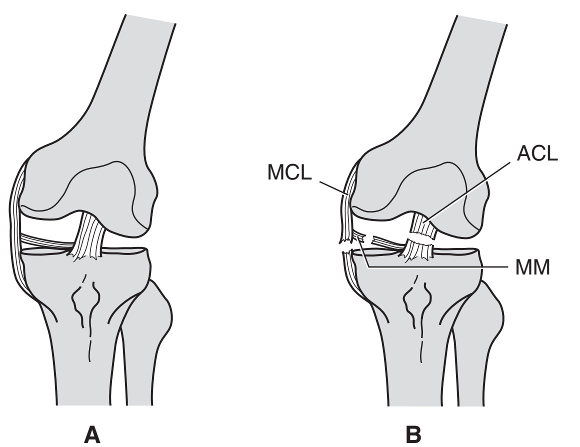

FIGURE 21.13 The "terrible triad," a combination of injuries to the medial meniscus (MM), medial collateral ligament (MCL), and anterior cruciate ligament (ACL). **(A)** Intact ligaments stretched by valgus force. **(B)** Rupture of the MCL, ACL, and MM. *(From McKinnis[173] Fig. 13.45 A and B, p. 395, with permission.)*

The most common noncontact mechanism is a rotational mechanism in which the tibia is externally rotated on the planted foot. Literature supports that this mechanism can account for as many as 78% of all ACL injuries.[202] The second most common noncontact mechanism is forceful hyperextension of the knee.

With prolonged ambulation on a knee that has a deficient ACL, the secondary restraints (lateral collateral ligament and posterolateral joint capsule) are stressed and become lax and a "quadriceps avoidance gait" may develop.[111] The quadriceps avoidance gait in ACL-deficient knees was originally documented and described by Berchuck and colleagues[15] as a reduction in the magnitude of the flexion moment about the knee during the limb loading phase of gait due to the patient's effort to reduce contraction of the quadriceps.

Posterior Cruciate Ligament

Injury to the posterior cruciate ligament (PCL) (Fig. 21.14) most commonly occurs as the result of a forceful blow to the anterior tibia while the knee is flexed, such as a blow to the dashboard or falling onto a flexed knee. A study by Schulz[247] evaluating 587 acute and chronic PCL-deficient knees reported that the three most common mechanisms of injury were a "dashboard"/anterior injury mechanism (38.5%), followed by a fall on the flexed knee with the foot in plantarflexion (24.6%), and lastly, a sudden, violent hyperflexion of the knee joint (11.9%).

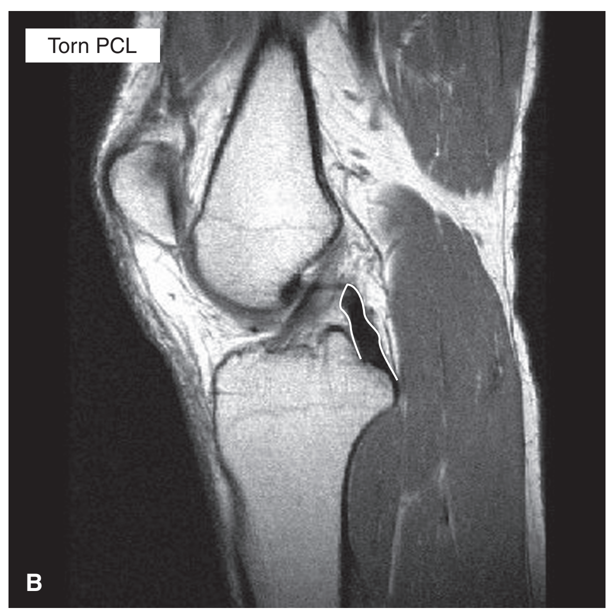

FIGURE 21.14 Sagittal MRI demonstrating a rupture of the posterior cruciate ligament seen as an interruption in the cordlike structure (outlined). *(From McKinnis[173] Fig. 13.47 B, p. 396, with permission.)*

Medial Collateral Ligament

Isolated injuries to the MCL can occur from valgus forces being placed across the medial joint line of the knee. Whereas most injuries to the ACL and PCL are complete tears of the ligament, injuries to the MCL can be partial or incomplete

and are graded utilizing a I, II, III grading classification of ligament injuries described in Chapter 10 (see Fig. 21.13).

Lateral Collateral Ligament

Injuries to the lateral collateral ligament (LCL) are infrequent and are usually the result of a traumatic varus force across the knee. It is not uncommon that more than one ligament or joint capsule and sometimes the menisci are damaged as the result of a single injury creating posterolateral instability.

Ligament Injuries in the Female Athlete

With an increase in the number of female athletes since the passage of Title IX in 1972, a concurrent increase in the number of injuries to female athletes has been seen, most significantly an increase in the number of knee injuries. Interestingly, when injury to the ACL is sustained in a noncontact manner, a woman is three times more likely to tear the ACL than a man is.[7] With the increased number of noncontact ACL injuries in female athletes being reported, the American Academy of Orthopaedic Surgeons published a consensus paper examining the risk factors and prevention strategies of noncontact ACL injuries.[98] In addition, clinicians and scientists interested in ACL-injury gender bias have met in retreat three times, the most recent in 2006, to present research, develop a consensus statement, and suggest future investigations on gender bias in ACL injuries.[53]

Risk factors identified in these consensus papers fall into four major categories: biomechanical, neuromuscular, structural, and hormonal, and they are summarized here.[53,98]

- *Biomechanical risk factors* include the effect of the total chain (trunk, hip, knee, and ankle) on ACL injuries, including awkward or improper dynamic body movements, deceleration, and change of direction. For example, increased hip adduction is related to increased knee valgus, which is associated with ACL injury risk in the female. Also, decreased hip flexion angles and knee flexion has been demonstrated during cutting activities in the female athlete.
- *Neuromuscular risk factors* have an influence on biomechanical factors in that neuromuscular control influences joint position and movement. Valgus collapse at the knee and decreased use of the hip extensors has been reported to be more common in women than in men who have sustained an ACL injury. It has been suggested that this is related to increased anterior shear of the tibia and strain of the ACL during loading (hip-knee flexion when landing following a jump).[227] Not only are females weaker in hip and knee strength compared to males (normalized to body weight), but muscle timing and activation patterns of the quadriceps, hamstrings, and gastrocnemius muscles also differ between males and females.
- *Structural risk factors* include femoral notch size, ACL size, and lower extremity alignment. The femoral notch height is smaller and notch angle larger in the male compared to the female, which may affect ACL size. The female ACL is smaller than the male ACL, even when adjusted for body size. The ACL in the female has a lower modulus of elasticity (i.e., less stiff) and a lower failure strength (i.e., fails at a lower load); thus, the joint is more lax than in the male.
- *Hormonal differences* between males and females has also been postulated to be one possible factor related to the increased incidence of female ACL injuries. There are hormone receptor sites for estrogen, progesterone, and testosterone in the ACL of humans. The sex hormones have a time-dependency effect that influences ACL tissue characteristics, such as increasing risk of injury during the preovulatory phase of the menstrual cycle in females.[149]

Common Structural and Functional Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations/Disabilities)

- Following trauma, the joint usually does not swell for several hours. If blood vessels are torn, swelling is usually immediate.
- If tested when the joint is not swollen, the patient feels pain when the injured ligament is stressed.
- If there is a complete tear, instability is detected when the torn ligament is tested.
- When effused, motion is restricted, the joint assumes a position of minimum stress (usually flexed 25°), and the quadriceps muscles are inhibited (shut down).[272]
- When acute, the knee cannot bear weight, and the person cannot ambulate without an assistive device.
- With a complete tear, there is instability, and the knee may give way during weight bearing, which would prevent the individual from returning to specific work or sport and recreation activities that require dynamic knee stability.

Ligament Injuries: Nonoperative Management

Acute sprains, partial ligament tears, and sometimes complete rupture of a single knee ligament can be treated conservatively with rest, joint protection, and exercise. After the acute stage of healing, exercises should be geared toward regaining normal ROM, balance, a normal gait pattern, and strength, endurance, and neuromuscular control of muscles that support and dynamically stabilize the joint during functional activities.[64,77,117] The degree of instability following a ligament tear affects the demands the patient can place on the knee when returning to full activity.

A patient's preinjury activity level and the postinjury level of activity to which he or she expects to return influence the success of a nonoperative treatment program. Relatively sedentary individuals can usually function with some loss of knee stability and can expect to return to preinjury activities following a course of nonoperative management. For select athletes who wish to return to high-demand activities following ACL injury, an intensive rehabilitation program,

including balance/perturbation training to stimulate neuromuscular control and develop dynamic knee stability, has been shown to be effective.[76,77] In contrast, for patients with extensive ligament damage or concomitant injuries (such as meniscus damage) and poor dynamic knee stability after a period of nonoperative treatment, surgical reconstruction typically is recommended to return to high-level work or sports and a preinjury level of function.

FOCUS ON EVIDENCE

The descriptive terms "potential coper" and "potential noncoper" have been used in the literature[64,77,117,185] to identify and classify those individuals early after ACL injury who are good versus poor candidates for nonoperative rehabilitation based on the results of an initial screening examination. (Potential copers are described as having sufficient dynamic knee stability, the ability to compensate following injury, and good potential to return to preinjury, high-level activities following a course of nonoperative treatment. In contrast, potential noncopers are thought to have poor potential to return to preinjury activities following nonoperative treatment; these individuals typically have poor dynamic knee stability and are advised to consider surgical management.) A study by Moksnes and associates[185] evaluated both copers and noncopers after 1 year of intensive rehabilitation. For those not undergoing surgery, 19 of the 27 noncopers (70%) showed excellent knee function and were reclassified as true copers. In the coper group, 15 of 25 (60%) were true copers. (The term "true coper" applies to individuals able to return to preinjury activity level 1 year after ACL injury with no episodes of the knee giving way during activities.)

The results suggest that the prognostic accuracy of the screening examination is poor and therefore support the importance of including all patients with ACL injury in intensive rehabilitation, not just those who initially meet the definition of coper.

If the collateral or coronary ligaments are involved, because of their superficial location, they may benefit from cross-fiber massage, which helps align the healing fibers and maintain their mobility. Because of the structural characteristics of the MCL (a broad, flat ligament with deep and superficial portions, parallel alignment of collagen fibers, and fan-shaped attachments both proximally and distally), injuries to the MCL are typically managed with a conservative (nonsurgical) approach.[301] Conservative management of MCL injuries is described in Table 21.5; progression is based on presenting signs and symptoms.[204] A similar rehabilitation program for ACL injuries is followed with appropriate precautions (as noted below) regarding stress to the ligament.

Nonoperative Management: Maximum Protection Phase

Follow the principles described for an acute joint lesion earlier in this chapter.

- If possible, examine before effusion sets in.
- Utilize cold and compression with rest and elevation.
- Teach protected weight bearing with use of crutches and partial weight bearing as tolerated.

TABLE 21.5 Nonoperative Management of MCL Injuries: Intervention for Each Phase of Rehabilitation*

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–3	Moderate Protection Phase: Weeks 3–6	Minimum Protection Phase: Weeks 5–8	Return to Activity Phase: Weeks 8–12
Patient presentation				
	■ Joint effusion ■ Pinpoint tenderness ■ Decreased ROM	■ Minimal tenderness ■ Joint effusion controlled ■ No increased instability ■ Full of nearly full ROM	■ No instability ■ No effusion of tenderness ■ 4/5 to 5/5 strength (MMT) ■ Unrestricted ADL function	■ No instability ■ Muscle function 70% of noninvolved extremity ■ No symptoms of instability, pain, or swelling during the previous phase
Key examination procedures				
	■ Pain scale ■ Joint effusion ■ Ligament stability ■ ROM ■ Muscle control ■ Functional status ■ Patellar mobility	■ Pain scale ■ Joint effusion ■ Ligament stability ■ ROM ■ Muscle control/strength ■ Functional status	■ Ligament stability ■ Muscle control ■ Functional status	■ Full clinical examination ■ Ligament stability ■ Muscle strength ■ Functional status

TABLE 21.5 Nonoperative Management of MCL Injuries: Intervention for Each Phase of Rehabilitation—cont'd

Phase and General Time Frame	Maximum Protection Phase: Weeks 1–3	Moderate Protection Phase: Weeks 3–6	Minimum Protection Phase: Weeks 5–8	Return to Activity Phase: Weeks 8–12
Goals				
	▪ Protect healing tissues ▪ Prevent reflex inhibition of muscle ▪ Decrease joint effusion ▪ Decrease pain ▪ Establish home exercise program	▪ Full, pain-free ROM ▪ Restore muscular strength ▪ Normalize gait without assistive device ▪ Normalize ADL function ▪ Adherence to home program	▪ Increase strength ▪ Increase power ▪ Increase endurance ▪ Improve neuromuscular control ▪ Improve dynamic stability	▪ Increase strength ▪ Increase power ▪ Increase endurance ▪ Regain ability to function at highest desired level ▪ Transition to maintenance program
Interventions				
	▪ PRICE (protective bracing, rest, ice, compression elevation) ▪ Ambulation training with crutches; weight bearing as tolerated ▪ PROM/A-AROM ▪ Patellar mobilization (grades I and II) ▪ Muscle setting quadriceps, hamstrings, and adductors (may augment with E-stim) ▪ SLRs ▪ Aerobic conditioning	▪ Continue multiple-angle isometrics ▪ Initiate PRE ▪ Closed-chain strengthening ▪ LE flexibility exercises ▪ Endurance training (e.g., bike, pool, ski machine) ▪ Perturbation/balance training ▪ Stabilization exercises ▪ Initiate a walk/jog program at the end of this phase ▪ Initiate skill-specific drills at the end of this phase	▪ Continue LE flexibility ▪ Advance PRE strengthening ▪ Advance closed-chain exercises ▪ Advance perturbation training ▪ Advance endurance training ▪ Isokinetic training (if available) ▪ Progress running program; full speed jog, sprints, figure-eight running, and cutting	▪ Continue flexibility and strengthening; advance as appropriate ▪ Advance agility drills ▪ Advance running drills ▪ Advance perturbation drills ▪ Implement drills specific to sport or occupation ▪ Determine need for protective bracing prior to return to sport or work

*Note: This is based on grade II ligament injury but may be accelerated for grade I or decelerated for grade III injuries.
Adapted from Wilk and Clancy,[301] with permission.

- Teach safe transfer activities to avoid pivoting on the involved extremity.
- Initiate quadriceps-setting exercises. The knee may not fully extend for end-range muscle-setting exercises, so begin the exercises in the range most comfortable for the patient. As the swelling decreases, initiate ROM within tolerance.

Nonoperative Management: Moderate Protection (Controlled Motion) Through Return to Activity Phases

As swelling decreases, examine the patient for impairments and functional losses. Initiate joint movement and exercises to improve muscle performance, functional status, and cardiopulmonary conditioning.[64,149]

Improve Joint Mobility and Protection

Joint mobility. Use supine wall slides (see Fig. 21.19), patellar mobilizations, and stationary cycling; encourage as much movement as possible. Unless there has been an extended period of immobilization, there should be minimal need to stretch contractures.

Protective bracing. Bracing may be necessary for weight-bearing activities to decrease stress to the healing ligament or to provide stability when ligament integrity has been compromised. Bracing can be one of two types: (1) range-limiting

postoperative type braces that are used to protect healing tissues and then discontinued during later phases of rehabilitation; or (2) functional braces that are used during advanced rehabilitation and also when returning to functional activities. The patient must be advised to modify activities until appropriate stability is obtained.

Improve Muscle Performance

Strength and endurance. Initiate isometric quadriceps and hamstring exercises, and progress to dynamic strength and muscular endurance training. Quadriceps strength is important for knee stability.[149]

- Utilize both open-chain and closed-chain resistance.
  - Open-chain resistance has been shown to be more effective for increasing quadriceps strength than closed-chain single-leg squat in patients with an ACL injury.[282]
  - Progress closed-chain exercises using partial squats, step-ups, leg press, and heel raises.
- Reinforce quadriceps contractions with high-intensity electrical stimulation if there is an extensor lag.[267]

FOCUS ON EVIDENCE

Eitzen and associates[64] reported results of a progressive 5-week exercise program with patients (n=100) who had a recent ACL injury (within 3 months) prior to deciding on whether or not to have reconstructive surgery. Pre- and post-tests included isokinetic quadriceps and hamstring strength, four single-leg hop tests, two self-assessment questionnaires, and a global rating of knee function. Both potential copers and noncopers without additional symptomatic injuries were included in the study. The program utilized progressive strength training (heavy resistance open and closed chain); plyometric, balance, and stability exercises; and perturbation training. A standardized response mean for each variable was calculated and demonstrated clinically relevant improvements in both groups. Adverse events (swelling, pain, or knee giving way) occurred in only five subjects.

Neuromuscular control. Neuromuscular control is compromised when stabilizing muscles fatigue.[113] Emphasize neuromuscular reeducation (proprioceptive training) with stabilization, acceleration, deceleration, and perturbation training in weight-bearing positions.[149] Begin with low-intensity, single-plane movements and progress to high-intensity, multiplane movements. These exercises are described in Chapter 8 and summarized in the last section of this chapter.

FOCUS ON EVIDENCE

In a randomized, controlled study, 26 level I or level II athletes with an acute ACL injury or rupture of ACL grafts participated in a standard rehabilitation program or a standard rehabilitation program with perturbation training.[76] Of those in the perturbation group (n=12), only one had unsuccessful rehabilitation, with the knee giving way while playing football prior to completing the program. In the control group (no perturbation training; n=14), one-half of the subjects had unsuccessful outcomes and were considered at high risk for reinjury at the 6-month follow-up examination. The authors stated that although both groups returned to high-level physical activities, those in the perturbation-training group demonstrated greater long-term success.

Improve Cardiopulmonary Conditioning

Utilize a program that is consistent with the patient's goals, such as biking (begin with a stationary bike), jogging (begin with walking on a treadmill), using a ski machine, or swimming.

Progress to Functional Training

Develop activity-specific exercises and drills that replicate the demands of the individual's outcome goals.[288] Suggestions for functional training are described in the exercise section of this chapter and Chapter 23.

Ligament Injuries: Surgical and Postoperative Management

Background

Ligaments of the knee provide the key stabilizing forces for accessory motions of the knee (see Fig. 21.2). Specifically, these accessory motions are anterior and posterior translation and medial/lateral pivots (valgus/varus/rotation). Strong ligamentous support is necessary, in part, because of the shallow design of the concave tibial articulating surface that allows significant translatory motions if unrestrained. Acute traumatic disruption or chronic laxity of the ligaments results in excessive accessory motions of the joint, which can impair functional abilities. Although injuries to each of the four primary knee ligaments (ACL, PCL, MCL, LCL) are discussed extensively in the literature, the ACL is, by far, the most frequently injured and surgically repaired.[19,202]

General considerations and indications for ligament surgery. Factors influencing the decision for surgical reconstruction of a knee ligament include the ligament injured (differences in healing capacities among ligaments), the location and size of the lesion, the degree of instability experienced by the patient, the presence of concomitant pathology such as a meniscal or articular cartilage damage, and the potential for achieving the desired level of function to which the patient wishes to return.[1,2,73,133,181,280] The risk of reinjury and prevention of future impairment are also considerations because acute ligament injury, if not managed adequately, can lead to chronic instability.[19] In turn, chronic instability is thought to contribute to degeneration of articular cartilage over time and early-onset OA.[150]

Surgical intervention for ligament injury is indicated if the patient has failed to achieve functional goals established in a conservative rehabilitation program or has early degenerative changes of the joint are apparent. Many authors[19,32,83,181,258,280] recommend surgical intervention for acute, isolated ACL and LCL injuries after a brief period of acute symptom management in recreationally active individuals. Surgical management of chronic ligament deficiency is advocated when a patient's function has become compromised or when secondary pathology (e.g., meniscus damage, other ligament involvement, articular degeneration) has developed. However, there is no evidence to suggest that ACL reconstruction prevents or reduces the rate of progression of early-onset joint destruction.[150]

Types of ligament surgery. Ligament surgeries are classified as *intra-articular*, *extra-articular*, or combined procedures and can be performed using an open, arthroscopically assisted, or all-arthroscopic approach.[32,141,181] Initially, intra-articular procedures were performed through an open approach and involved a *direct repair* of the ligament. The repair was accomplished by reopposing and suturing the torn ligament. Postoperatively, a long period (usually 6 weeks) of immobilization and restricted weight bearing were required because of extensive tissue disruption associated with the open approach and the poor healing qualities of ligamentous tissue.[141] Outcomes were unacceptable due to postimmobilization contractures, patellofemoral dysfunction, muscle weakness, and an unacceptably high incidence of rerupture. Consequently, use of direct repair was abandoned as procedures involving intra-articular or extra-articular *reconstruction* were developed.

Intra-articular reconstruction of ligament injuries, which has evolved over the past four decades, has become the primary means by which ACL and PCL injuries are managed surgically. In general terms, reconstruction involves the use of a tissue graft to replicate the function of the damaged ligament and act as an inert restraint of the knee.[20,32,141,158,181,199,280] Initially, intra-articular reconstruction procedures also were performed through an open approach. Although the reconstruction restored knee stability, the need for lengthy postoperative immobilization continued.[141] Today, intra-articular ligament reconstruction is performed through an arthroscopically assisted or an all-arthroscopic approach, causing far less tissue morbidity and resulting in a more rapid postoperative recovery.

NOTE: Overviews of intra-articular ACL and PCL reconstruction procedures are described later in this chapter.

Extra-articular reconstruction procedures, which involve the transposition of dynamic musculotendinous stabilizers or inert restraints around the knee, such as the IT band, were designed to provide external stability to the knee joint. Extra-articular procedures, in common use in the past, particularly for MCL and LCL injuries, are used rarely today as primary procedures because they do not restore normal kinematics to the knee as effectively as intra-articular procedures. Use of extra-articular procedures to augment intra-articular reconstruction in difficult cases also has been shown to have little benefit.[141]

Grafts: Types, healing characteristics, and fixation. Intra-articular reconstruction is achieved through the use of tissue grafts, most often an *autograft* (the patient's own tissue) or occasionally an *allograft* (donor tissue) or a *synthetic graft* (Fig. 21.15).[134,177,199,258] An allograft or synthetic graft is used only when a suitable autogenous graft is not available—for example, when a patient's own tissue is not suitable for graft harvesting.[141,199] However, there is concern that remodeling and incorporating the graft after implantation may be slower with an allograft (possibly due to sterilization to prevent disease transmission) or a synthetic graft than with an autograft.[177] (Refer to Chapter 12 and Box 12.9 for additional information about tissue grafts.)

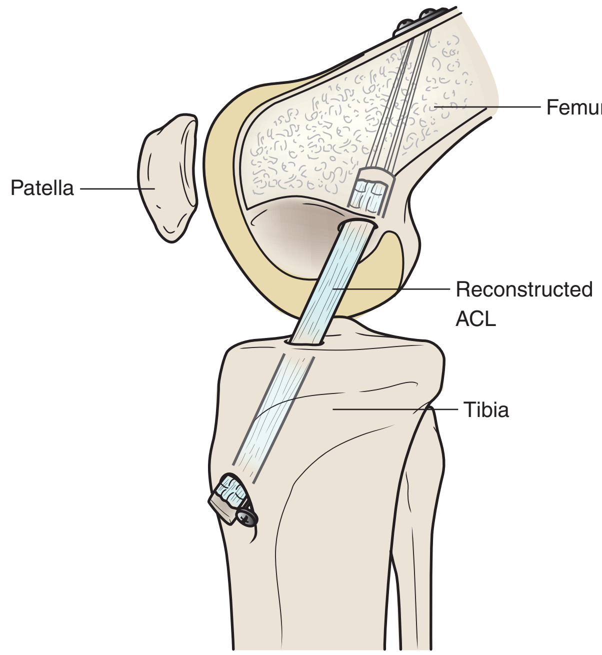

FIGURE 21.15 Lateral view of the knee depicting graft placement for ACL reconstruction.

Although a variety of tissues have been used for knee ligament reconstruction,[134,143,158,177,186,199] a bone-patellar tendon-bone autograft has been used reliably and has been considered the gold standard for ACL reconstruction for several decades.[32,71,141,143,203] It remains the most frequently selected graft material for this procedure.[20,73,82,134,143,158,181] A frequently selected alternative to a patellar tendon graft for ACL reconstruction is a semitendinosus-gracilis tendon graft.[71,141,143,186,254,281] Research has shown that the strength and stiffness of a bone-patellar tendon-bone graft and a quadrupled (four-strand) hamstring tendon graft are actually greater than that of the native ACL ligament.[254]

An extensive body of knowledge exists on graft healing, placement, and fixation as well as the strength and stiffness of various tissues selected as grafts and their responses to

imposed loads. Most research has focused on grafts for ACL reconstruction.[20,29,82,133,143,264]

CLINICAL TIP

Because the characteristics of grafts and graft fixation affect the rehabilitation process and the outcome of surgery, it is important to understand that a graft undergoes a series of changes after implantation as it heals. Initially, there is a period of avascular necrosis during which the graft loses substantial strength. This period is followed by a period of revascularization, then remodeling, and finally maturation, which typically takes at least 1 year. During the first 6 to 8 weeks postoperatively, the graft is most vulnerable to excessive loads because the strength of the graft is derived solely from the fixation device, not the graft itself.[20,29,133,134]

The need for a long postoperative period of immobilization and protected weight bearing after ligament reconstruction has been eliminated following primary ACL reconstruction because of advances in graft selection, preparation, placement, and fixation and because of the evolution of arthroscopic techniques.[20,29,264] Nevertheless, there is still a need to carefully select and progress the stresses imposed on the healing graft during early rehabilitation.

General considerations for rehabilitation. The expected outcomes following surgery and postoperative rehabilitation after ligament reconstruction are: (1) restoration of joint stability and motion, (2) pain-free and stable weight bearing, (3) sufficient postoperative strength and endurance to meet functional demands, and (4) the ability to return to preinjury activities.

Successful postoperative outcomes start, whenever possible, with a *preoperative* program that includes edema control, exercise to minimize atrophy and maintain as much ROM as possible, protected ambulation, and patient education.[59,185,220,256] Preoperative intervention is often possible because ligament reconstruction typically is delayed until postinjury symptoms subside. Exercises are similar to those used for the early phase of nonoperative management of ligament injuries discussed in the previous section of this chapter. Depending on the location and extent of injury, an exercise program may be carried out for several weeks to several months before a decision is made to go forward with surgery.[185] Regardless of the duration of the preoperative exercise program, exercises should not further irritate the injured tissues or cause additional swelling or pain.

The *progression and duration* of postoperative rehabilitation programs published in the literature vary. No program has been shown to be optimal. Throughout rehabilitation, open communication with the surgeon enables the therapist to discuss any precautions or concerns specific to individual patients and procedures.

Regardless of the ligament injured or operative procedures performed, the emphasis of rehabilitation is placed on restoring a patient's functional abilities while protecting the healing graft and preventing postoperative complications and reinjury. Early controlled motion and weight bearing, hallmarks of current-day rehabilitation, have been shown to decrease the incidence of postoperative complications, such as contracture, patellofemoral pain, and muscle atrophy,[220,256,259,303] and to allow patients to return to activity as quickly as possible without compromising the integrity of the reconstructed ligament.[193,259]

For more than a decade there has been a move away from adherence to strict time-based rehabilitation protocols toward guidelines that are progressed based on the attainment of specific criteria and measurable goals or performance on functional tests.[108,155,157,193,204,303] For example, an exercise program is progressed only after full, active knee extension has been achieved or arthrometer testing indicates that a particular level of joint stability is present. A criterion-based progression is advocated to ensure a safe return to high-level sporting activities and to prevent reinjury.[193,303]

CLINICAL TIP

Clinical practice guidelines have been published recently to summarize available evidence and provide recommendations to support evidence-based decision-making during rehabilitation of knee stability following ligament injury and surgery.[149]

Anterior Cruciate Ligament Reconstruction

Unlike the MCL, which heals readily with nonoperative management, the healing capacity of a torn ACL is poor, giving rise to the frequent recommendation for surgical reconstruction to restore knee stability, particularly in the young, active individual.[19,133] Although the incidence of reinjury of the knee is lower after ACL reconstruction than with nonoperative management, particularly in patients younger than 25 years of age,[63] many individuals who have sustained an acute, primary ACL injury participate in a conservative course of treatment before a decision is made to undergo surgical reconstruction or to continue with nonoperative treatment.[64,185]

Indications for Surgery

Although there are no rigid criteria for patient selection, the most frequently cited indications for ACL reconstruction include the following.[19,32,158,181,185,186]

- Disabling instability of the knee due to ACL deficiency caused by a complete or partial acute tear or chronic laxity
- Frequent episodes of the knee giving way (buckling) during routine ADL as the result of significantly impaired dynamic knee stability despite a course of nonoperative management

- A positive pivot-shift test because an ACL deficit is often associated with a lesion of other structures of the knee, such as the MCL, resulting in rotatory instability of the joint
- Injury of the MCL at the time of ACL injury to prevent lax healing of the MCL
- High risk of reinjury because of participation in high-demand, high joint-load activities related to work, sports, or recreational activities

NOTE: Increased anterior translation of the tibia on the femur compared with the contralateral, noninvolved knee, as measured by an arthrometer, is considered a questionable indication because a strong correlation between these measurements of stability and a patient's symptoms of instability has not been established.[19]

CONTRAINDICATIONS: Relative, not absolute, contraindications for ACL reconstruction are noted in Box 21.8.[19,32,158,186]

BOX 21.8 Relative Contraindications to ACL Reconstruction

- Relatively inactive individual with little to no exposure to work, sport, and recreational activities that place high demands on the knee
- Ability to make lifestyle modifications to eliminate high-risk activities
- Ability to cope with infrequent episodes of instability
- Advanced arthritis of the knee
- Poor likelihood of complying with postoperative restrictions and adhering to a rehabilitation program

Procedures

Operative Overview

Surgical approach, graft selection, and harvesting. In the past 30 years, surgical management of the deficient ACL has evolved and continues to be refined with a move away from entirely open reconstruction to the current practice of most procedures now using arthroscopically assisted or endoscopic techniques to reduce tissue morbidity and reduce recovery time.[19,20,71,141] In an arthroscopically assisted approach, only the intra-articular portions of the procedure, such as meniscus débridement or repair, enlargement of the intercondylar notch of the femur, or drilling the femoral and tibial bone tunnels, are performed arthroscopically.[141]

The most common ACL reconstruction procedure today is an arthroscopically assisted or endoscopic procedure using an autograft. If a bone-patellar tendon-bone graft is selected, it is harvested through a small, longitudinal incision over the patellar tendon from the patient's involved knee[20,32,73,158,181] or occasionally from the contralateral knee.[258] The central one-third portion of the tendon is dissected along with small bone plugs attached to the tendon. If a semitendinosus-gracilis tendon autograft (hamstring tendon graft) is selected, it is harvested through an incision centered over the tibial insertion of the semitendinosus and gracilis tendons.[71,186,254,261,264,273,281]

Although a summary of systematic reviews has shown no significant difference in outcomes following the use of bone-patellar tendon-bone versus hamstring tendon grafts if coupled with appropriate postoperative rehabilitation,[149] there are a number of advantages, disadvantages, and potential complications associated with these two classifications of autografts. For example, transition from mechanical fixation to biological fixation is thought to occur more rapidly with a patellar tendon graft, which involves bone-to-bone healing, than with a hamstring tendon graft, which requires tendon-to-bone healing (6 to 8 weeks versus 12 weeks, respectively).[264] Other reported advantages and disadvantages of these two types of autografts are summarized in Boxes 21.9 and 21.10.[1,71,141,143,162,241,254,261,273,281] It should be noted, however, that recently the use of a bone-hamstring tendon-bone autograft for ACL reconstruction was reported, allowing bone-to-bone healing and affording some of the same advantages associated with a bone-patellar tendon-bone autograft.[162]

Graft placement and fixation. After the graft is harvested and prepared for implantation, the arthroscopic instrumentation is reinserted to drill femoral and tibial bone tunnels.[20,83,141,158] Graft placement (see Fig. 21.15) is achieved by passing the graft through the tunnels to its final position in the tibia and femur. Precise, anatomical graft placement is crucial for restoration of joint stability and mobility. Improper graft placement can lead to loss of ROM postoperatively.[1] A graft placed too far posteriorly may result in failure to regain full flexion, and a graft placed too far anteriorly may limit extension.[29]

BOX 21.9 Advantages and Disadvantages/Complications of the Bone-Patellar Tendon-Bone Autograft

Advantages
- High tensile strength/stiffness, similar or greater than the ACL
- Secure and reliable bone-to-bone graft fixation with interference screws
- Rapid revascularization/biological fixation (6 weeks) at the bone-to-bone interface permitting safe, accelerated rehabilitation
- Ability to return to preinjury, high-demand activities safely

Disadvantages/Potential Complications
- Anterior knee pain in area of graft harvest site
- Pain during kneeling
- Extensor mechanism/patellofemoral dysfunction
- Long-term quadriceps muscle weakness
- Patellar fracture during graft harvest (rare, but significant adverse effects)
- Patellar tendon rupture (rare)

BOX 21.10 Advantages and Disadvantages/ Complications of the Semitendinosus-Gracilis Autograft

Advantages

- High tensile strength/stiffness greater than ACL with quadrupled graft
- No disturbance of epiphyseal plate in skeletally immature patient
- Evidence of hamstring tendon regeneration at donor site
- Loss of knee flexor muscle strength remediated by 2 years postoperatively

Disadvantages/Potential Complications

- Tendon-to-bone fixation devices (particularly tibial fixation) not as reliable as bone-to-bone fixation
- Longer healing time (12 weeks) at tendon-bone interface
- Hamstring muscle strain during early rehabilitation
- Short- and long-term knee flexor muscle weakness (not associated with functional limitation)
- Possible increased anterior knee translation (not associated with functional limitations)

NOTE: Limited ROM into extension also may be caused by graft impingement due to an inadequate femoral notch size or buildup of scar tissue in the notch.[1] A *femoral notchplasty* (enlargement of the intercondylar notch) is performed to ensure adequate clearance of the graft as the knee extends.

Graft fixation is vital to the success of ACL reconstruction. With a bone-patellar tendon-bone graft, the bone plugs are secured at each end in the prepared tunnels (bone-to-bone fixation) by means of screw fixation (metal or bioabsorbable interference screws).[29,32,83,143,158,264] Several types of soft tissue fixation devices have been used to secure a hamstring tendon graft, including endobuttons, washers, and staples. Use of interference and transfixation screws also has been advocated.[29,71,41,186,254] Despite these advances, strong tendon-bone fixation, particularly tibial fixation, remains a challenge.

An advantage of current-day fixation devices is that they can withstand early but controlled tensile forces placed across the graft with a low risk of compromising the security of the graft itself, provided proper placement and fit of the fixation devices are achieved.[20,29,71] This, in turn, permits early initiation of weight bearing and ROM of the knee, both typical elements of contemporary, accelerated rehabilitation programs.[21,90,108,157,193,254,259,303]

After graft fixation and prior to closure, the knee is moved through the ROM to check the graft's integrity and the tension on the graft during knee movement. As with graft placement, proper graft tension at the time of fixation has a direct effect on postoperative joint mobility and stability. Too little tension can result in excessive knee laxity and potential instability, and too much tension can limit knee ROM.[20] After the incision is closed, a small compression dressing is immediately placed on the knee, and the leg may be placed in a knee immobilizer for protection.

Complications

There are a number of operative and postoperative complications that can compromise outcomes after ACL reconstruction. Some of these complications have been noted (see Boxes 21.9 and 21.10). Even minor technical errors during reconstruction can affect function adversely. As discussed in the previous section, inappropriate placement of the graft or bone tunnels, problems with graft harvesting such as inadequate graft length, and improper graft tension can adversely affect joint stability and mobility.[1,252] Insufficient graft length occurs more frequently during hamstring than patellar tendon graft harvesting. If graft fixation is insufficient, graft slippage and early failure can occur.[252, 254] With a bone-patellar tendon-bone graft, a bone plug can fracture during harvesting or implantation, necessitating an alternative autograft or an allograft.[252]

Postoperatively, potential complications are knee pain, loss of motion, persistent strength deficits, and inadequate joint stability.[1,186,252] Anterior knee pain at the donor site of a patellar tendon graft or at the patellofemoral joint may affect functional activities. A neuroma of the infrapatellar branch of the saphenous nerve can cause significant knee pain during kneeling.

Loss of full knee extension and persistent quadriceps weakness are recognized as significant complications after ACL reconstruction, particularly if full extension is not achieved preoperatively.[163] There may be permanent damage to the extensor mechanism after patellar tendon graft harvesting, leading to quadriceps weakness or even patellar tendon rupture in rare instances. Limited ROM of the knee may have been present prior to surgery or may develop after surgery. One possible cause is a buildup of scar tissue in the intercondylar notch, necessitating arthroscopic notchplasty. Loss of patellar mobility also may be a source of limited knee ROM. It has been suggested that a patient's preoperative strength and ROM also may have an impact on postoperative knee motion and strength.

FOCUS ON EVIDENCE

McHugh and associates[170] evaluated 102 patients (age 31 ±1 year) within 2 weeks of primary ACL reconstruction and 6 months after surgery to determine preoperative indicators of postoperative motion loss (lack of full knee extension) and quadriceps weakness. They found that patients with loss of knee extension preoperatively (in comparison to the noninvolved contralateral knee) were more likely to have limited knee extension postoperatively. However, a preoperative deficit of quadriceps muscle strength ($\geq$ 20% compared with contralateral quadriceps strength) was not an indicator of postoperative quadriceps weakness 6 months after surgery.

Lastly, graft failure and the need for revision reconstruction may occur even in the absence of risk factors related to surgical technique. It has been shown that graft failure is most

likely to occur during the early months after surgery.[84] It has also been suggested that the most common cause of graft failure is poor adherence to postoperative rehabilitation, in particular returning to high-risk, high joint-load activities prematurely.[1,84,252]

Postoperative Management

In the past, rehabilitation after ACL reconstruction involved long periods of continuous immobilization of the knee in a position of flexion and an extended period (often 6 to 8 weeks) of restricted weight bearing. Return to full activity often took a full year.[30,257] With advances in surgical techniques and a better understanding of graft healing and the impact of stress on the healing graft, early postoperative motion and weight bearing—often referred to as "accelerated rehabilitation"—has become the standard of care after primary ACL reconstruction with an autogenous graft for the active, typically young patient.[21,36,90,108,157,193,217,220,256,257,303]

Accelerated rehabilitation is based on the premise that a precisely placed and appropriately tensioned graft not only is strong enough to withstand the stresses of early motion and weight bearing but also responds favorably to these stresses during the healing process.[20,36,256,257,259,303]

Table 21.6 outlines a contemporary, accelerated program for postoperative management after primary ACL reconstruction. The sequence of goals and interventions identified in Table 21.6 and described in the phases of rehabilitation that follow reflects guidelines common to a number of programs published in the literature.*

*21,36,90,108,147,157,176,193,217,220,234,236,256, 259, 282,303

TABLE 21.6 ACL Reconstruction: Interventions for Accelerated Postoperative Rehabilitation

Phase and General Time Frame	Maximum Protection Phase: Day 1–Week 4	Moderate Protection Phase: Weeks 4–10	Minimum Protection Phase: Weeks 11–24
Patient presentation			
	■ Pain and hemarthrosis ■ Decreased ROM ■ Diminished voluntary quadriceps activation ■ Ambulation with crutches ■ Use of protective bracing (if prescribed)	■ Pain controlled ■ Joint effusion controlled ■ Full or near full knee ROM ■ Fair plus to good muscle strength (3+/5 to 4/5) ■ Muscular control of joint ■ Independent ambulation	■ No joint instability ■ No pain or swelling ■ Full knee ROM ■ Muscle function: 75% of noninvolved extremity ■ Symmetrical gait ■ Unrestricted ADL ■ Possible use of functional brace or sleeve
Key examination procedures			
	■ Pain scale ■ Joint effusion—girth ■ Ligament stability—joint arthrometer (days 7–14) ■ ROM ■ Patellar mobility ■ Muscle control ■ Functional status	■ Pain scale ■ Effusion—girth ■ Ligament stability—joint arthrometer ■ ROM ■ Patellar mobility ■ Muscle strength testing ■ Functional testing	■ Ligament stability—joint arthrometer ■ Muscle strength testing ■ Functional testing ■ Full clinical examination
Goals			
	■ Protect healing tissues ■ Prevent reflex inhibition of muscle ■ Decrease joint effusion ■ ROM 0°–110° ■ Active control of ROM ■ Weight bearing: 75% to weight bearing as tolerated ■ Establish home exercise program	■ Full, pain-free ROM ■ 4/5 muscular strength (MMT) ■ Dynamic control of knee ■ Improved kinesthetic awareness ■ Normalize gait pattern and ADL function ■ Adherence to home program	■ Increase muscle strength, endurance, and power ■ Improve neuromuscular control, dynamic stability, and balance ■ Regain cardiopulmonary endurance ■ Transition to maintenance program ■ Regain ability to function at highest desired level ■ Reduce risk of reinjury

TABLE 21.6 ACL Reconstruction: Interventions for Accelerated Postoperative Rehabilitation—cont'd

Phase and General Time Frame	Maximum Protection Phase: Day 1–Week 4	Moderate Protection Phase: Weeks 4–10	Minimum Protection Phase: Weeks 11–24
Interventions			
	Weeks 0–2 ▪ PRICE: (protective bracing, rest, ice, compression, elevation) ▪ Gait training: crutches, partial weight bearing to WBAT ▪ PROM/A-AROM (range-limiting brace, if prescribed ▪ Patellar mobilization (grades I/II) ▪ Muscle setting, isometrics: quadriceps, hamstrings, adductors at multiple angles (may augment with E-stim) ▪ Assisted SLRs—supine ▪ Ankle pumps Weeks 2–4 ▪ Continue as above ▪ Progress to full weight-bearing; begin closed chain squats; heel/toe raises ▪ SLRs in four planes ▪ Low-load PRE: hamstrings ▪ Open-chain knee extension (range 90°–40°) ▪ Trunk/pelvis stabilization ▪ Aerobic conditioning: stationary cycle	Weeks 5–6 ▪ Multiple-angle isometrics ▪ Closed-chain strengthening and PRE ▪ LE stretching program ▪ Endurance training (bike, pool, elliptical trainer) ▪ Proprioceptive training in single-leg stance: balance board, BOSU ▪ Stabilization exercises, elastic bands, band walking Weeks 7–10 ▪ Advance strengthening (include PNF), endurance, and flexibility exercises ▪ Proprioceptive training: high speed stepping drills, unstable surface challenge drills, balance beam ▪ Initiate a walk/jog program at the end of this phase	Weeks 11–24 ▪ Continue LE stretching ▪ Advance PRE/initiate isokinetic training (if desired) ▪ Advance closed-chain exercise ▪ Initiate plyometric drills: bounding, jumping ▪ Initiate plyometric drills (bouncing, jumping rope, box jumps: double-/single-leg) ▪ Advance proprioceptive and balance training ▪ Progress agility drills (figure-eight, skill-specific patterns) ▪ Simulated work or sport-specific training ▪ Transition to full-speed jogging, sprints, running, and cutting

NOTE: It is important to recognize that although the descriptor "accelerated" is used frequently in the literature to characterize current-day rehabilitation after primary ACL reconstruction, there is no consensus on the initiation, progression, or duration of postoperative exercise, weight bearing, and other interventions.

Immobilization and Bracing

The rationale for a brief period of immobilization and the use of bracing in the early phase of rehabilitation after ACL reconstruction is based on protecting the graft from excessive strain and preventing the loss of full knee extension.[20,235,309] However, with advances in graft fixation, the need for and benefits of early versus delayed motion and/or protective bracing have become a point of debate—recommended by some but not by others.[20,21,217,256,303]

Decisions about whether ROM is initiated early after surgery or postoperative bracing is prescribed are based on many factors. They include the surgeon's philosophy, the type of graft used, intraoperative observations about the quality of fixation, comorbidities and concomitant surgical procedures (e.g., meniscus or collateral ligament repair), and an assessment of the patient's expected level of adherence to a postoperative rehabilitation program.[108,220]

Types of postoperative bracing. Protective bracing after ACL reconstruction falls into two broad categories: *rehabilitative bracing* and *functional bracing*.[20,235,309] Rehabilitative bracing, if prescribed, usually is a hinged, range-limiting orthosis with a locking mechanism. It is typically is worn for just the first 6 weeks after surgery. In contrast, a functional brace is worn when returning to high-demand sports or work-related activities to potentially reduce the risk of reinjury.

Brace use and initiation and progression of knee ROM. If a rehabilitative brace is prescribed after surgery, it may or may not be locked initially to hold the knee in full extension. (Even though the greatest stress on the graft occurs between 20° of knee flexion and full extension, precise graft placement and tension allow full knee extension without disrupting the

graft's integrity.) If locked in full extension for a short period of time, the brace is unlocked for exercise as soon as ROM is permitted. It is worn throughout the day for a few weeks to 6 weeks[20] and sometimes is worn during sleep for protection for the first week postoperatively.[220] Initially, the brace is locked in full extension during ambulation with crutches in the event of a fall.[108,147,220,256,303] When ROM is initiated, the rehabilitative brace can be set to limit the range of knee flexion during exercise and functional activities so that flexion is progressed gradually.

CLINICAL TIP

Guidelines for the duration of immobilization in extension and the initiation and progression of knee ROM vary somewhat in the literature.[6,20,21,108,186,193,217,220,256,303] The literature supports the initiation of immediate or at least early knee motion (within the first week after primary, isolated ACL reconstruction) to reduce pain and adverse effects on articular cartilage and soft tissues surrounding the joint and improve ROM outcomes.[20,36,149]

Full, active knee extension and 90° to 110° of flexion is expected by 4 to 6 weeks postoperatively. The patient is weaned from brace use at about 6 weeks postoperatively if full extension has been achieved. Depending on the stability of the knee, sometimes the protective brace may need to be worn longer. These timelines are progressed more slowly when ACL reconstruction is combined with another procedure, such as a collateral ligament, meniscus, or articular cartilage repair.[217]

Some patients are advised to wear a functional brace to reduce the risk of reinjury during the advanced phases of rehabilitation and when participating in high-demand sports or heavy manual labor after completing their rehabilitation program. However, the effectiveness of functional bracing after ACL reconstruction is unclear because the literature contains conflicting evidence.[149]

Despite the widespread use of protective bracing following ACL reconstruction, the literature provides a critical analysis of its efficacy during early rehabilitation and when returning to high-risk activities.

FOCUS ON EVIDENCE

The literature reflects a common belief that protective bracing (rehabilitative and functional) during early recovery and when returning to activities after ACL reconstruction leads to improved outcomes by decreasing pain, joint swelling, and wound drainage by improving knee extension and by protecting the graft from excessive strain and the risk of reinjury. However, results of a recent systematic review by Wright and Fetzer[309] of 12 Level I randomized, controlled trials demonstrated that there is insufficient evidence to support the effectiveness of bracing. All but one of these studies focused on bracing during early rehabilitation. The studies reviewed revealed no significant differences in outcomes, such as postoperative pain, anterior-posterior knee stability, ROM, and functional testing, in groups who did and did not use protective bracing during early recovery. No conclusions could be drawn about the effectiveness of functional bracing in preventing reinjury during high-demand activities because the rate of reinjury was so low in the one randomized, prospective study that was identified in the systematic review. The overall conclusion of the investigators was that the available evidence does not support the routine use of protective bracing after ACL reconstruction.

Weight-Bearing Considerations

As with ROM, early weight bearing is possible after primary ACL reconstruction with a bone-patellar tendon-bone or hamstring tendon autograft because of advances in graft fixation. However, recommendations for a period of protected weight bearing immediately after surgery vary, ranging from some degree of restricted weight bearing the first 2 weeks to weight bearing as tolerated with use of two crutches immediately after surgery.[21,71,147,193,217,241,256,288,303] Weight bearing is increased during the next 2 to 3 weeks based on the patient's symptoms. Protected weight bearing continues for a longer period of time if other structures in the knee have been injured and/or repaired (e.g., after repair of an articular cartilage defect of a femoral or tibial condyle).[303]

Full weight bearing and ambulation without crutches and with or without an unlocked protective brace usually is permitted by 4 weeks if weight bearing is pain-free and the patient has achieved full, *active* knee extension and sufficient strength of the quadriceps to control the knee.[21,108,186,193,220]

Weight-bearing recommendations do not appear to be based on the type of graft or graft fixation used or whether protective bracing is worn but rather are determined on an empirical basis. The few randomized studies in the literature indicate that immediate and delayed weight bearing during the first few weeks after surgery produce similar outcomes.[20]

FOCUS ON EVIDENCE

Tyler and colleagues[289] conducted a prospective, randomized, controlled study with 49 patients comparing the effects of immediate versus delayed weight bearing during the first 2 weeks after ACL reconstruction with a bone-patellar tendon-bone graft. The immediate weight-bearing group was advised to bear weight as tolerated and discontinue crutch use as soon as they felt comfortable doing so. The delayed weight-bearing group was advised not to wear a shoe on the operated side and remain nonweight-bearing during ambulation with crutches for the first 2 weeks. After that, there were no restrictions placed on the progression of weight bearing. Neither group

wore protective bracing. With the exception of weight-bearing status, the rehabilitation program for all patients was the same.

At a mean of 7.3 months, there were no significant differences between groups with respect to knee ROM, knee stability (measured by clinical examination and arthrometer), VMO activation (measured by EMG activity), or overall function. However, patients in the immediate weight-bearing group had a lower incidence of anterior knee pain than patients in the delayed weight-bearing group (8% and 35%, respectively). The investigators concluded that immediate weight bearing did not compromise knee joint stability or function and was beneficial in that it resulted in a lower incidence of postoperative anterior knee pain.

Exercise Progression

A progression of carefully selected exercises and functional activities coupled with patient education is a foundation of rehabilitation following ACL injury and reconstruction.

Preoperative exercise. Because surgery typically is delayed after injury until acute symptoms have subsided, there is ample time to implement a *preoperative* exercise program to restore full knee ROM, particularly extension, prevent atrophy and weakness of thigh musculature, and improve the strength and flexibility of hip and ankle musculature.[59,104,185,220,256,303]

Postoperative exercise progression. After reconstruction of the ACL, exercise begins immediately on the first postoperative day. Use of strong grafts, such as bone-patellar tendon-bone and quadrupled hamstring autografts, and reliable graft fixation make early motion possible.[21,108,193,217,220,256,303]

Sometimes CPM is used while a patient is hospitalized or at home after discharge. Although a valid mechanism for controlling postoperative pain and initiating early motion,[164,256] it is used less frequently today than in the recent past.[108] Two recent systematic reviews indicate no additional long-term benefit with the use of CPM after ACL reconstruction.[266,310]

CLINICAL TIP

It is important to remember that a tendon graft goes through a necrotizing process the first 2 to 3 weeks postoperatively before revascularization commences and maturation gradually occurs.[20,82,133,134] Therefore, exercises are progressed cautiously during each phase of rehabilitation, even during an accelerated program. If protective bracing has been prescribed, exercises are carried out while wearing the brace.

The *rate of progression* of exercise and functional training after ACL reconstruction depends on many factors. For example, patient-related facts, such as age and preinjury health status, affect the healing process, enabling younger, healthier patients to progress exercises more rapidly. The type of graft and graft fixation also may influence the progression of exercise. Some resources advocate more rapid progression of exercise for bone-to-bone fixation with a patellar tendon graft than for tendon-to-bone fixation with a quadrupled hamstring graft, suggesting that bone-to-bone healing may be faster than soft tissue-to-bone healing.[108,220,303] In contrast, others advocate the same accelerated program for both procedures.[71,241,254]

If, in addition to an ACL reconstruction, concomitant injuries are present or were managed surgically, the progression of exercises, as with weight bearing, typically is more gradual than after isolated ACL injury and reconstruction.[217]

Exercises for progressive phases of rehabilitation after ACL reconstruction, summarized in Table 21.6, are described in the following sections. Exercise precautions are noted in Box 21.11.[21,90,108,170,193,217,236,256,267,299,303]

Exercise: Maximum Protection Phase

During the early postoperative period, a delicate balance exists between adequate protection of the healing graft and donor site and prevention of adhesions, contractures, articular degeneration, muscle weakness, and atrophy associated with

BOX 21.11 Exercise Precautions After ACL Reconstruction

Resistance Training—General Precautions

- Progress exercises more gradually for reconstruction with hamstring tendon graft than bone-patellar tendon-bone graft.
- Progress knee flexor strengthening exercises cautiously if a hamstring tendon graft was harvested and knee extensor strengthening if a patellar tendon graft was harvested.

Closed-Chain Training

- When squatting in an upright position, be sure that the knees do not move anterior to the toes as the hips descend because this increases shear forces on the tibia and could potentially place excess stress on the autograft.
- Avoid closed-chain strengthening of the quadriceps between 60° to 90° of knee flexion.*

Open-Chain Training

- During PRE to strengthen hip musculature, initially place the resistance above the knee until knee control is established.
- Avoid resisted, open-chain knee extension (short-arc quadriceps training) between 45° or 30° to full extension for at least 6 weeks or as long as 12 weeks.*
- Avoid applying resistance to the distal tibia during quadriceps strengthening.*

*Contraction of the quadriceps in these positions and ranges causes the greatest anterior tibial translation and can create potentially excessive stress to the graft during the early stage of healing.[67,99,299,303]

immobilization. Early motion places beneficial stresses that strengthen the graft but must be carefully controlled to avoid stretching the graft while in a weakened state, particularly during the first 6 to 8 weeks after implantation.

The following goals and exercise interventions are emphasized during the first 4 weeks after surgery when considerable protection of knee structures is warranted.[21,108,147,157,170,193,217,220,256,303]

Goals. Immediately after surgery through the first few postoperative weeks, in addition to controlling pain and swelling and initiating ambulation with crutches, exercise goals are to prevent reflex inhibition of knee musculature, prevent adhesions, restore knee mobility, regain kinesthetic awareness and neuromuscular control (static and dynamic) of the lower extremity, and improve strength and flexibility of hip and ankle musculature.

The goal for knee ROM is to achieve 90° of flexion and full passive extension by the end of the first 1 to 2 weeks as joint swelling subsides and then 110° to 125° of flexion by 3 to 4 weeks.

Interventions. Pain, joint swelling, and peripheral edema are controlled in a standard manner. Exercises begin the day of or the day after surgery with an emphasis on: (1) preventing vascular complications (DVTs); (2) activating knee musculature; and (3) reestablishing knee mobility. Patient education during the first phase of rehabilitation focuses on these points in the home exercise program.

CLINICAL TIP

It is important to activate and strengthen the quadriceps early in the rehabilitation process to reestablish knee control, particularly for safe weight-bearing activities. However, it is equally important to activate and strengthen the hamstrings as they provide a dynamic restraint to limit anterior translation of the tibia on the femur.

When weight-bearing exercises are initiated, they are performed in a protective brace if one has been prescribed. Low-intensity closed-chain exercises and proprioceptive/neuromuscular control training are initiated as soon as weight bearing is permissible. The value of early closed-chain/weight-bearing exercises and proprioceptive/neuromuscular control training for quadriceps control after ACL reconstruction has been supported by many authors and is discussed in the exercise section of this chapter.[11,36,59,108,117,157,176,193,234,236,256,259,303]

The following exercises are advocated for the maximum protection phase.[21,90,108,147,157,170,176,193,217,220,234,236,256,299,303]

- ***Ankle pumping exercises.*** Perform ankle pumping frequently throughout the day to reduce the risk of a DVT.
- ***Voluntary isometric and dynamic activation of knee musculature.***
  - Begin muscle setting of quadriceps, hamstrings, and hip abductors, adductors, and extensors within the patient's comfort level. An isometric quadriceps contraction with the knee in full extension generates little to no anterior translation of the tibia on the femur because the knee is in a closed-pack position.
  - Use electrical stimulation or biofeedback to augment quadriceps activation. A recent literature review concluded that neuromuscular electric stimulation may be more effective in improving quadriceps strength than exercise alone. However, there were no differences found in long-term functional performance.[135]
  - Perform four-position SLRs, first with assistance, then progress to active hip motions with the knee maintained in extension. Add external resistance when the patient is able to maintain knee control during hip movements.
  - When knee movement is permissible, initiate low-intensity, multiple-angle isometrics of the knee musculature with emphasis on quadriceps control and co-contraction of the quadriceps and hamstrings.
  - Consider *low-intensity*, eccentric quadriceps training between 20° and 60° on a motorized, eccentric ergometer, if available. Negative work training, if progressed gradually, has been shown to be safe when initiated as early as 3 weeks after ACL reconstruction.[90]
  - To activate the hamstrings dynamically, include supine heel-slides to a comfortable level of hip and knee flexion, knee flexion in a standing position (hamstring curls without resistance added), and scooting *forward* while seated on a rolling stool.

PRECAUTION: Postpone dynamic activation of the knee flexors if a hamstring graft was used for reconstruction (see Box 21.11).

- ***ROM and patellar mobility.***
  - Begin ROM in a protected range. Include therapist-controlled PROM or A-AROM within the patient's comfort level.
  - Include patellar mobilization to prevent adhesions.
  - To increase passive knee extension, have the patient assume a supine or long-sitting position and prop the heel on a rolled towel or bolster with the knee unsupported (see Fig. 21.18)
  - To increase knee flexion, include supine, gravity-assisted wall slides (see Fig. 21.19) or dangle the leg while sitting on the side of a bed.
  - Stretch hip and ankle musculature if flexibility is limited.
- ***Neuromuscular control/responses, proprioception, stability, and balance.***
  - Begin neuromuscular training with trunk and lower extremity stabilization exercises in bilateral stance. Have the patient wear a protective brace locked in extension, if prescribed. Distribute weight equally on both lower extremities, and put some weight on the hands for support. Have the patient maintain a stable, well-aligned position as alternating resistance with varying directions and speeds is applied at the pelvis.

- Progress training with weight-shifting activities and bilateral minisquats in the 0° to 30° range and with stepping and marching movements. Gradually decrease upper extremity support. When the knee is pain-free and full weight bearing is possible, progress to unilateral stabilization activities.
- Perform *nonresisted,* multi-joint movements, such as stationary cycling and exercise on a seated leg press machine or in a semireclining position on a Total Gym® unit, at 3 to 4 weeks. If incision healing allows, begin exercises in a pool.

Criteria to progress to next phase. Criteria include:

- Minimal pain and swelling
- Full, *active* knee extension (no extensor lag)
- At least 110° knee flexion
- At least 50% to 60% quadriceps strength (measured isometrically at 60°)
- Greater than 110° of knee flexion
- No evidence of excessive joint laxity (determined by arthrometric measurements)

Exercise: Moderate Protection/Controlled Motion Phase

The moderate protection phase, which begins about 4 to 5 weeks postoperatively or at a point when identified criteria have been met, extends to about 10 to 12 weeks postoperatively. The emphasis of this phase is to achieve full knee ROM and increase strength, dynamic stability, and endurance, as well as normalize gait and neuromuscular control/response time and balance in preparation for a transition to functional activities without compromising the stability of the knee. The hinged, protective brace may be worn for gait and most exercises until about 6 weeks when brace use is gradually discontinued.

CLINICAL TIP

By 8 to 10 weeks revascularization of the graft is becoming well established; therefore, exercises can be performed more vigorously while continuing to closely monitor the patient's responses to increasing activity.[82,133,134]

Goals. Rehabilitation goals during the intermediate phase are to attain full ROM (full knee extension and 125° to 135° flexion); improve lower extremity strength and muscular endurance; ambulate without assistive device and protective brace using a normal gait pattern; continue to improve neuromuscular control/response time, proprioception, and balance; and regain cardiopulmonary fitness.

Interventions. Include and progress the following interventions during the moderate protection phase.[21,90,108,147,157,170,176,193,220,234,236,256,303]

- ***ROM and joint mobility.***
  - Continue low-intensity, end-range self-stretching to gain full knee ROM.
  - Use grade III joint mobilization techniques to restore full knee flexion.
  - Continue flexibility exercises for hip and ankle musculature, especially the hamstrings, IT band, and plantarflexors.
- ***Strength and muscle endurance.***
  - Continue closed-chain exercises against body weight resistance (bridging, wall slides, partial squats, straight-line lunges, step-ups/step-downs, heel raises).
  - Progress from double-leg to single-leg exercises.
  - Initiate open-chain hip extension and abduction and knee extension/flexion against light-grade elastic resistance in appropriate portions of knee ROM (see Box 21.11). The literature supports both closed-chain and open-chain training for concentric and eccentric strengthening for ACL deficiency[64,282] or following ACL reconstruction.[149]

FOCUS ON EVIDENCE

Although an emphasis has been placed on closed-chain strengthening during the past decade or two,[36] subsequent studies demonstrated value in including both open- and closed-chain exercises in an ACL rehabilitation program.[176] Bynum and colleagues[36] conducted a prospective, randomized, controlled study comparing open- and closed-chain rehabilitation after primary ACL reconstruction with a bone-patellar tendon-bone autograft. Immediately after surgery, all patients followed the same exercise program, emphasizing early ROM (against no external resistance) and isometric quadriceps control. All patients wore a protective brace and ambulated with crutches, bearing weight as tolerated. When strengthening exercises were initiated, one group followed an open-chain regimen and the other a closed-chain regimen. One year after surgery, 66% of patients participated in a follow-up examination that included subjective and objective measurements; it was conducted by someone blind to group assignment. Patients in the closed-chain exercise group compared with the open-chain group had significantly less anterior knee pain, closer to normal knee stability as measured by an arthrometer, earlier return to functional activities, and greater overall satisfaction with the outcome of the surgery.

A subsequent prospective, matched study by Mikkelsen and associates,[176] which also included closed-chain training at 2 weeks following surgery, demonstrated that the addition of open-chain quadriceps strengthening at 6 weeks postoperatively resulted in no significant differences in anterior knee laxity between the group that performed closed- and open-chain strengthening and the group that performed only closed-chain strengthening. A significantly greater number of the participants who performed the additional open-chain training returned to sports at the prelevel than did those who trained with closed-chain exercises only.

- ***Neuromuscular control/responses, proprioception, and balance.***
  - Progress neuromuscular training with stabilization and static and dynamic balance activities in bilateral, progressing to unilateral stance on stable and then unstable surfaces. Focus on developing quick responses to alternating resistance and unexpected perturbations in varying directions.
  - Emphasis on hip and lumbopelvic stability as well as awareness of proper lower extremity alignment and knee control is crucial to correct pathomechanical alignment or movements.[227]
- ***Gait training.*** Practice ambulation in a controlled environment without bracing or with the protective brace unlocked and without crutches. Emphasize symmetrical alignment, step length, and timing to reestablish a normal gait pattern.
- ***Aerobic conditioning.*** Continue stationary cycling, increasing the duration and speed, or initiate a swimming or pool walking/running program, treadmill walking, or use of an elliptical trainer or stepping machine.
- ***Activity-specific training.*** Integrate simulated functional activities or components of activities into the exercise program.

Criteria to progress to next phase. Criteria to progress to the advanced phases of rehabilitation include:

- Absence of pain and joint effusion
- Full, active knee ROM
- At least 75% strength of knee musculature compared to the contralateral side
- Hamstrings/quadriceps ratio > 65%
- Functional hop test > 70% of contralateral side
- No evidence of knee instability on arthrometer readings or clinical examination

Exercise: Minimum Protection/Return to Function Phase

The advanced phase of rehabilitation and preparation for a return to a preinjury level of activity begins at about 10 to 12 weeks postoperatively or at a point when the patient has met specified criteria. Most post-ACL reconstruction rehabilitation programs described in the literature continue until about 6 months postoperatively.[20,21,108,193,217,220,303] The intensity and duration of training typically are based on the patient's goals and the level of activity to which the patient wishes to return. Individuals involved in high joint-loading, work-related activities, or competitive sports are advised to participate in a maintenance exercise program.

Goals. From 12 to 24 weeks postoperatively, the aim is to further increase strength, endurance, and power; further enhance neuromuscular control and agility; and participate in progressively demanding functional activities.

Interventions. Exercise interventions during the final phase of rehabilitation include PRE with an emphasis on eccentric training, advanced closed-chain strengthening (lunges, step-ups, step-downs against elastic resistance); advanced neuromuscular, balance, and agility training with directional changes, acceleration, and deceleration; plyometrics; and activity-specific drills coupled with a gradual return to progressively demanding activities. Patient education emphasizing prevention of reinjury continues throughout the advanced phases of rehabilitation and as the patient returns to full activity. Refer to the exercise section of this chapter and to Chapter 23 for examples of exercises and activities.

A functional knee brace may be worn to reduce the risk of reinjury during high-demand activities, particularly those that involve turning, twisting, cutting, or jumping motions. As noted previously in this section, conflicting evidence exists for the use of functional bracing following ACL reconstruction.[149] For additional information on efficacy of functional bracing, refer to the next section on Outcomes.

Return to activity. Recommended timelines for returning to vigorous activities, including competitive sports, vary considerably, ranging from as early as 6 months to a year after surgery.[21,241,254,259] Criteria to return to a preinjury level of activity must be individualized for each patient and are contingent on clinical examination findings, particularly quadriceps strength, the stability of the knee, and the expected work-related, recreational, or sports-related demands. Box 21.12 identifies criteria, suggested by several sources,[104,140,147,193,259,299,303] that should be met prior to a return to high-risk, high joint-loading activities.

Outcomes

Reconstruction of the ACL followed by a carefully progressed postoperative rehabilitation program is a reliable means of reestablishing knee stability. Long-term success rates following

BOX 21.12 Criteria to Return to High-Demand Activities After ACL Reconstruction

- No knee pain or joint effusion during final phase of rehabilitation
- Full, active knee ROM
- Quadriceps strength > 85% to 90% of contralateral side or peak torque/body mass 40% and 60% for men and 30% and 50% for women (tested at 300°/sec and 180°/sec, respectively).
- Hamstring strength 100% of contralateral side
- Hamstring/quadriceps ratio > 70%
- No postoperative history of knee instability/giving way
- Negative pivot shift test
- Knee stability measured by arthrometer: < 3 mm difference between reconstructed and uninjured side
- Proprioceptive testing: 100%
- Functional testing (a series of hop, jump, and/or squat tests): > 85% or > 90% of contralateral side or normative values
- Acceptable patient-reported score on comprehensive, quantitative knee function measurement tool, such as the International Knee Documentation Committee Subjective Knee Form

ACL reconstruction range from 82% to 95%, and graft failure leading to recurrent instability is reported to occur in approximately 8% of patients.[2] However, outcomes are predicated on numerous factors, including the patient's age, sex, overall health status, and preinjury activity level, the presence or absence of injuries associated with the ACL injury, various aspects of the surgical procedure, postoperative complications, and the patient's adherence to the rehabilitation program. The effects of several of these variables are addressed in this section.

Graft selection and outcomes. Numerous prospective and retrospective studies have been conducted comparing the effects of graft selection on outcomes. Bone-patellar tendon-bone and hamstring tendon autografts are studied most often. An extensive review and analysis of the literature revealed that, although both types of grafts have their merits and limitations (summarized in Boxes 21.9 and 21.10), long-term (2 years or more) functional outcomes are essentially the same.[261]

Approaches to rehabilitation. There is limited evidence in the literature to determine the effects of variables in a postoperative exercise program, such as the components and rate of progression of rehabilitation and the degree of supervision on outcomes. The inclusion of neuromuscular training, for example, has become an important element of rehabilitation after ACL reconstruction. To investigate its effectiveness, Risberg and colleagues[234] conducted a randomized, controlled, single-blind study comparing a program of neuromuscular training to a traditional strength-training program over a 6-month period after ACL reconstruction. At the conclusion of the study, the neuromuscular training group had significantly better scores on selected functional tests than the traditional strength-training group. There were no significant differences between groups in knee pain, joint laxity, proprioception, or knee muscle strength. Although the study did not include long-term follow-up outcomes, the investigators concluded that neuromuscular training is an important component of rehabilitation following ACL reconstruction.

Beynnon and co-investigators[21] conducted a prospective, randomized, double-blind study comparing the results of an accelerated (19 weeks) and nonaccelerated (32 weeks) rehabilitation program following ACL reconstruction with bone-patellar tendon-bone autografts. The two programs contained the same components but were implemented over two different timelines. A total of 25 patients entered the study, and 22 patients (10 in the accelerated 19-week program and 12 in the nonaccelerated 32-week program) completed the program and were available for final follow-up. At 24 months postoperatively, there were no significant differences in knee laxity, functional testing, or patient satisfaction and activity level.

The effect of supervision during rehabilitation has also been studied. Specifically, home-based rehabilitation with limited therapist supervision has been compared with clinic-based rehabilitation with therapist supervision throughout the program. Two reviews of the literature revealed that, for the most part, these two approaches produced similar outcomes.[20,310] However, all patients who participated in the various studies had some instruction and supervision from a therapist. The reviewers emphasized the importance of therapist-directed assessments and initial instruction in an exercise program but recommended periodic, rather than continuous, supervision over the course of rehabilitation.

Functional bracing. The effect of functional bracing during the intermediate and advanced phases of rehabilitation and its use during high-risk sports after completion of rehabilitation is unclear. Risberg and colleagues[235] carried out a prospective investigation in which 60 patients were randomly assigned to a braced or a nonbraced group. After ACL reconstruction with a patellar tendon autograft, patients in the braced group wore a protective brace for 2 weeks and then wore a functional brace most of the time for an additional 10 weeks. At the conclusion of rehabilitation, the braced group was advised to wear the functional brace for all high joint-loading activities. The nonbraced group had no brace at any time during or after rehabilitation. Otherwise, both groups underwent the same rehabilitation program and patient education. At a 2-year follow-up, there were no significant differences between groups for knee ROM, knee joint laxity, muscle strength, functional testing, or incidence of reinjury to the ACL. The results of this study are similar to the findings of a more recent randomized, controlled multicenter study by McDevitt and associates,[168] who found that use of an "off-the-shelf" functional brace for 1 year after ACL reconstruction during all high-demand activities (jumping, pivoting, cutting) had no significant impact on knee function or reinjury.

Sterret and colleagues[277] also investigated the role of functional bracing in preventing reinjury in patients returning to an advanced, high-demand activity after ACL reconstruction, specifically snow skiing. Over several consecutive ski seasons at a large ski resort, the investigators conducted a prospective, nonrandomized cohort study of 820 skiers who were employees of the ski resort and had undergone ACL reconstruction with a patellar tendon autograft at least 2 years previously. Of the 820 post-ACL reconstruction skier/employees, 257 were considered at significant risk for reinjury of the ACL based on the results of preseason screening. These individuals were given and advised to wear a functional knee brace during skiing. The remaining 563 skier/employees were not determined to be at significant risk for reinjury and were not issued a functional brace.

Analysis of data during the course of the study over several years indicated that 61 ACL reinjuries occurred: 51 in the nonbraced skiers and 10 in the braced skiers. The nonbraced group was 2.74 times more likely to sustain reinjury to the ACL than the braced group. Based on the results of their study, the authors recommended functional knee bracing after recovery from ACL reconstruction for patients returning to the high-risk sport of skiing regardless of their assessed risk of reinjury. The authors, although noting the limitations of this nonrandomized study, suggested that the findings of this

study were of interest because of the large number of participants in the study.

Posterior Cruciate Ligament Reconstruction

In contrast to injury of the ACL, injury of the PCL is relatively infrequent.[307] When an injury does occur, it usually is accompanied by damage to other structures of the knee. There is general agreement that a PCL injury, combined with an injury to another ligament or other structures of the knee, usually warrants early surgical intervention.[74,205,206]

When an isolated PCL injury occurs, most patients respond well to nonoperative management and are able to return to a preinjury level of activity without surgical intervention. However, after a severe PCL injury, an increased incidence of OA in the medial compartment of the knee over time has been observed.[307] Motion analysis of the PCL-deficient knee, as the result of an isolated rupture, has demonstrated altered kinematics of the medial compartment of the knee, specifically anterior subluxation of the medial femoral condyle (posterior subluxation of the medial tibial plateau).[146] These findings provide a possible explanation for the degenerative changes observed in the PCL-deficient knee and lend support for surgical intervention.

Indications for Surgery

Although there is limited consensus, the most frequently cited indications for surgical reconstruction of the PCL include the following.[5,44,74,206,280,307]

- Complete tear or avulsion of the PCL with posterolateral, posteromedial, or rotary instability of the knee combined with damage to another ligament and often the menisci or articular cartilage
- Isolated, symptomatic, grade 3 PCL tear with greater than 8 to 10 mm posterior displacement compared with the contralateral, noninjured knee, resulting in instability during functional activities
- Persistent pain and instability after an unsuccessful course of nonoperative treatment following an isolated PCL injury
- Chronic PCL insufficiency associated with posterolateral instability, pain, limitations in functional activities, and deterioration of articular surfaces of the knee

Procedures

Operative Overview

There are a number of arthroscopic, arthroscopically assisted, or open procedures available for management of a torn or ruptured PCL. Although an acute boney avulsion occasionally is managed with primary repair, reconstruction is by far the more frequently selected option.[74] As with ACL reconstruction, PCL reconstruction involves implantation of a graft to replace the damaged ligament. Graft options using single-bundle or double-bundle reconstruction include a bone-patellar tendon-bone autograft, a hamstring (semitendinosus-gracilis) or quadriceps tendon autograft, an Achilles tendon or anterior tibialis tendon allograft, or, occasionally, a synthetic graft.[5, 44,74,206,280,307]

The operative procedure begins with diagnostic arthroscopy followed by graft harvest if an autograft is to be used for reconstruction. There are two broad categories of methods of graft placement—transtibial tunnel and tibial inlay.[44] With the transtibial (all-arthroscopic) technique, after femoral and tibial tunnels are drilled and prepared, the graft is drawn through and secured in the tunnels with boney or soft tissue fixation devices. The tibial inlay technique can be performed as an open procedure through a posteromedial incision or less frequently as an arthroscopic procedure. No significant differences in outcomes have been identified following the transtibial versus the open tibial inlay procedures.[44]

Graft placement must be precise to mimic the function of the native PCL regardless of the technique used. Prior to closure, the knee is flexed and extended to be certain that graft placement and tension allow full ROM. After wound closure, a sterile compression dressing is applied, and the knee is immobilized in full extension.

Complications

Because PCL reconstruction involves the posterior aspect of the knee, there is risk of damage to the popliteal neurovascular bundle. Risk is highest during drilling of the tibial bone tunnel. Postoperatively, bleeding can lead to compartment syndrome. If a patellar tendon autograft was harvested, the patient may experience anterior knee pain and pain during kneeling. If motion is lost postoperatively, usually knee flexion becomes limited. As with any ligament reconstruction, graft failure can occur, leading to loss of joint stability and the need for revision reconstruction.[44,74]

Postoperative Management

Immobilization, Protective Bracing, and Weight Bearing

Initially, the knee is immobilized in a hinged, range-limiting protective brace locked in full extension. The immobilizer is worn during the day and even during sleep for the first 4 to 8 weeks to prevent posterior displacement of the tibia as the result of gravity or sudden contraction of the knee flexors. It may be removed after the first postoperative week for bathing and exercise. It is unlocked or removed for exercise 1 day to a week after surgery.[5,44,74,205,206,307] The protective brace remains locked in extension during weight bearing and ambulation for an extended period of time.

FOCUS ON EVIDENCE

In theory, protective bracing is prescribed following PCL reconstruction to prevent posterior tibial translation that potentially could disrupt the graft in the early stage of healing. However, the results of a recent literature review indicate that there is no evidence to support this assumption.[149]

In contrast to weight bearing after ACL reconstruction, weight bearing is progressed more gradually after PCL surgery.[44,74,205,206,307] The time frame for initiating and progressing weight bearing varies considerably in the literature. Recommendations range from partial weight bearing (about 30%[44]) immediately after surgery using two crutches and wearing the protective brace locked in extension[51,205,206] to nonweight-bearing for a week to 5 weeks postoperatively.[74,307] Weight bearing is increased over several weeks while keeping the brace locked in extension. As quadriceps control improves, enabling the patient to fully extend the knee, and pain and joint effusion are well controlled, the brace is unlocked, allowing movement in a protected range during ambulation with crutches and weight-bearing exercises.

Crutches are discontinued and full weight bearing with the brace unlocked is permitted when the patient has met specified criteria (Box 21.13). These criteria typically are met at approximately 8 to 10 weeks postoperatively.[44,51,205,206] Brace use is then discontinued gradually.

Exercise Progression

After PCL reconstruction many of the postoperative exercises performed during progressive phases of rehabilitation are similar to those following ACL reconstruction (see Table 21.7).[44,51,74,205,206] The key differences are that exercises are progressed more gradually, and those that place posterior shear forces on the tibia are postponed during the initial and intermediate phases of rehabilitation when the graft is most vulnerable.

Strengthening the quadriceps is emphasized for knee control after PCL reconstruction because it acts as a dynamic restraint to posterior tibial translation. When resistance exercises for hamstring strengthening are initiated during advanced rehabilitation, they are adjusted based on the stability of the knee. Box 21.14 summarizes precautions for exercise and functional activities after PCL reconstruction.[44,51,205,206]

Exercise: Maximum Protection Phase

The emphasis during the first, maximum protection phase of rehabilitation, which extends for 4 to 6 weeks, is to protect the integrity of the graft while simultaneously regaining a functional degree of mobility and developing quadriceps control.[44,51,74,205,206]

Goals. During this phase of rehabilitation, goals are to control or reduce acute symptoms (pain, swelling), prevent vascular complications (DVTs), reestablish control of the quadriceps mechanism, maintain patellar mobility, regain approximately 90° of knee flexion by 2 to 4 weeks after initiating knee motion, begin to reestablish neuromuscular control and balance, improve strength and flexibility of the hip and ankle musculature if limited, and improve cardiopulmonary fitness.[44,51,205,206]

Interventions. Control pain and swelling in a standard manner. Immediately after surgery, begin ankle-pumping

BOX 21.13 Suggested Criteria for Ambulation Without Crutches After PCL Reconstruction

- Minimal to no pain or joint effusion
- Full, active knee extension (no extensor lag) with a straight-leg raise in the supine position.
- Passive and active knee flexion from 0° to at least 90°
- Quadriceps strength: approximately 70% compared with the contralateral side or at least 4/5 manual muscle test grade
- No gait deviations

BOX 21.14 Exercise Precautions After PCL Reconstruction

General Precautions
- Avoid exercises and activities that place excessive posterior shear forces and cause posterior displacement of the tibia on the femur, thus disrupting the healing graft.
- Throughout the rehabilitation process, limit the numbers of repetitions of knee flexion to lessen abrasion to the PCL graft.

Early and Intermediate Rehabilitation
- Begin exercise to restore knee flexion while in a seated position, allowing gravity to passively flex the knee and the hamstrings to remain essentially inactive.
- During squatting exercises to increase quadriceps strength:
  - Avoid excessive trunk flexion, because it causes increased activity in the hamstrings.
  - Avoid knee flexion past 60° to 70°, because it tends to cause posterior translation of the tibia.
- When performing open-chain exercises to strengthen hip musculature, such as resisted SLRs in standing, place resistance above the knee.
- Postpone open-chain, active knee flexion against the resistance of gravity (prone or standing) for 6 to 12 weeks.

Advanced Rehabilitation
- Postpone resistance training for the knee flexors, such as use of a hamstring curl machine, for 5 to 6 months.
- When performing resisted hamstring curls, use low-loads.
- Avoid downhill inclines during walking, jogging, or hiking.
- Avoid activities that involve knee flexion combined with rapid deceleration when one or both feet are planted.
- Postpone returning to vigorous functional activities for at least 9 to 12 months.
- Consider wearing a functional knee brace during high-demand activities.

exercises, patellar-gliding techniques, quadriceps-setting exercises (augmented by neuromuscular electrical stimulation), and four-position SLRs while wearing the protective brace locked in full extension. Use an upper extremity ergometer for aerobic conditioning. Establish a home exercise program.

When knee motion is permitted, follow the exercise precautions for early rehabilitation previously noted (see Box 21.14). Begin multiple-angle isometrics of the quadriceps from full extension to 25° to 30° of flexion. Perform assisted knee extension, progressing to active knee extension while seated. To regain knee flexion, begin with *gravity-assisted* flexion in a seated position. Hold the patient's leg in full knee extension and have the patient control leg lowering as gravity flexes the knee.

To the extent that weight-bearing restrictions allow and while wearing the locked brace, begin trunk and lower extremity stabilization exercises and heel raises in a supported standing position (in the parallel bars or with crutches). When it is permissible to unlock the protective brace, begin closed-chain quadriceps strengthening in bilateral stance (terminal knee extension and minisquats) while holding on to a stable surface for support. As with ACL reconstruction, hip and lumbopelvic stabilization is critical to prevent pathomechanical movements at the knee.[227] Stretch the hip and ankle musculature, in particular the hamstrings, IT band, and plantarflexors.

Criteria to progress to next phase. Criteria to advance to the intermediate phase of treatment include[44,51,205,206]:

- Minimal joint swelling
- Full, active knee extension (no extensor lag)
- At least 100° of knee flexion
- A grade of 3/5 quadriceps strength on manual muscle test
- Understanding of home program and exercise and activity precaution

Exercise: Moderate and Minimum Protection Phases

Goals and interventions. As with early rehabilitation, the goals and interventions during the intermediate and advanced phases of rehabilitation following PCL reconstruction are similar to those following ACL reconstruction (see Table 21.6). However, the suggested timelines continue to be more extended, particularly for hamstring strengthening.

The exercises and activities during the intermediate phase of rehabilitation are essentially an extension of those initiated during the first phase. By 9 to 12 weeks postoperatively, the patient should have achieved full knee ROM (0° to 135°), making it possible to discontinue use of the protective brace if quadriceps control is sufficient.[44,51,205,206]

During the intermediate and advanced phases of rehabilitation, precautions to prevent excessive posterior shear forces on the tibia during exercises and functional activities continue (see Box 21.14). Strengthening focuses on the quadriceps to reestablish full, active knee extension and sufficient strength in the quadriceps, hip, and ankle musculature for functional weight-bearing activities.

Initiation of resistance training to improve strength and muscular endurance of the hamstrings is based on the posterior stability of the knee. Strengthening of the knee flexors typically is delayed until 2 to 3 months postoperatively and, when initiated, is progressed cautiously. Begin hamstring strengthening with closed-chain exercises, such as bilateral, progressing to unilateral bridging. A recent review of the literature indicates that an eccentric squat program often is recommended following PCL reconstruction.[149] Add open-chain hamstring strengthening (hamstring curls) when posterior knee stability allows.

Advanced neuromuscular training with plyometrics, balance activities, and agility drills, progressive aerobic conditioning, and activity-specific training are critical for a safe transition to a full level of functional activities. A full return to vigorous activities after PCL reconstruction may take 9 months to a year.[44,51,74,205,206]

Meniscus Tears: Nonoperative Management

Mechanisms of Injury

The medial meniscus is injured more frequently than the lateral meniscus. Insult may occur when the foot is fixed on the ground and the femur is rotated internally, as when pivoting, getting out of a car, or receiving a clipping injury. An ACL injury often accompanies a medial meniscus tear. Lateral rotation of the femur on a fixed tibia may tear the lateral meniscus. Simple squatting or trauma may also cause a tear.

Common Structural and Functional Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations/Disabilities)

A meniscus tear can cause acute locking of the knee or chronic symptoms with intermittent catching/locking. Pain during forced hyperextension or maximum flexion occurs along the joint line (due to stress to the coronary ligament) along with joint swelling and some degree of quadriceps atrophy.[148] When there is joint catching/locking, the knee does not fully extend, and there is a springy end feel when passive extension is attempted. If the joint is swollen, there is usually slight limitation of flexion or extension. The McMurray test or Apley's compression/distraction test may be positive.[153]

When the meniscus tear is acute, the patient may be unable to bear weight on the involved side. Unexpected locking or giving way during ambulation often occurs, causing safety problems.

Management

- Often the patient can actively move the leg to "unlock" the knee, or the unlocking happens spontaneously.
- Passive manipulative reduction of the medial meniscus may unlock the knee (Fig. 21.16).

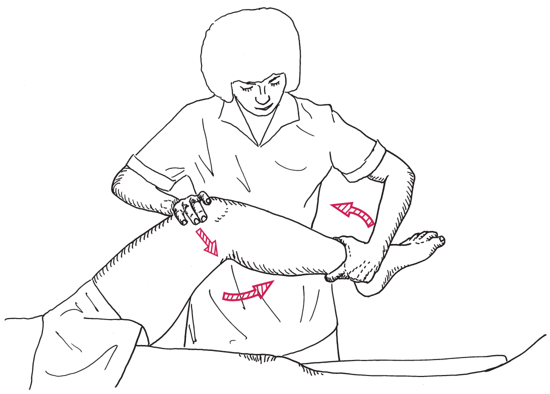

FIGURE 21.16 Manipulative reduction of a medial meniscus. Internally and externally rotate the tibia as you flex the hip and knee (not shown); then laterally rotate the tibia and apply a valgus stress at the knee as you extend it. The meniscus may click into place.

  - *Patient position and procedure:* Supine. Passively flex the involved knee and hip, and simultaneously rotate the tibia internally and externally. When the knee is fully flexed, externally rotate the tibia and apply a valgus stress at the knee. Hold the tibia in this position, and extend the knee. The meniscus may click into place.
  - Once reduced, the knee may react as an acute joint lesion. If this occurs, treat as described earlier in the chapter in the section on nonoperative management of joint hypomobility.
- After acute symptoms have subsided, exercises should be performed in open- and closed-chain positions to improve strength and endurance in isolated muscle groups and to prepare the patient for functional activities.

Meniscus Tears: Surgical and Postoperative Management

When a significant tear or rupture of the medial or lateral meniscus occurs or if nonoperative management of a partial tear has been unsuccessful, surgical intervention often is necessary. Current-day surgical procedures are designed to retain as much of the meniscus as possible as a means of preserving the load transmission and shock-absorbing functions of the menisci and to reduce stress on the tibiofemoral articular surfaces.

Primary surgical options are *partial meniscectomy* and *meniscal repair*, both of which are considered preferable to total meniscectomy.[278,286] The location and nature of the tear influences the selection of a procedure, as does the patient's age and level of activity. Tears of the outer area of a meniscus, which has a rich vascular supply, heal well, whereas tears extending into the central portion, where the vascular supply is considerably less, have marginal healing properties (Fig. 21.17).[287] Age and the patient's activity level factor into the decision-making process because it has been shown that loss of even a portion of a meniscus increases the long-term risk of articular degeneration.[287]

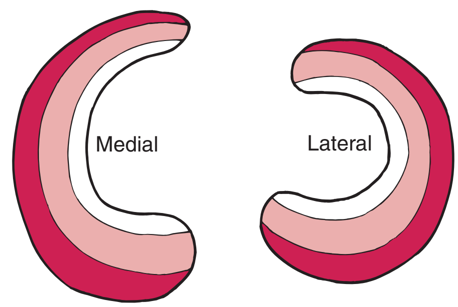

FIGURE 21.17 Vascularity of the medial and lateral menisci. The peripheral zone (outer one-third) is highly vascular; the central one-third is relatively avascular; and the inner one-third is avascular.

Traditionally, partial meniscectomy has been performed to manage complex, fragmented tears and tears involving the central (middle third), relatively avascular zone of a meniscus.[286] In contrast, peripheral tears involving the highly vascular portion of a meniscus have been shown to lend themselves well to repair rather than excision of the torn portion.[287] However, if a patient with a central zone tear is young or physically active but older, some sources now advocate repair of the torn meniscus.[107,197,198] If there is extensive damage to a major portion of the meniscus and it is determined to be unsalvageable, total meniscectomy remains the only surgical option.[286]

For the relatively young and/or active patient who previously underwent total meniscectomy and now is symptomatic as the result of early osteoarthritic changes in the tibiofemoral joint, a recently developed option—*meniscal transplantation*—using human allograft tissue has become available.[107,200,221]

The progression of postoperative rehabilitation and the time required to return to full activity after each of these procedures depends on the extent and location of the tear and the type of surgical approach and procedure performed. Rehabilitation proceeds more conservatively after repair or transplantation of a meniscus or total meniscectomy than after partial meniscectomy. Damage and repair or reconstruction of other soft tissues of the knee, such as the ACL, also affect the course and progression of rehabilitation after surgery.

Meniscus Repair

Indications for Surgery

Repair of a torn meniscus is indicated in the following situations.[107,197, 286]

- A lesion in the vascular outer third of the medial or lateral meniscus
- A tear extending into the central, relatively avascular third of the meniscus of a young (younger than age 40 to 50) or physically active older (older than age 50) individual

CONTRAINDICATIONS: Contraindications include the presence of a tear localized to the inner, avascular third of the meniscus, a tear in which there is considerable tissue fragmentation, or a tear that cannot be completely reopposed during surgery.[107]

Procedure

Operative Overview

Prior to the operative procedure, a comprehensive arthroscopic examination of the joint is performed to determine if a meniscus tear is suitable for repair and to identify any concomitant injuries, such as ACL damage. The meniscus repair itself typically is performed using an arthroscopically assisted open approach or a fully arthroscopic approach.[107,187,188,197] The determination of which approach is selected generally is based on the location and nature of the tear.[286]

There are several surgical procedures—referred to as inside-out, outside-in, or all-inside techniques—for meniscus repair. The inside-out and outside-in techniques are arthroscopically assisted, with a portion of the procedure being performed through an incision at the posteromedial or posterolateral aspect of the knee.[187,197] The all-inside technique is fully arthroscopic.[188, 287]

There are also various suturing techniques with nonabsorbable or bioabsorbable sutures that can be used during the repair. Use of other fixation devices, such as darts or staples, also has been reported. Of the many variations of meniscus repair, the arthroscopically assisted, inside-out suture repair is most common and considered by some in the orthopedic community to be the "gold standard."[107,187,197,287]

At the beginning of the procedure, small incisions are made at the knee for portals, and saline is arthroscopically introduced into the joint to distend the capsule. After the joint has been examined, arthroscopic débridement is performed to remove all unstable tissue fragments and prepare the torn meniscus for repair. During the repair itself (performed endoscopically or through a posteromedial or posterolateral incision), the edges of the tear are closely approximated, and sutures are placed every 3 to 4 mm to ensure complete closure (no gapping) along the tear line. All sutures are tied with the knee fully extended or in 10° of flexion to allow full extension postoperatively without causing undue stress on the repaired meniscus.

After closure, a compression dressing, extending above and below the knee, is applied to control postoperative joint effusion, and the knee is placed in an immobilizer.

NOTE: Detailed descriptions of medial and lateral meniscal allograft transplantation techniques are published in several resources.[91,107,200,201,221]

Complications

Complications specific to meniscus surgery include intraoperative damage to the neurovascular bundle at the posterior aspect of the knee during the suturing process. With a medial meniscus repair, there is a risk of damage to the saphenous nerve; with a lateral meniscus repair, there is risk of damage to the peroneal nerve. Postoperatively, these same nerves can become entrapped by adherent scar tissue.[187,286,287]

A flexion contracture or an extensor lag postoperatively compromises knee alignment and stability during gait and functional activities. The risk of failure of the repair is greatest during activities that involve joint loading and knee flexion beyond 45°. This risk is greatest during the first few postoperative months.[174, 278]

Postoperative Management

Factors that influence the components and progression of postoperative rehabilitation after meniscus repair are noted in Box 21.15.[51,107,174,197] Some variables permit relatively rapid rehabilitation, whereas others necessitate a more cautious progression. For example, exercise and weight bearing are progressed more rapidly after repair of a peripheral zone tear than after a central tear and after a single tear than after a complex pattern tear.

Another factor, malalignment of the knee, affects forces placed on a repaired meniscus and thus influences the progression of weight bearing during ambulation and exercise. With varus alignment, a repaired medial meniscus is subjected to increased stress and increased risk of displacement during healing. Therefore, weight bearing must be progressed more slowly in this situation than is necessary when there is normal alignment of the knee.[51]

NOTE: Although timelines vary somewhat in published postoperative guidelines, the progression of exercises presented in the following rehabilitation program is appropriate after *isolated* meniscus repair in a cruciate-stable knee. These same guidelines are appropriate after meniscal transplantation, although the duration of rehabilitation and protection of the

BOX 21.15 Factors Influencing the Progression of Rehabilitation After Meniscus Repair

- Location and size of the tear (i.e., the zone[s] affected and their vascularity)
- Type of tear (tear pattern and complexity)
- Type of surgical fixation device used
- Alignment of the knee joint (normal, varus, valgus)
- Concomitant injuries (ligament, chondral defect) with or without reconstruction or repair

transplanted meniscus is longer.[107,221] If a concomitant procedure, such as ligament reconstruction, is performed, adjustments also are made to protect the affected structure.

Immobilization, Protective Bracing, and Weight Bearing

Immobilization and protective bracing. The knee is held in full extension, first in the postoperative immobilizer and then in a long-leg brace when the bulky compression dressing is removed a few days after surgery.[51,107,286] Occasionally, for carefully selected patients with a peripheral zone repair, no protective bracing is used after the postoperative dressing is removed.[187] The patient continues to wear a thigh-high compression stocking to control swelling.

To protect the repaired meniscus during the first few postoperative weeks, the range-limiting brace is worn continuously (day and night) and is locked in full extension. However, soon after surgery, it is unlocked periodically during the day to initiate early ROM exercises and for bathing. Depending on the site of the lesion and repair, the protective brace is set to allow 0° to no more than 90° of flexion for the first 2 weeks or longer. Each week the ROM allowed by the brace is increased by about 10° until full flexion has been achieved.[107] The brace is unlocked throughout the day as early as 2 weeks if the patient has achieved full knee extension.

After a central zone repair, the patient typically wears the brace for about 6 weeks or until adequate quadriceps control has been reestablished. After a meniscal transplant, the brace may be worn a few weeks longer.

Weight bearing. Following a peripheral zone repair, partial weight bearing (ranging from 25% to 50%) during ambulation with crutches and with the brace locked in full extension is allowed during the immediate postoperative period (first 2 weeks).[107] The percent of body weight permitted during weight bearing is progressed more cautiously after a central zone repair or meniscus transplantation. If quadriceps control is sufficient, full weight bearing may be permitted by 4 weeks after a peripheral repair[107] and by 6 to 8 weeks after a central repair or transplantation.[51,107,174,200,221]

FOCUS ON EVIDENCE

A recent review of the literature summarized the results of several studies that compared outcomes of "standard" with "accelerated" rehabilitation programs following several types of meniscus repair procedures.[148] In the standard programs, knee ROM and weight bearing were delayed for a period of time after surgery, whereas in the accelerated programs, ROM and weight bearing as tolerated were permitted immediately after surgery. The findings of each of the studies reviewed demonstrated no deleterious effects from accelerated rehabilitation and no significant differences in patient outcomes between the standard versus accelerated groups. It is important to point out, however, that there were conflicting timeframes for the rate of progression of knee motion and weight bearing. Therefore, ROM and weight bearing must be progressed gradually, regardless of the procedure, and must be based on the patient's signs and symptoms.

Exercise: Maximum Protection Phase

Exercises and gait training with crutches are begun the first postoperative day. A standard approach (cold, compression, elevation) to control pain, joint effusion, and vascular complications (ankle-pumping exercises) is used. Patient education focuses on establishing a home exercise program and reinforcing weight-bearing precautions. Exercise precautions are noted in Box 21.16.[51,107,174,286,287]

BOX 21.16 Exercise Precautions After Meniscus Repair*

General Precautions

- Progress exercises and weight bearing more gradually after a central zone meniscus repair or meniscus transplantations than after a peripheral zone repair.
- If the patient experiences a clicking sensation in the knee during exercise or weight-bearing activities, report it immediately to the surgeon.

Early and Intermediate Rehabilitation

- Increase knee flexion gradually, especially after a central zone repair.
- If a stationary bicycle is used for cardiopulmonary conditioning, set the seat height as high as possible to limit the range of knee flexion.
- During weight-bearing exercises, such as lunges and squats, do not perform knee flexion beyond 45° for 4 weeks or beyond 60° to 70° for 8 weeks. Flexion beyond 60° to 70° places posterior translation forces on a repaired meniscus, increasing the risk of displacement during early healing.
- Postpone use of a leg press machine until about 8 weeks. Limit motion from 0° to 60°.
- Avoid twisting motions during weight-bearing activities.
- Postpone hamstring curls until about 8 weeks.

Advanced Rehabilitation

- Do not perform exercises that involve deep squatting, deep lunges, twisting, or pivoting for at least 4 to 6 months. (The greater the flexion angle, the greater the stress on the meniscus.)
- Do not begin jogging or running program until 5 to 6 months.

Return to Activity

- Refrain from recreational and sports activities that involve repetitive, high joint compressions and shear forces.
- Avoid prolonged squatting in full flexion.

*These precautions also are applicable after meniscus transplantation, but time frames for the precautions are longer.

Goals. During the first 4 weeks after surgery, exercise goals are to regain functional ROM, prevent patellar restrictions, reestablish control of knee musculature, restore postural stability, improve strength and flexibility of the hip and ankle, and maintain cardiopulmonary fitness. By 4 weeks, the patient should achieve full, active knee extension. Recommendations for maximum flexion during the first 2 weeks vary from 60° to 90°.[27,51,107,174,286] After 4 weeks, the patient should attain 120° of knee flexion.[107]

Interventions. During the first 4 weeks after meniscus repair, the following interventions are included.[27,51,107,174]

- ***Knee ROM.*** CPM may be prescribed at the surgeon's discretion. The day after surgery, begin A-AROM and AROM exercises of the knee within a protected range. Knee flexion may be restricted by a hinged, range-limiting brace. Include exercises such as gravity-assisted knee flexion in a sitting position and with assistance, then progress to active heel slides in a supine position.
- ***Patellar mobility.*** Teach the patient grade I and II patellar gliding exercises.
- ***Activation of knee musculature.***
  - Emphasize quadriceps control in full extension with quadriceps-setting exercises, assisted SLRs in the supine position, and assisted progression to active open-chain knee extension/flexion in a sitting position for concentric/eccentric quadriceps control. Augment quadriceps activation with neuromuscular electrical stimulation or biofeedback.
  - Perform hamstring-setting exercises and multiple-angle isometrics.
- ***Neuromuscular control/responses, proprioception, and balance.***
  - Begin balance training in a standing position within the limits of weight-bearing restrictions and with the brace locked in extension.
  - Emphasize trunk and lower extremity stabilization exercises.
  - When it is permissible to unlock the brace during carefully controlled weight bearing, initiate bilateral closed-chain exercises, such as minisquats and standing wall slides, initially limiting flexion to no more than 45°.
- ***Flexibility and strength of the hip and ankle musculature.***
  - Stretch the hamstrings and plantarflexors, if restricted.
  - Begin gluteal and adductor setting exercises the first postoperative day. Perform four-position SLRs with the brace locked or with the brace unlocked when the patient can perform an SLR in supine position without an extensor lag.
  - Perform bilateral heel raises when 50% weight bearing on the operated extremity is permitted.
- ***Cardiopulmonary function.*** Use an upper body ergometer for aerobic conditioning exercises.

Criteria to progress to next phase. The following criteria should be met:

- Minimal joint effusion and pain
- Evidence of superior gliding of the patella with quadriceps setting
- Full, active knee extension (no extensor lag)
- Approximately 120° of knee flexion

Exercise: Moderate Protection/Controlled Motion Phase

The moderate protection phase extends from 4 to 6 weeks to about 12 weeks postoperatively. The knee brace is discontinued at about 6 to 8 weeks if there is adequate control of the knee and no extensor lag. Use of a cane or single crutch is advisable to provide some degree of protection during ambulation.

Goals. Restoring full knee ROM, improving lower extremity flexibility, strength, and muscular endurance, continuing to reestablish neuromuscular control and balance, and improving overall aerobic fitness are emphasized during the moderate protection phase of rehabilitation.

Interventions. Include and progress the following exercises and activities during the intermediate phase of rehabilitation.[27,51,107,174]

- ***ROM.*** Progress low-load, long-duration stretching exercises if the patient is having difficulty achieving full knee ROM.
- ***Muscle performance (strength and muscular endurance).***
  - Initiate stationary cycling against light resistance.
  - Use elastic resistance for low-intensity, open-chain, and closed-chain exercises.
  - Progress hip- and ankle-strengthening exercises. Emphasize strengthening of the hip abductors and extensor.
- ***Neuromuscular control/responses, proprioception, and balance.*** With each of these activities, emphasize maintaining proper lower extremity alignment.
  - Continue or—if not initiated previously—begin closed-chain exercises. Add disturbed balance activities (perturbation training) standing on an unstable surface, such as a minitrampoline or BOSU.
  - When full weight bearing is permissible, begin unilateral balance activities, partial lunges, step-ups, and step-downs. Practice walking on an unstable surface, such as high-density foam rubber.
  - Initiate low-intensity agility drills.
- ***Flexibility of the hip and ankle.*** Stretch the IT band and rectus femoris after the patient has achieved full knee flexion with hip flexion.
- ***Cardiopulmonary fitness.*** Begin stationary cycling or a pool-walking program at the beginning of this phase. Initiate treadmill training, land walking, or use of a cross-country ski machine or elliptical trainer at around 9 to 12 weeks.
- ***Functional activities.*** Gradually resume light functional activities during this phase.

Criteria to progress to next phase. By 12 to 16 weeks postoperatively, the following criteria should be met:

- No pain or joint effusion
- Full, active knee ROM
- Lower extremity strength (maximum isometric contraction): 60% to 80% compared to the contralateral side

Exercise: Minimum Protection/Return to Function Phase

Some degree of protection is still warranted at the beginning of the final phase of rehabilitation, which typically begins at around 12 to 16 weeks and may continue until 6 to 9 months. The return to a high level of physical activity depends on achieving adequate strength, full, nonpainful ROM, and an acceptable clinical examination.[51,107,174]

Goals. The primary goal of this phase is to prepare the patient to resume a full level of functional activities using normal movement patterns while continuing patient education to reinforce the importance of selecting activities that do not overstress the repaired meniscus (see Box 21.16).

Interventions. During advanced resistance training, focus on movement patterns that simulate functional activities. Begin and gradually progress drills, such as plyometric training and agility drills, to improve power, coordination, and rapid response times. Continue to stress the importance of proper trunk and lower extremity alignment. Increase the duration or intensity of the aerobic conditioning program. Transition from a walking program to a jogging/running program, if desired, at about 4 to 6 months. A detailed progression of aerobic conditioning activities after meniscus repair is available in published resources.[107,174]

Outcomes

Repair of a torn medial or lateral meniscus using any one of several surgical techniques is a well-tested procedure designed to preserve these important structures, and it results in predictably successful outcomes. This is particularly true for suture repair of a peripheral zone tear.[107,187,287] Although the results of repair of tears extending into the central zone are not as predictable, there is increasing evidence that repairs in this zone heal well and provide long-term relief of symptoms.[197,198]

Although the use of various surgical techniques and the frequency of concomitant pathologies and surgeries make it difficult to compare outcomes of studies, several generalizations can be made. One of the most important factors influencing outcomes of meniscus repair is the status of the ACL. When an ACL injury occurs in combination with a meniscus tear, patients who undergo ACL reconstruction have better outcomes than patients with ACL deficiency. A recurrent tear of a repaired meniscus occurs more frequently in an ACL-deficient knee than in an ACL-stable knee.[198,287]

Although the age of a patient typically is cited as a factor influencing the decision of whether to repair a torn meniscus, particularly a tear in the central zone, and although most repairs are performed in patients younger than age 40, a study by Noyes and colleagues[197] demonstrated a high success rate in a group of patients 40 years of age or older who had central zone tears. With regard to postoperative rehabilitation, no single protocol has been shown to result in superior outcomes.[287]

Lastly, short-term results of meniscus transplantation with an allograft appear to be promising but are challenging to summarize because of evolving surgical techniques. Long-term effectiveness of current-day procedures has yet to be determined.[91,200,221]

Partial Meniscectomy

Indications for Surgery

The following are indications for partial meniscectomy as a surgical option for a tear of the medial or lateral meniscus.[286]

- A symptomatic (pain and locking), displaced tear of the meniscus sustained by an older, inactive individual associated with pain and locking of the knee
- A tear extending into the central, less vascular third of the meniscus if not determined repairable when arthroscopically visualized and probed
- A tear localized to the inner, avascular third of the meniscus

Procedure

Arthroscopic meniscectomy typically is performed on an outpatient basis under local anesthesia. Small incisions are made at the knee for portals (usually three), and saline solution is injected through one of the portals, distending the knee. The torn portion of the meniscus is identified, grasped, and divided endoscopically by knife or scissors and removed by vacuum. Intra-articular debris or loose bodies also are removed. After the knee is irrigated and drained, skin incisions at the portal sites are closed, and a compression dressing is applied to the knee.[278,286]

Postoperative Management

The overall goal of rehabilitation after partial meniscectomy is to restore ROM of the knee and develop strength in the lower extremity to reduce stresses on the knee and protect its articular surfaces. The progression of exercises and functional activities depends on the patient's presenting signs and symptoms.

Immobilization and Weight Bearing

A compression dressing is placed on the knee, but it is not necessary to immobilize the knee postoperatively with a splint or motion-controlling orthosis. For the first few postoperative days, cryotherapy, compression, and elevation of the operated leg are used to control edema and pain. Weight bearing is progressed as tolerated.[51,286]

Exercise: Maximum and Moderate Protection Phases

Although the ideal situation is to begin exercise instruction on the day of or after surgery, most patients do not see a therapist for supervised exercise immediately after an outpatient procedure. When a patient is referred for supervised therapy, the emphasis typically is placed on establishing a home exercise program. Under these circumstances, it is preferable to teach the patient initial exercises to reduce atrophy and prevent contracture *preoperatively*, so he or she can initiate the exercises at home immediately after surgery.

After arthroscopic partial meniscectomy, there is no need for an extended period of maximum protection postoperatively, because there is little soft tissue trauma during surgery. However, moderate protection is warranted for approximately 3 to 4 weeks. All exercises and weight-bearing activities should be pain-free and progressed gradually during the first few postoperative weeks.[27]

Goals. During the early phase of rehabilitation, the emphasis of treatment is to control inflammation and pain, reestablish independent ambulation, and restore knee control and ROM.

Interventions. Immediately after surgery, begin muscle-setting exercises, SLRs, active knee ROM, and weight bearing as tolerated. Full weight bearing is usually achieved by 4 to 7 days, and at least 90° of knee flexion and full extension are attained by 10 days. Initiate closed-chain exercises and stationary cycling a few days after surgery, or as pain and weight bearing status allow, with the goal of regaining dynamic strength and endurance of the knee.

PRECAUTION: Patients who have undergone partial meniscectomy must be cautioned not to push themselves too quickly. Too rapid a progression of exercise can cause recurrent joint effusion and possible damage to articular cartilage.

Exercise: Minimum Protection/Return to Function Phase

By 3 or 4 weeks postoperatively, minimum protection of the knee is necessary, but full, pain-free, active knee ROM and a normal gait pattern should be achieved before progressing to high-demand exercises. Resistance training, endurance activities, bilateral and unilateral closed-chain exercises, and proprioceptive/balance training to develop neuromuscular control can all be progressed rapidly. Advanced activities such as plyometrics, maximum effort isokinetic training, and simulated high-demand functional activities can be initiated as early as 4 to 6 weeks or 6 to 8 weeks postoperatively with emphasis on reestablishing normal mechanics in movement.

PRECAUTION: High-impact weight-bearing activities such as jogging or jumping, if included in the program, should be added and progressed cautiously to prevent future or additional articular damage to the knee. Improper lower extremity alignment during weight bearing, such as valgus collapse and/or pelvic drop should be corrected prior to advancing with plyometric and high-impact activities.

Exercise Interventions for the Knee

Strength and flexibility imbalances between muscle groups can result from a variety of causes, some of which are disuse, faulty joint mechanics, joint swelling, immobilization (due to fracture, surgery, or trauma), and nerve injury. In addition to the hamstrings and rectus femoris, most of the two-joint muscles cross the knee function primarily at the hip or the ankle, yet they also have an effect on the knee. If there is an imbalance in length or strength in the hip or ankle muscles, altered mechanics usually occur throughout the lower extremity.[109,244] Refer to the chapters on the hip and the ankle and foot for a complete picture of these interrelationships.

Exercise Techniques to Increase Flexibility and Range of Motion

When attempting to increase ROM, the mechanics of the tibiofemoral and patellofemoral joints and their importance in lower extremity function must be respected. Because the knee is a weight-bearing joint, the need for stability takes precedence over the need for mobility, although mobility coupled with adequate strength is also necessary for normal function.

Principles of passive stretching and PNF stretching were presented in Chapter 4, joint mobilization/manipulation of the extremities in Chapter 5, and techniques directed toward specific joint restrictions at the knee and patella earlier in this chapter. Additional manual and self-stretching techniques to increase knee ROM are described in this section.

To Increase Knee Extension

Decreased extensibility of the hamstring musculature and periarticular tissue posterior to the knee can restrict full knee extension. Increasing knee extension is a two-step process. First, full extension of the knee is obtained without placing tension on the hamstrings at the hip (the hip is maintained at or near 0° extension). After full knee extension has been attained, a stretch is applied to the two-joint hamstring muscle group by progressively flexing the hip while maintaining the knee in extension (SLR position). Techniques to stretch the hamstrings using SLRs are described in Chapter 4 and the exercise section of Chapter 20.

PNF Stretching Techniques

- *Patient position and procedure:* Supine, with the hip and knee extended as much as possible. Have the patient perform an isometric contraction of the knee flexors as you resist with your hand placed proximal to the heel. Then ask the patient to relax as you passively extend the knee into the newly gained range, or have the patient actively extend the knee as far as possible (hold-relax and hold-relax/agonist-contraction techniques, respectively).
- *Patient position and procedure:* Prone, with the hip and knee extended as much as possible. Place a small pad or folded hand towel under the femur proximal to the patella to protect the patellofemoral joint from compressive forces. Stabilize the pelvis to prevent hip flexion, and then apply the hold-relax technique to increase knee extension.

Gravity-Assisted Passive Stretching Techniques

Use a low-intensity, long-duration stretch to ensure that the patient stays as relaxed as possible.

Prone Hang

- *Patient position and procedure:* Prone, hips extended with the patient's foot off the edge of the treatment table. Place

a rolled towel under the patient's femur just proximal to the patella and a cuff weight around the ankle. As the muscle relaxes, the weight places a sustained passive stretch on the hamstrings, which increases knee extension.

Supine Heel Prop

- *Patient position and procedure:* Supine, with the knee extended as far as possible. Place a rolled towel or padding under the distal leg and heel to elevate the calf and knee off the table (Fig. 21.18). For a sustained stretch, secure a cuff weight across the distal femur but proximal to the patella to avoid patellar compression.

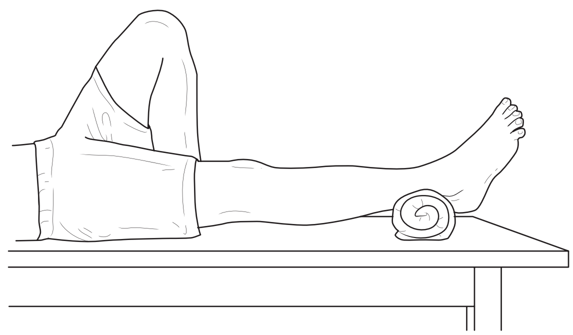

FIGURE 21.18 Heel prop in supine to increase knee extension. A cuff weight or sandbag placed across the distal femur increases the stretch force.

NOTE: This position is not effective for severe knee flexion contractures. Use it only for restrictions that are near the end of the range of knee extension.

Self-Stretching Technique

Patient position and procedure: Long-sitting, with the distal leg supported on a rolled towel. Have the patient press down with the hands against the femur just above (not on) the patella to cause a sustained force to increase knee extension.

To Increase Knee Flexion

Before stretching to increase knee flexion, be sure the patella is mobile and is able to glide distally in the trochlear groove as the knee flexes; otherwise, it restricts knee flexion. Patellar mobilization techniques to increase patellar gliding are described in Chapter 5 (see Figs. 5.53 and 5.54). Techniques to increase mobility of the IT band at the knee to improve patellar tracking are described later in this section. Once full range of knee flexion is restored, the two-joint rectus femoris and TFL muscles should be stretched across the hip joint while maintaining the knee in flexion. These techniques are described in Chapter 20.

PNF Stretching Techniques

Patient position and procedure: Sitting, with the knee at the edge of the treatment table and flexed as far as possible. Place your hand just proximal to the ankle and manually resist an isometric contraction of the knee extensors. Have the patient relax as you passively flex the knee to the end of the range, or have the patient actively flex as far as possible.

Gravity-Assisted Passive Stretching Technique

Patient position and procedure: Sitting with the lower legs dangling and knee flexed to the end of the available range. Instruct the patient to relax the thigh muscles and let the weight of the leg create a low-intensity, long-duration stretch. Place a light cuff weight around the distal leg to increase the stretch force.

Self-Stretching Techniques

Gravity-Assisted Supine Wall Slides

Patient position and procedure: Supine, with buttocks close to the wall and lower extremities resting vertically against the wall (hips flexed, knees extended). Have the patient slowly flex the involved knee by sliding the foot down the wall until a gentle stretch sensation is felt. Hold the position for a period of time, then slide the foot back up the wall (Fig. 21.19).

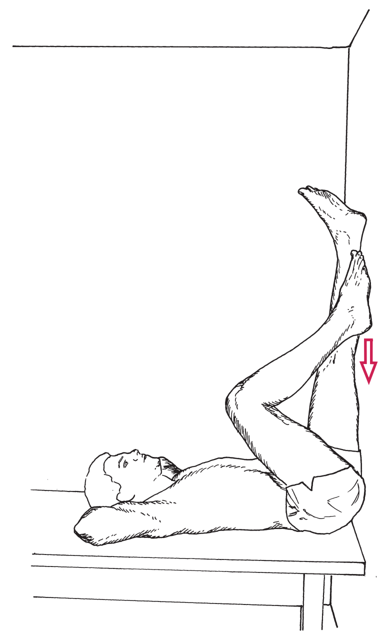

FIGURE 21.19 Gravity-assisted supine wall slide. The patient flexes the knee to the limit of its range and holds it there for a sustained stretch to the quadriceps femoris muscle.

Self-Stretch with Uninvolved Leg

Patient position and procedure: Sitting with legs dangling over the edge of a bed and ankles crossed. Using the uninvolved leg, have the patient apply sustained pressure to the involved leg just above the ankle to increase knee flexion.

Rocking Forward on a Step

Patient position and procedure: Standing, with the foot of the involved knee on a step. Have the patient rock forward over the stabilized foot, flexing the knee to the limit of its range, then rock back and forth in a slow, rhythmic manner, or sustain the stretched position (Fig. 21.20). Begin with a low step or stool; increase the height as more range is obtained.

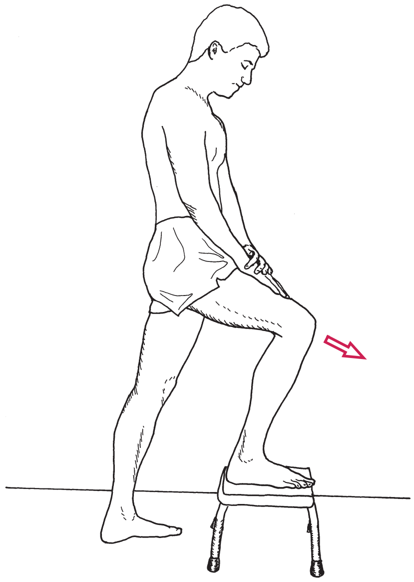

FIGURE 21.20 Self-stretching on a step to increase knee flexion. The patient places the foot of the involved side on a step, then rocks forward over the stabilized foot to the limit of knee flexion to stretch the quadriceps femoris muscle. A higher step is used for greater flexion.

PRECAUTION: Do not allow the patient to move into a position that causes pinching at the anterior aspect of the ankle.

Sitting

Patient position and procedure: Sitting in a chair, with the involved knee flexed to the end of its available range and the foot firmly planted on the floor. Have the patient move forward in the chair, not allowing the foot to slide. Hold the position for a comfortable, sustained stretch of the knee extensors (Fig. 21.21).

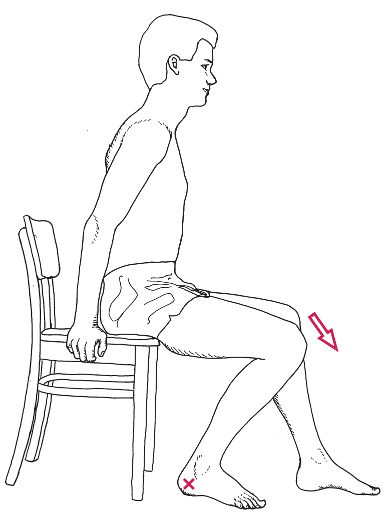

FIGURE 21.21 Self-stretching in a chair to increase knee flexion. The patient fixates the foot of the involved leg on the floor and then moves forward in the chair over the stabilized foot to place a sustained stretch on the quadriceps femoris muscle and increase knee flexion.

To Increase Mobility of the IT Band at the Knee

The IT band is a strong fibrous band of connective tissue that is not easily stretched, although mobility of its distal attachment at the knee is necessary for proper patellar tracking and knee flexion (restricted mobility may contribute to patellofemoral pain or patellar maltracking). The distal attachment of the TFL and approximately one-third of the gluteus maximus insert into the proximal IT band and therefore affect its mobility. Stretching of these muscles is described in Chapter 20. The "foam roller fascial release" that follows is used to increase the mobility of the IT band and its effect at the knee.

Foam Roller Fascial Release

Patient position and procedure: Side-lying with the involved thigh on a foam roller (dense foam cylinder) positioned perpendicular to the femur. Maintain the hip of the involved side in extension, flex the top hip and knee, and plant the foot on the floor (Fig. 21.22). Have the patient prop on the forearm or hands to lift the trunk and adduct the hip of the involved leg. Then roll the lateral thigh proximally and distally on the roll along the IT band or maintain a sustained pressure against the IT band.

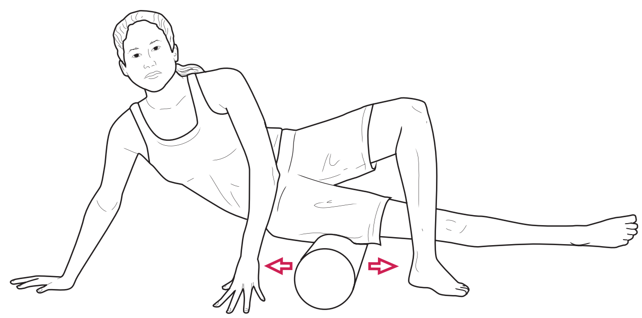

FIGURE 21.22 Foam roller fascial release for a tight IT band.

NOTE: The planted foot, along with the hands, serve to guide the rolling motion and can partially reduce the pressure on the lateral thigh, making the release technique more tolerable.

Exercises to Develop and Improve Muscle Performance and Functional Control

When strengthening exercises for knee musculature are selected, implemented, and progressed in a rehabilitation program, dynamic knee stability (which involves co-contraction of the quadriceps and hamstrings muscles) and safe patellofemoral and extensor mechanism biomechanics (for appropriate patellar tracking) are primary concerns. After stability and patellar mechanics are well established, coordination and

timing of muscle contractions, as well as endurance, are emphasized. To prepare for dynamic control of the knee during weight-bearing activities, closed-chain exercises with an emphasis on low-intensity (low resistance) and a high number of repetitions are more effective than open-chain (nonweight-bearing) exercises for improving stability and muscular endurance of the knee.

Although closed-chain control of the knee is essential, remember that the knee functions in both an open- and closed-chain fashion during most daily activities. The quadriceps and hamstrings must contract simultaneously (co-contraction), as well as contract concentrically and eccentrically during functional activities. Therefore, exercises under all of these varying conditions should be incorporated into a comprehensive knee rehabilitation program. It is also important to change the position of the hip during quadriceps- and hamstring-strengthening exercises to affect the length-tension relationship of the rectus femoris and hamstrings.[75] Only after a thorough examination for an understanding of a patient's pathology, structural and functional impairments, and activity limitations can a therapist select and design an exercise plan to meet an individual patient's needs.

- In the exercises that follow, open-chain exercises are described before closed-chain exercises simply because weight bearing after knee injury or surgery is often restricted for a period of time.
- Isolated activation of knee musculature also is necessary for functional activities that involve open-chain movements, such as lifting the leg to get in and out of bed or a car or flexing and extending the knee during dressing.
- The quadriceps has been shown to develop greater strength using resisted open-chain than closed-chain exercises.[282]
- Closed-chain strengthening should be initiated first in partial weight bearing and later in full weight bearing as healing allows and then integrated with balance and proprioceptive training and functional weight-bearing activities.

Considerable research has been done comparing joint reaction forces and muscle function during open- and closed-chain exercises. Comparisons of outcomes are difficult because of differing research designs and exercise variables.[67] Table 21.7 summarizes results from a recent study comparing two dynamic exercises, with recommendations for exercise modification with specific knee impairments. Special adaptations also have been highlighted in the conservative management and surgical management sections of this chapter.

Open-Chain (Nonweight-Bearing) Exercises

To Develop Control and Strength of Knee Extension (Quadriceps Femoris)

A wide variety of static and dynamic exercises can be used to improve the function of the quadriceps femoris muscles in open-chain positions. Because of variations in muscle fiber orientation and attachments of the knee extensor muscles, individual components of the quadriceps femoris muscle group place different biomechanical stresses on the patella.

Although it is not possible to isolate contraction of the different parts of the quadriceps femoris muscle because of the

TABLE 21.7 Comparison of Forces and Muscle Action at the Knee During Dynamic Open-Chain and Closed-Chain Exercises[67,299]

Parameter	Open-Chain Exercise—Variable Resistance: Sitting, Knee Extension Machine	Closed-Chain Exercise–Variable Resistance: Squatting, Leg-Press Machine (Body Moving Away from Fixed Feet)
Rectus femoris development	More effective	Less effective
VMO development	Less effective	More effective for VMO (and VL)
Other muscle development	None	Effective for hamstrings
ACL tensile forces*	ACL under tension at < 25°	
PCL tensile forces*	PCL under tension from 25°–95° (peak at 1.0 × body weight)	PCL under tension throughout range (1.5–2.0 × body weight)
Patellofemoral compression	Peak stress at 60°, peak compression at 75°‡	Compression increases with knee flexion, peaking at 90°†
Tibiofemoral compression	Higher compression (more stability) < 30°	Higher compression (more stability) > 70°

*The 0°–25° range should be excluded in open-chain exercises following ACL injury but may be included after PCL injury.
†Squat exercises: exercise only from 0°–50° with patellofemoral dysfunctions.
‡Open-chain exercise from 0°–30° and 75°–90° with patellofemoral dysfunctions. (Note: there is controversy in the literature regarding compressive forces in the patellofemoral joint from 0° to 30°.)

common innervation, emphasis is often placed on activation of the VMO and vastus medialis (VM) muscles to develop appropriate patellar tracking. Tactile cues, biofeedback, and electrical muscle stimulation over the VMO can reinforce awareness of the muscle contracting for patellar control. In this section, the effectiveness of various quadriceps exercises with regard to training and strengthening the VMO are discussed.

Quadriceps Setting (Quad Sets)

CLINICAL TIP

Of the many variations of static and dynamic exercises that have been proposed to selectively train the VMO, quadriceps setting coupled with electrical stimulation or biofeedback has been shown to be most effective.[268]

Patient position and procedure: Supine, sitting in a chair (with the heel on the floor) or long-sitting with the knee extended (or flexed a few degrees) but not hyperextended. Have the patient contract the quadriceps isometrically, causing the patella to glide proximally; then hold for a count of 10, and repeat.

- Use verbal cues such as, "Try to push your knee back and tighten your thigh muscle" or "Try to tighten your thigh muscle and pull your kneecap up." When the patient sets the muscle properly, offer verbal reinforcement immediately and then have the patient repeat the activity.
- Have the patient dorsiflex the ankle and then hold an isometric contraction of the quadriceps.[6]
- Monitor the gluteus maximus to make sure that the patient is not compensating with hip extension as a result of an inhibited quadriceps.

Straight-Leg Raise

CLINICAL TIP

An SLR in supine combines dynamic hip flexion with an isometric contraction of the quadriceps. The effective resistance of gravity (or any additional weight added at the ankle) decreases as the lower extremity elevates because of the decreasing moment arm of the resistance force. Consequently, the greatest resistance is encountered during the first few degrees of the SLR. The rectus femoris (which is also a hip flexor) is the primary muscle in the quadriceps group that is active during the SLR exercise.[268]

Patient position and procedure: Supine, with the knee extended. To stabilize the pelvis and low back, the opposite hip and knee are flexed, and the foot is placed flat on the exercise table. First, have the patient set the quadriceps muscle, and then lift the leg to about 45° of hip flexion while keeping the knee extended. Have the patient hold the leg in that position for a count of 10 and then lower it.

- To progress, have the patient lift to only 30° and then to only 15° of hip flexion, and hold the position.
- To increase resistance, place a cuff weight around the patient's ankle.

FOCUS ON EVIDENCE

It has been proposed that if an SLR in the supine position is coupled with external rotation or isometric adduction of the hip, the VMO or VM muscles are preferentially activated and strengthened.[6,34,61,166] The rationale for advocating these exercises is that many fibers of the VMO muscle originate from the adductor magnus tendon.[6,130] Although a number of authors[6] have advocated these adaptations to SLRs to increase the medially directed forces on the patella, there is lack of evidence to substantiate the effect. In two quantitative studies comparing quadriceps muscle activity during quad sets and variations of SLRs, quad sets were found to be associated with significantly more VMO or VM activity than several variations of SLRs.[130,268]

Straight-Leg Lowering

Patient position and procedure: Supine. If the patient cannot perform an SLR because of a quadriceps lag or weakness, begin by passively placing the leg in 90° of SLR position (or as far as the flexibility of the hamstrings allows), and have the patient gradually lower the extremity while keeping the knee fully extended.

- Be prepared to control the descent of the leg with your hand under the heel as the torque created by gravity increases.
- If the knee begins to flex as the extremity is lowered, have the patient stop at that point, then raise the extremity upward to 90°.
- Have the patient repeat the motion and attempt to lower the extremity a little farther each time while keeping the knee extended.
- When the patient can keep the knee extended while lowering the leg through the full ROM, SLRs can be initiated.

Multiple-Angle Isometric Exercises

- *Patient position and procedure:* Supine or long-sitting. Have the patient perform bent leg raises with the knee in multiple angles of flexion.
- *Patient position and procedure:* Seated at the edge of a treatment table. When tolerated, apply resistance just above the ankle to strengthen the quadriceps isometrically in varying degrees of knee flexion. Co-contraction of the quadriceps and hamstrings can be activated (except in the last 10° to 15° of knee extension) by having the patient push the thigh into the table while holding the knee in extension against resistance.[101]

Short-Arc Terminal Knee Extension

CLINICAL TIP

Although in the past it was thought that the VMO was responsible for the terminal phase of knee extension, it is now well documented that all components of the quadriceps femoris muscle group are active throughout active knee extension and that the VMO primarily affects patellar alignment.[268]

Patient position and procedure: Supine or long-sitting. Place a rolled towel or bolster under the knee to support it in flexion (Fig. 21.23). The patient can also assume a short-sitting position at the edge of a table with the seat of a chair or a stool placed under the heel to stop knee flexion at the desired angle. Begin with the knee in a few degrees of flexion. Increase the degrees of flexion as tolerated by the patient or dictated by the condition.

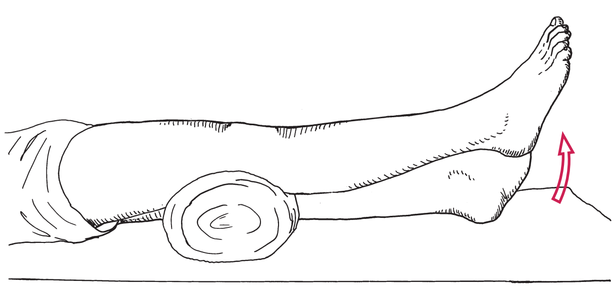

FIGURE 21.23 Short-arc terminal extension exercise to strengthen the quadriceps femoris muscle. When tolerated, resistance is added proximal to the ankle.

- Initially, have the patient extend the knee only against the resistance of gravity. Later, add a cuff weight around the ankle to increase the resistance if the patient does not experience pain or crepitation.
- Combine short-arc terminal knee extension with an isometric hold and/or a SLR when the knee is in full extension.
- To reduce lateral shear forces at the knee, have the patient invert the foot as he or she extends the knee.[6,99]

PRECAUTION: When adding resistance to the distal leg, the amount of torque generated by the quadriceps muscle increases significantly in the terminal ranges of knee extension. In this portion of the range, the quadriceps has a poor mechanical advantage and poor physiological length while having to contract against an external resistance force that has a long lever arm. The amount of muscle force generated causes an anterior translation force on the tibia, which is restrained by the ACL. This exercise is not appropriate for a patient during the early phase of postoperative rehabilitation when the reconstructed ligament is most vulnerable to imposed loads.

Full-Arc Extension

Patient position and procedure: Sitting or supine. Have the patient extend the knee from 90° to full extension. Apply resistance to the motion as tolerated.

CLINICAL TIP

Resistance applied from 90° to 60° in a nonweight-bearing position causes less anterior tibial translation than squatting (a closed-chain activity) in this range. Resistance applied in open-chain extension from 30° to 0°, however, increases anterior translation more than does performing minisquats in the same range.[299]

- Apply resistance through the full arc of motion only during the later phases of rehabilitation if the knee is pain-free, stable, and asymptomatic. If there is pain, resistance should be applied only through those portions of the range with no symptoms.
- Various forms of resistance equipment discussed in Chapter 6 can be used to strengthen the knee extensors. Emphasize high-repetition, low-resistance training with weight-training equipment and medium- to high-velocity training with isokinetic equipment to minimize compressive and shear forces on knee joint structures during exercise. When using equipment, the tibial pad against which the patient pushes while extending the knee can be placed proximally on the lower leg to decrease excessive stress on supporting structures of the knee.[300]
- If a cuff weight is applied to the tibia to provide resistance, it causes a distraction to the joint and stress on the ligaments when the patient sits or lies supine with the knee flexed to 90° and the tibia over the edge of the treatment table. To avoid this stress on ligaments, place a stool under the foot so it is supported when the leg is in the dependent position.[37]

To Develop Control and Strength of Knee Flexion (Hamstrings)

Hamstring Setting (Hamstring Sets)

Patient position and procedure: Supine or long-sitting, with the knee in extension or slight flexion with a towel roll under the knee. Have the patient isometrically contract the knee flexors just enough to feel tension develop in the muscle group by gently pushing the heel into the treatment table and holding the contraction. Have the patient relax and then repeat the contraction.

Multiple-Angle Isometric Exercises

Patient position and procedure: Supine or long-sitting. Apply either manual or mechanical resistance to a static hamstring muscle contraction with the knee flexed to several positions in the ROM.

- Place the tibia in internal or external rotation prior to resisting knee flexion to emphasize the medial or lateral hamstring muscles, respectively.

- Teach the patient to apply self-resistance at multiple points in the ROM by placing the opposite foot behind the ankle of the leg to be resisted.

Hamstring Curls

- *Patient position and procedure:* Standing, holding onto a solid object for balance. Have the patient lift the foot and flex the knee (Fig. 21.24). Maximum resistance from gravity occurs when the knee is at 90° flexion. Apply resistance with ankle weights or a weighted boot. If the patient flexes the hip, stabilize it by having the patient place the anterior thigh against a wall or solid object.

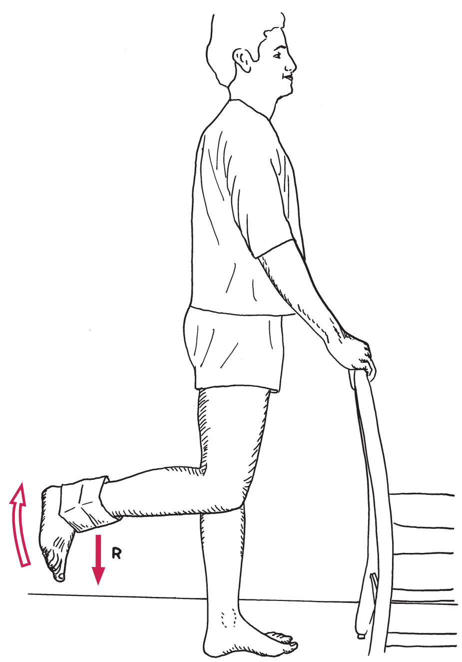

FIGURE 21.24 Hamstring curls; resistance exercises to the knee flexors with the patient standing. Maximal resistance occurs when the knee is at 90°.

- *Patient position and procedure:* Prone. Place a small folded towel or piece of foam rubber under the femur just proximal to the patella to avoid compression of the patella between the treatment table and the femur. With a cuff weight around the ankle, have the patient flex the knee to only 90°. Maximum resistance from gravity occurs when the knee first starts to flex at 0°. If hamstring curls are performed in the prone position using manual resistance, a weight-pulley system or isokinetic equipment resistance to the knee flexors can be applied throughout the full range of knee flexion.

PRECAUTION: Open-chain hamstring curls performed against resistance placed on the distal tibia cause posterior tibial translation. A patient with a PCL injury or reconstruction should avoid this exercise during the early stages of rehabilitation.

Closed-Chain (Weight-Bearing) Exercises

Progressive closed-chain exercises are beneficial for activating and training the musculature of the lower extremity to respond to specific functional demands. As the quadriceps contract eccentrically to control knee flexion or concentrically to extend the knee, the hamstrings and soleus function to stabilize the tibia against the anterior translating force of the quadriceps at the knee joint. This synergy, along with the compressive loading on the joints, provides support to the cruciate ligaments.[67,213] In addition, because the hip extends and the ankle plantarflexes as the knee extends (and vice versa) during closed-chain activities, the two-joint hamstrings and gastrocnemius and the one-joint soleus are maintaining favorable length-tension relationships through action at the hip and ankle, respectively.

Initiation of closed-chain exercises. During rehabilitation, closed-chain exercises can be incorporated in an exercise regimen as soon as partial or full weight bearing is safe. In certain portions of the ROM, closed-chain strengthening exercises generate less shear force on knee ligaments, particularly anterior tibial translation, than open-chain quadriceps-strengthening activities. Therefore, resistance can be added to closed-chain activities sooner after injury or surgery than can be added to open-chain exercises while still protecting healing structures such as the ACL. Clinically, closed-chain exercises enable a patient to develop strength, endurance, and stability of the lower extremity in functional patterns sooner after knee injury or surgery than do open-chain exercises. The progression of closed-chain exercises described in Chapter 20 is also appropriate for knee rehabilitation programs.

Partial weight-bearing and support techniques. If the patient does not tolerate or is not permitted to bear full weight on the involved extremity, begin exercises with upper extremity assistance, such as in the parallel bars or in a pool, to partially unload body weight and avoid excessive biomechanical stress. Also consider use of supportive taping techniques or bracing to ensure proper alignment during weight bearing. Begin exercises at a level tolerated by the patient and at which there is complete control and no exacerbation of symptoms.

CLINICAL TIP

Because the knee is the intermediate link in the lower extremity chain, it is significantly influenced by hip and trunk function, as well as foot and ankle function, during weight bearing.[109,228] Therefore, exercises for these regions should be included in the rehabilitation of the knee if impairments are detected during the examination. Specifically, look for:

- Tightness of the TFL, gluteus maximus, rectus femoris, hamstrings, or gastrocnemius-soleus muscle group

- Weakness of the gluteus medius, external rotators, or gluteus maximus

Closed-Chain Isometric Exercises

Closed-chain isometric exercises are done to facilitate co-contraction of the quadriceps and hamstrings.

Setting Exercises for Co-Contraction

Patient position and procedure: Sitting on a chair, with the knee extended or slightly flexed and the heel on the floor. Have the patient press the heel against the floor and the thigh against the seat of the chair and concentrate on contracting the quadriceps and hamstrings simultaneously to facilitate co-contraction around the knee joint. Hold the muscle contraction, relax, and repeat. Use biofeedback to enhance learning of the co-contraction.

Alternating Isometrics and Rhythmic Stabilization

Patient position and procedure: Standing, with weight equally distributed through both lower extremities. Apply manual resistance to the pelvis in alternating directions as the patient holds the position. This facilitates isometric contractions of muscles in the ankles, knees, and hips.

- Increase the speed of application of the resistive forces to train the muscles to respond to sudden shifts in forces.
- Progress the stabilization activity by applying the alternating resistance against the shoulders to develop trunk stabilization and then by having the patient bear weight only on the involved lower extremity while resistance is applied.
- Progress to weight bearing on unstable surfaces as balance and stability improve.

Closed-Chain Isometrics Against Elastic Resistance

Patient position and procedure: Standing on the involved extremity, with elastic resistance looped around the thigh of the opposite extremity and secured to a stable object (see Fig. 20.26). Have the patient flex and extend the hip of the nonweight-bearing lower extremity at varying speeds to facilitate co-contraction of muscles and stability of the weight-bearing leg. This closed-chain exercise also facilitates proprioceptive input and balance on the weight-bearing (involved) lower extremity.

Closed-Chain Dynamic Exercises

Scooting on a Wheeled Stool

Patient position and procedure: Sitting on a rolling stool or chair. Have the patient "walk" the feet forward to use the hamstrings or "walk" backward to use the quadriceps (Fig. 21.25). Be certain the knee is aligned vertically over the foot to avoid hip adduction, internal rotation, and subsequent valgus alignment of the lower leg.

- Increase the challenge of the exercise by having the patient steer around an obstacle course, roll the stool across carpeting, or pull against a resistance, such as pulling another person who is also on a rolling stool.

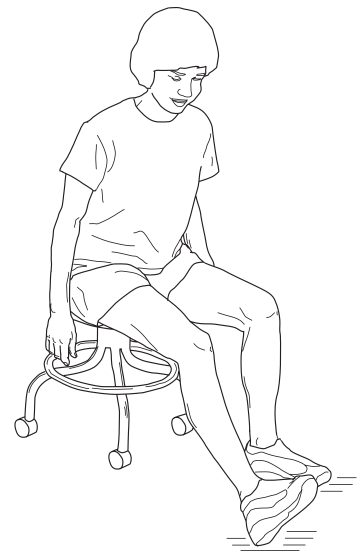

FIGURE 21.25 Forward scooting on a wheeled stool to strengthen knee flexors and backward scooting to strengthen knee extensors.

NOTE: Patient position is standing in all of the following exercises.

Unilateral Closed-Chain Terminal Knee Extension

Patient position and procedure: Standing, elastic resistance looped around the distal thigh and secured to a stationary structure (Fig. 21.26). Have the patient actively perform terminal knee extension while bearing partial to full weight on the involved extremity.

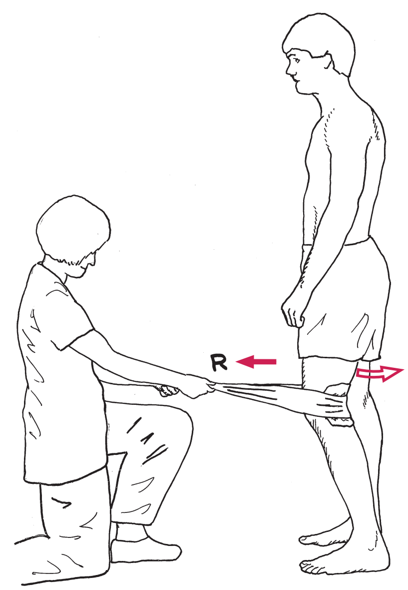

FIGURE 21.26 Unilateral closed-chain terminal knee extension.

Partial Squats, Minisquats, and Short-Arc Training

Patient position and procedure: Begin by having the patient flex both knees up to 30° to 45° and then extend them. Progress by using elastic resistance placed under both feet (Fig. 21.27 A) or by holding weights in the hands. The patient

should maintain the trunk upright, concentrate on maintaining a posterior weight shift, and lower the hips as though sitting down before moving the knees. The knees should maintain alignment with the toes to prevent valgus collapse and should not move forward beyond the toes to ensure gluteal activation and decreased forces on the patellofemoral joint.

- Progress squats to greater ranges of knee flexion during the advanced phases of treatment if necessary.
- Increase the difficulty of the exercise by performing unilateral resisted minisquats (Fig. 21.27 B) or squatting on unstable surfaces. Advanced activities are described and illustrated in Chapter 23.

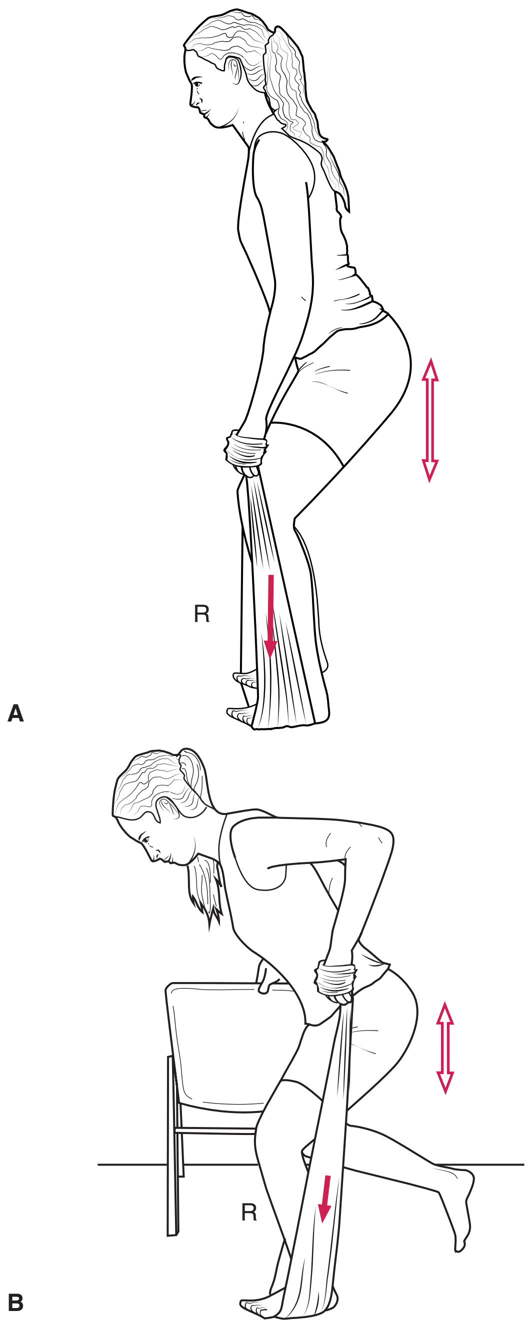

FIGURE 21.27 Resisted minisquats using elastic resistance; closed-chain short-arc training in **(A)** bilateral stance and **(B)** unilateral stance.

Standing Wall Slides

Patient position and procedure: Standing, with back against the wall (see Fig. 20.29 A). Flex the hips and knees, and slide the back down and then up the wall, lowering and lifting the body weight.

- Apply elastic resistance around both thighs just proximal to the knees to provide tactile cueing to the hip abductors. This helps the patient maintain vertical alignment over the toes to avoid or correct a valgus collapse.
- As control improves, have the patient move into greater knee flexion, up to a maximum of 60°. Knee flexion beyond 60° is not advocated to avoid excessive shear forces on ligamentous structures of the knee and compressive forces on the patellofemoral joint.
- Add isometric training by having the patient stay in the partial-squat position. If the patient is able, he or she maintains the partial squat and alternately extends one leg and then the other.
- Wall slides performed with a gym ball behind the back decrease stability and require greater control (see Fig. 20.29 B).
- Increase the difficulty of the exercise by performing wall slides in unilateral stance (see Fig. 23.29).

Forward, Backward, and Lateral Step-Ups and Step-Downs VIDEO 21.1

Patient position and procedure: Begin with a low step, 2 to 3 inches in height, and increase the height as the patient is able. Make sure the patient keeps the trunk upright and the knee aligned with the foot to avoid "valgus collapse."

- To reinforce proper lower extremity alignment and stimulate firing of the gluteus medius during forward step-ups, apply a graded manual resistive force to the lateral aspect of the forward thigh (Fig. 21.28 A).
- Emphasize control of body weight during concentric (step-up) and eccentric (step-down) quadriceps activities. To emphasize the quadriceps and minimize pushing off with the plantarflexors of the trailing extremity, teach the patient that the heel must be the last to leave the floor and the first to return or to "keep the toes up.
- Add resistance with a weight belt or handheld weights, or place elastic resistance (Fig. 21.28 B) or a belt attached to a pulley system around the patient's hips. Have the patient step up and step down while maintaining alignment, and control against the added resistance.
- Progress to stepping up onto or down from higher surfaces, and add rotational movements.

Partial and Full Lunges

Lunges may be performed by varying the length of the stride, by stepping into a lunge and bringing the trailing leg forward, or by stepping into a lunge and pushing back to the starting position. In addition, lunges may be performed by maintaining the lunge position and raising and lowering the body with the trunk erect.

Patient position and procedure: Begin with the feet together, and then have the patient lunge forward with the involved extremity using a small stride and a small amount of knee

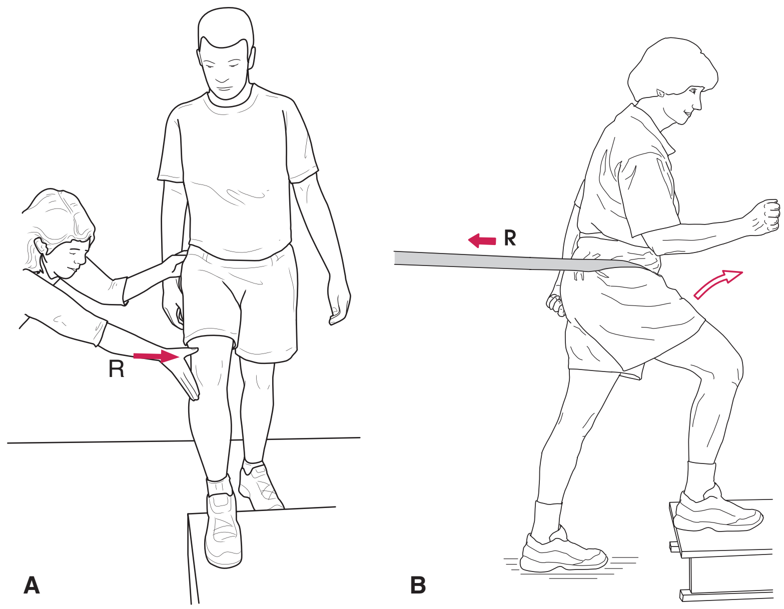

FIGURE 21.28 (A) A forward step-up with manual pressure applied to the lateral thigh to reinforce proper lower extremity alignment and stimulate the gluteus medius. **(B)** Resisted step-ups against elastic resistance or a pulley to strengthen knee extensors.

flexion (see Fig. 20.32). Then return to the upright position by extending the knee and bringing the foot back beside the other foot. As the patient gains control, increase the stride length and knee flexion accordingly.

- Maintain the knee in alignment with the toes (to avoid hip adduction and internal rotation), and do not flex the forward leg beyond a vertical line coming up from the toes.[68]
- To increase the challenge, add weights around the trunk or in the patient's hands, and increase the speed of the activity as control improves.
- Progress by having the patient lunge forward in a diagonal direction, then out to the side, then diagonally backward, and then directly backward. See Chapter 23 for descriptions and illustrations of advanced progressions.

Functional Progression for the Knee

To prepare for functional activities, it is important to develop adequate strength, stability, power, muscular and cardiopulmonary endurance, coordination and timing of movements, and the ability to control balance and to respond to expected or unexpected perturbations. Each of these elements is necessary for skill acquisition. The principle of specificity of training is applied to progress the patient's activities toward the desired functional outcomes. A brief summary of the key components of a functional progression for knee rehabilitation follows with references to other chapters for additional information.

Strength and Muscle Endurance Training

Advanced strengthening often involves high-load eccentric exercises or velocity-spectrum training. Resistance equipment, such as a leg press unit, a Total Gym® unit, or an isokinetic dynamometer, provide progressive loading of knee musculature beyond that of elastic resistance and cuff weights. During high-load, open-chain, knee extension exercises, placement of the tibial pad in a proximal position has been shown to reduce anterior shear forces on the knee.[300]

To improve muscular endurance, exercises previously described in this chapter are progressed by increasing the number of repetitions or time element at each resistance level. Equipment typically used for cardiopulmonary training, such as a treadmill, stationary bicycle, or stair-stepping unit, also can be used to develop lower extremity muscular endurance. Characteristics of exercise regimens designed to progressively develop strength and muscular endurance and features of various types of equipment are addressed in Chapters 6 and 7.

Cardiopulmonary Endurance Training

A progression of aerobic activities, such as swimming, cycling, walking, running, and using an upper extremity ergometer, elliptical trainer, stair-stepper, or cross-country ski machine, are graded to the patient's tolerance and integrated into a rehabilitation program for cardiopulmonary endurance. These activities also increase muscular endurance in multiple muscle groups. If the patient is planning on returning to a sport activity, choose a conditioning activity that best replicates the muscle activity used. Refer to Chapter 7 for training guidelines.

Balance and Proprioceptive Activities (Perturbation Training)

A progression of balance activities requiring trunk and lower extremity control is an essential component of a rehabilitation program to improve or restore a patient's functional capabilities.[76,77,288,304] As soon as partial to full weight bearing

is permitted, balance training can progress from basic activities in bilateral stance on a stable surface, such as stabilization exercises against alternating resistive forces, maintaining balance during multidirectional arm movements, and controlled weight shifting, stepping and marching movements, to more challenging activities in unilateral stance on unstable surfaces. A sequence of activities for postural control and progressive balance training is described and illustrated in Chapters 8, 16, and 23.

Plyometric Training and Agility Drills

Plyometric training, also referred to as stretch-shortening drills, is designed to improve power and develop quick neuromuscular responses. This form of training is appropriate during the advanced phase of rehabilitation for selected patients intending to return to high-demand work- or sport-related activities. Training involves high-speed movements and quick changes of direction. Examples of lower extremity plyometric training include forward-backward and side-to-side shuffles, use of a Pro-Fitter®, and jumping on and off surfaces of varying heights and landing using proper mechanics to reduce the risk of injury. Refer to Chapter 23 for a progression of lower extremity plyometric activities.

Agility drills are designed to develop coordination (sequencing and timing of movements), balance, and quick neuromuscular responses. Drills involve practicing movements that include directional changes at varying speeds of movement. Activities include maneuvering around or stepping over obstacles in the environment first while walking and then while running, pivoting, cutting, or hopping. Examples of agility drills are in Chapter 23.

Simulated Work-Related Activities and Sport-Specific Drills

A final component of an individualized rehabilitation program involves practicing activities that simulate the physical demands of a patient's work or desired recreational or sport activity. Simulated activities and drills enable a patient to practice under supervised conditions to receive feedback on correct mechanics.

For example, a patient returning to a repetitive lifting job should practice activities that develop strength in the trunk stabilizers and hip and knee extensors, as well as balance, for safe body mechanics during lifting.

Examples of early balance activities for the lower extremity are described in the exercise section of Chapter 20. A progression of lifting tasks and application of proper body mechanics are described in Chapters 8 and 16. Descriptions of sport-specific drills are beyond the scope of this textbook but can be found in a number of resources.

Independent Learning Activities

Critical Thinking and Discussion

1. Observe a functional activity, such as putting on a pair of socks, rising from a chair, or climbing on to a city bus.
   - What ROM is needed in the knee joint? Also include hip and ankle in the analysis.
   - If motion is restricted, what muscles would have decreased mobility? What joint glides would have decreased mobility?
   - What muscles are functioning, and what level of strength is needed?
   - Assume there is 50% loss of range and strength. Design an exercise program to progress functional recovery.
2. Describe the function of all the two-joint muscles that cross the knee; include the function of each muscle at its "other joint" and how each muscle can function most efficiently at the knee in terms of its length-tension relationship.
3. Describe the role of the knee musculature during the gait cycle.
   - What ROM is needed, and when during the gait cycle does the maximum degree of flexion and extension occur?
   - During the gait cycle, when is each of the muscles active at the knee, and what are their functions?
   - What gait deviations occur when there is muscle shortening, muscle weakness, and joint pain? Explain why each deviation occurs.
4. Two patients, both in their seventies, who underwent TKA 10 days ago because of joint degeneration from OA of the right knee, have been referred to you in your home health practice. One patient had a cemented TKA, and the other had a "hybrid" TKA. How does their postoperative management differ, or how is it similar?
5. Differentiate among structures involved with a lateral retinacular release, a proximal realignment of the extensor mechanism, and a distal realignment procedure. How would these differences have an impact on postoperative rehabilitation?
6. A patient demonstrates a pelvic drop and valgus collapse at the knee during a single-leg knee bend and ascending and descending stairs 6 months following ACL reconstruction. What muscles, when weak or tight, typically cause these movement dysfunctions? Describe techniques that can be used to correct these problems.

Laboratory Practice

1. Design, set up, and then perform a circuit-training course for hamstring and quadriceps activation and strengthening

and balance exercises. Sequence the activities from basic to advanced. Observe the accuracy and safety with each exercise, and note the stresses involved.

2. Using mechanical resistance (pulleys, elastic resistance, and free weights), set up exercises to meet each of the following situations.
   - Strengthen the quadriceps with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 25°.
   - Strengthen the hamstrings with the greatest mechanical torque occurring when the knee is at 90°, at 45°, and at 0°.
3. Review all the joint mobilization techniques for the knee; include basic glides, accessory motions, patellar mobilizations, and mobilization with movement techniques.
   - Identify and practice techniques that increase knee extension, beginning with the knee at 45° and progressing by 15° increments until full extension is reached.
   - Do the same for knee flexion, beginning at 25° and progressing at 15° increments until full range is achieved. What accessory motions are necessary?
   - What motions are restricted if the patella does not glide distally?
   - What function is lost if the patella does not glide proximally?
4. Review and practice soft tissue and patellar mobilization techniques that can be used to increase the mobility of the lateral retinaculum/IT band around the patella. How does mobilizing this tissue improve patellar tracking? What proximal muscles help to support normal patellar alignment during dynamic activities?
5. Identify all the two-joint muscles that cross the knee. Review and practice self-stretching techniques with and without equipment for each of these muscles.

Case Studies

1. Mrs. J. is a 49-year-old mother of three children. She is in good health but recently has experienced considerable right knee pain, especially after sitting for prolonged periods and then standing up, when descending stairs, and when shopping at the mall for longer than 2 hours. She has a history of a proximal tibial fracture 15 years ago. She reports that it took about a year before relatively normal mobility returned. On examination, you note no obvious deformities or joint swelling. Knee flexion is 125° with firm end feel and pain on overpressure; extension is 0° with firm end feel and pain on overpressure. There is a slight decrease in posterior glide accessory motion of the tibia and decreased mobility of the patella on the right compared to the left. Strength of the knee flexors and extensors is 4/5 bilaterally. She complains of pain in the right knee when squatting; pain begins at 45° flexion. She stops when the knees are at 75°, saying it hurts too much. She bends forward from the waist to pick up objects from the floor. She has difficulty lowering herself down to a low chair in a controlled manner.
   - List her impairments and functional limitations, and state appropriate goals.
   - Develop an exercise program to meet the goals. How do you begin the exercises? How do you progress each exercise and the program?
   - Describe a rationale for each manual technique you would use and for each exercise you would teach the patient.
2. Mr. R., 25 years of age, was in a serious automobile accident and sustained multiple femoral and patellar fractures on the left side. His leg was immobilized in a long-leg cast for 3 months, followed by a short-leg cast for an additional month. He was allowed to perform partial weight bearing when in the short-leg cast. The cast was removed this morning, and now he is to begin his rehabilitation, although he will not be allowed to perform full weight bearing for an additional month. He describes significant stiffness and discomfort when attempting to flex his knee. Observation reveals significant atrophy in the thigh and leg. There are no open sores or joint swelling. Range is minimal: flexion to 25°, extension to 20°, and no joint play in the tibiofemoral or patellofemoral joints. He demonstrated the ability to do quad and hamstring sets, but strength could not be tested.
   - Answer the same questions as in the previous case.
   - Even though patients in this and the previous case have restricted motion and demonstrate weakness, what are the differences in your intervention strategies? Are there different precautions that you will follow during treatment? If so, what are they?

CHAPTER

22

The Ankle and Foot

The joints, ligaments, and muscles of the ankle and foot are designed to provide stability and mobility in the terminal structures of the lower extremity. During standing, the foot must bear the body weight with a minimum of muscle energy expenditure. In addition, the foot must be either pliable or relatively rigid depending on various functional demands, such as adapting to absorb forces and accommodating to uneven surfaces or serving as a structural lever to propel the body forward during walking and running.

A firm understanding of the complex anatomy and kinesiology of the ankle and foot is important when treating impairment in this region of the body. The first section of this chapter reviews highlights of these areas the reader should know and understand. The second section contains guidelines for the management of disorders and surgeries in the foot and ankle region, and the third section describes exercise interventions for this region. Chapters 10 through 13 present general information on principles of management; the reader should be familiar with the material in these chapters and should have a background in examination and evaluation in order to effectively design a therapeutic exercise program to improve ankle and foot function in patients with impairments from injury, pathology, or recovery following surgery.

Structure and Function of the Ankle and Foot

The bones of the ankle and foot consist of the distal tibia and fibula, seven tarsals, five metatarsals, and 14 phalanges (Fig. 22.1).

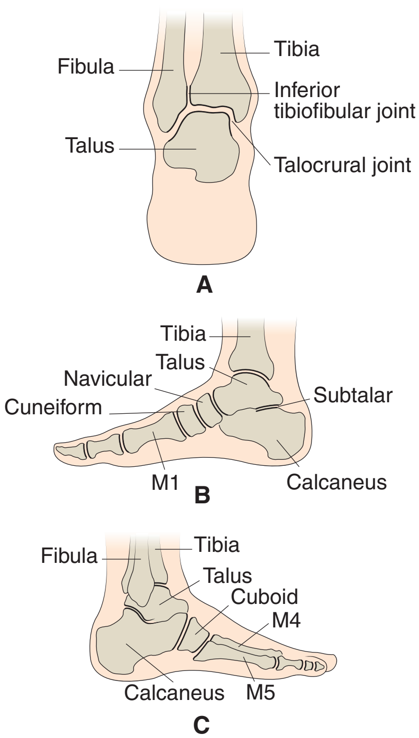

FIGURE 22.1 Bones of the ankle and foot. **(A)** Anterior view of the lower leg and ankle, **(B)** medial view, and **(C)** lateral view of the ankle and foot.

Structural Relationships and Motions

Anatomical Characteristics

The leg is structurally designed to transmit ground reaction forces from the foot upward to the knee joint and femur and adapt as needed to provide stability to or allow motion of the ankle. The resulting motions in the ankle and foot are defined using primary plane and triplanar descriptors.

Leg

The tibia and fibula make up the leg. These two bones are bound together by an interosseous membrane along the shafts of the bones, strong anterior and posterior inferior tibiofibular ligaments that hold the distal tibiofibular articulation together, and a strong capsule that encloses the proximal tibiofibular articulation. Unlike the radius and ulna in the upper extremity, the tibia and fibula do not rotate around each other, but there is slight movement between the two bones that allows greater movement of the ankle joints.

Foot

The foot is divided into three segments: the hindfoot, midfoot, and forefoot.

Hindfoot. The talus and calcaneus make up the posterior segment.

Midfoot. The navicular, cuboid, and three cuneiforms make up the middle segment.

Forefoot. Five metatarsals and 14 phalanges make up the anterior segment. Each toe has three phalanges except for the large toe, which has two.

Motions of the Foot and Ankle Defined

Primary Plane Motions

Although motions in the foot and ankle do not occur purely in the cardinal planes, they are still defined as follows.[24,82,118]

Sagittal plane motion around a frontal (coronal axis). *Dorsiflexion* is movement in a dorsal direction, which decreases the angle between the leg and dorsum of the foot, and *plantarflexion* is movement in a plantar direction. Motion occurring at the toes may also be called dorsiflexion, or extension, and plantarflexion, or flexion.

Frontal plane motion around a sagittal (anteroposterior) axis. *Inversion* is inward turning of the foot, and *eversion* is outward turning. Normally, an inward and outward motion is described by the terms abduction and adduction, but because the foot is at a right angle to the leg, the terms abduction and adduction are not used for this frontal plane motion.

Transverse plane motion around a vertical axis. *Abduction* is movement away from the midline, and *adduction* is movement toward the midline.

Triplanar Motion

Triplanar motion occurs around an oblique axis at each articulation of the ankle and foot. The definitions are descriptive of the movement of the distal bone on the proximal bone. When the proximal bone moves on the stabilized distal bone, as occurs in weight bearing, the motion of the proximal bone is opposite, although the relative joint motion is the same as defined.

Pronation. Pronation is a combination of dorsiflexion, eversion, and abduction. During weight bearing, pronation of the subtalar and transverse tarsal joints causes the arch of the foot to lower, and there is a relative supination of the forefoot with dorsiflexion of the first and plantarflexion of the fifth metatarsals. This is the loose-packed or mobile position of the foot and is assumed when the foot absorbs the impact of weight bearing and rotational forces of the rest of the lower extremity and when the foot conforms to the ground.[24]

Supination. Supination is a combination of plantarflexion, inversion, and adduction. In the closed-chain, weight-bearing foot, supination of the subtalar and transverse tarsal joints with a pronation twist of the forefoot (plantarflexion of the first and dorsiflexion of the fifth metatarsals) increases the arch of the foot and is the close-packed or stable position of the joints of the foot. This is the position the foot assumes when a rigid lever is needed to propel the body forward during the push-off phase of ambulation.[82,118]

NOTE: The terms *inversion* and *supination*, as well as *eversion* and *pronation*, are often used interchangeably.[103] This text uses the terms as defined above.

Joint Characteristics and Arthrokinematics: Leg, Ankle, and Foot

The characteristics of each joint in the leg, ankle, and foot dictate how they contribute to the function of the foot.[82,102,118]

Tibiofibular Joints

Anatomically, the superior and inferior tibiofibular joints are separate from the ankle, but provide accessory motions that allow greater movement at the ankle. Fusion or immobility in these joints impairs ankle function. The strong mortise formed by the distal ends of the tibia and fibula makes up the proximal surface of the ankle (talocrural) joint.

Superior tibiofibular joint characteristics. The superior tibiofibular joint is a plane synovial joint made up of the fibular head and a facet on the posterolateral aspect of the rim of the tibial condyle. The facet faces posteriorly, inferiorly, and laterally. Although near the knee joint, it has its own capsule that is reinforced by the anterior and posterior tibiofibular ligaments.

Inferior tibiofibular joint characteristics. The inferior tibiofibular joint is a syndesmosis with fibroadipose tissue between the two boney surfaces. This strong articulation is supported by the crural tibiofibular interosseous ligament and the anterior and posterior tibiofibular ligaments.

Accessory motions. With dorsiflexion and plantarflexion of the ankle, there are slight accessory movements of the fibula. The direction of movement is variable depending on facet orientation of the proximal tibiofibular joint and elasticity in the tibiofibular ligaments. However, movement is necessary to allow full range of the talus in the mortise during ankle dorsiflexion.

Ankle (Talocrural) Joint

Characteristics. The ankle (talocrural) joint is a synovial hinge joint formed by the mortise (distal end of the tibia and tibial and fibular malleoli) and trochlea (dome) of the talus. It is enclosed by a relatively thin and weak capsule. It, along with the subtalar joint, is supported medially by the medial collateral (deltoid) ligament and laterally by the lateral collateral (anterior and posterior talofibular and calcaneofibular) ligaments (Fig. 22.2).

The fibular malleolus extends farther distally and posteriorly than the tibial malleolus, so the mortise angles outward and downward. This causes the axis of motion to be rotated laterally 20° to 30° and inclined downward 10°. The surface of the mortise is congruent with the articulating surface of the body of the talus.

The surface of the talus is wedge-shaped, wider anteriorly, and also cone-shaped, with the apex pointing medially. As a result of the orientation of the axis and the shape of the talus when the foot dorsiflexes, the talus also abducts and slightly everts (pronation). When the foot plantarflexes, the talus also adducts and slightly inverts (supination). Dorsiflexion is the close-packed, stable position of the talocrural joint; plantarflexion is the loose-packed position.

CLINICAL TIP

It is important to recognize that the stable positions of the ankle and the foot do not always coincide. For example, when a person walks in high heels, the ankle joint is more vulnerable to injury, because the talocrural joint is in a less stable, plantarflexed position while the subtalar and transverse tarsal joints are in a close-packed (rigid) position.

Arthrokinematics. The concave articulating surface is the mortise; the convex articulating surface is the body of the talus. With physiological motions of the foot, the articulating surface of the talus slides in the opposite direction (Box 22.1).

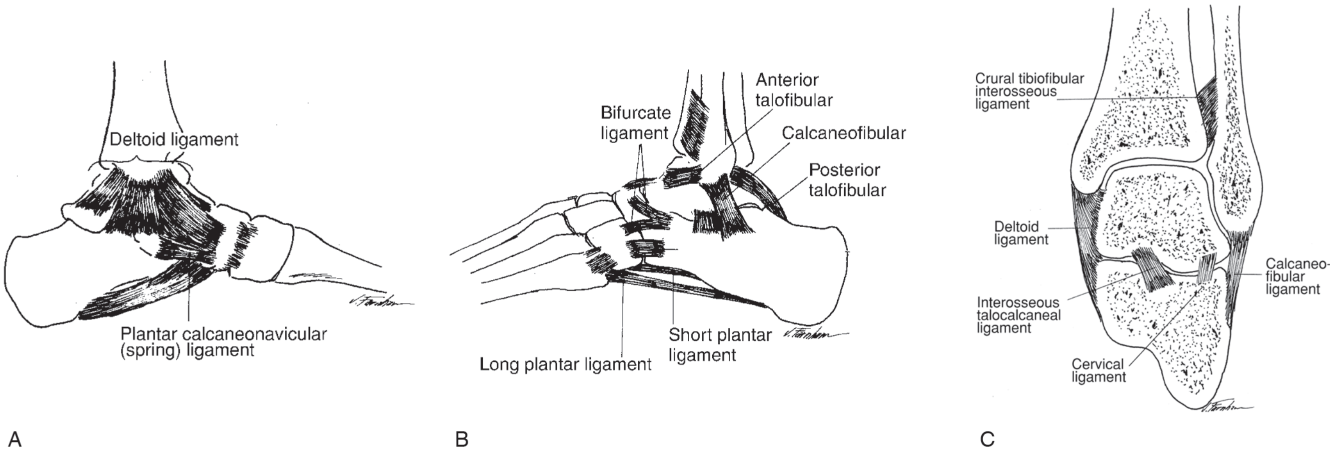

FIGURE 22.2 Ligaments of the ankle and foot. **(A)** Medial view, **(B)** lateral view, and **(C)** posterior (cross-sectional) view. *(From Martin in Levangie and Norkin,[82] A and B, p 445; C p 449, with permission.)*

BOX 22.1 Arthrokinematics of the Ankle and Foot Joints

Physiologic motion	Roll	Slide
Talocrural joint: motion of talus		
Dorsiflexion	Anterior	Posterior
Plantarflexion	Posterior	Anterior
Subtalar joint: motion of calcaneus (posterior articulating surface)		
Supination with inversion	Medial	Lateral
Pronation with eversion	Lateral	Medial
Talonavicular joint: motion of navicular (open-chain)		
Supination	Plantar and medial	Plantar and medial
Pronation	Dorsal and lateral	Dorsal and lateral
Metatarsophalangeal and interphalangeal joints: motion of the phalanges		
Flexion	Plantar	Plantar
Extension	Dorsal	Dorsal

Subtalar (Talocalcaneal) Joint

Characteristics. The subtalar (talocalcaneal) joint is a complex joint with three articulations between the talus and calcaneus. It has an oblique axis of motion that lies approximately 42° from the transverse plane and 16° from the sagittal plane, allowing the calcaneus to pronate and supinate in a triplanar motion on the talus.

Frontal plane inversion (turning heel inward) and eversion (turning heel outward) can be isolated only with passive motion. The subtalar joint is supported by the medial and lateral collateral ligaments, which also support the talocrural joint; the interosseous talocalcaneal ligament in the tarsal canal; and the posterior and lateral talocalcaneal ligaments (see Fig. 22.2). In closed-chain activities, the joint attenuates the rotatory forces between the leg and foot so that, normally, excessive inward or outward turning of the foot does not occur as the foot maintains contact with the supporting surface.

Of the three articulations between the talus and calcaneus, the posterior is separated from the anterior and middle by the tarsal canal. The canal divides the subtalar joint into two joint cavities. The posterior articulation has its own capsule. The anterior articulations are enclosed in the same capsule as the talonavicular articulation, forming the talocalcaneonavicular joint. Functionally, these articulations work together.

Arthrokinematics. The facet on the bottom of the talus in the posterior compartment is concave, and the opposing facet on the calcaneus is convex. The facets of the anterior and middle articulations on the talus are convex, whereas the opposing facets on the calcaneus are concave. With open-chain physiological motions of the subtalar joint, the convex posterior portion of the calcaneus slides opposite to the motion; the concave anterior and middle facets on the calcaneus slide in the same direction, similar to turning a doorknob. With the component motion of eversion, as the calcaneus swings laterally, the posterior articulating surface slides medially, and with inversion, the posterior articulating surface slides laterally (see Box 22.1).

Talonavicular Joint

Characteristics. Anatomically and functionally, the talonavicular joint is part of a complex articulation between the talus and navicular as well as the anterior and medial facets of the subtalar joint. It is supported by the spring, the deltoid, the bifurcate, and the dorsal talonavicular ligaments. The triplanar motions of the navicular on the talus function with the subtalar joint, resulting in pronation and supination.

During pronation, in the weight-bearing foot, the head of the talus drops plantarward and medially, resulting in a pliable foot and decreased medial longitudinal arch. In essence, as the calcaneus everts, it cannot also dorsiflex and abduct with the foot on the ground, so the talus plantarflexes and inverts on the calcaneus. This downward and inward motion of the talar head results in an upward and outward motion of the navicular and a flattening of the arch. During supination, the opposite occurs, resulting in a structurally stable foot and an increased medial longitudinal arch. The calcaneus inverts, and the talus dorsiflexes and everts, resulting in the navicular plantarflexing, inverting, and adducting.

Arthrokinematics. The head of the talus is convex; the proximal articulating surface of the navicular is concave. With physiological motions of the foot, the navicular slides in the same direction as the motion of the forefoot. In the open-chain motion of pronation, the navicular slides dorsally and laterally (abduction and eversion), resulting in a flattening of the medial longitudinal arch. With supination, the navicular slides volarly and medially (adduction and inversion) (see Box 22.1).

Transverse Tarsal Joint

Characteristics. The transverse tarsal joint is a functionally compound joint between the hind- and midfoot that includes the anatomically separate talonavicular and calcaneocuboid joints. The talonavicular joint is described in the previous section. The calcaneocuboid joint is saddle-shaped. The transverse tarsal joint participates in the triplanar pronation/supination motions of the foot and makes compensatory movements to accommodate variations in the ground. Passive accessory motions include abduction/adduction, inversion/eversion, and dorsal/plantar gliding.

Arthrokinematics. The articulating surface of the calcaneus is convex in a dorsal-to-plantar direction and concave in a medial-to-lateral direction. The articulating surface of the cuboid is reciprocally concave and convex.

Remaining Intertarsal and Tarsometatarsal Joints

The remaining intertarsal and tarsometatarsal joints are plane joints that reinforce the function of transverse tarsal joints and during weight bearing, help regulate the position of the forefoot on the ground.

Metatarsophalangeal and Interphalangeal Joints of the Toes

The metatarsophalangeal (MTP) and interphalangeal (IP) joints of the toes are the same as the metacarpophalangeal and interphalangeal joints of the hand except that, in the toes, extension range of motion (ROM) is more important than flexion (the opposite is true in the hand). Extension of the MTP joints is necessary for normal walking. Also, unlike the thumb, the large toe does not function separately.

Function of the Ankle and Foot

Structural Relationships

Interdependence of leg and foot motions. In the weight-bearing foot, subtalar motion and tibial rotation are interdependent. Supination of the subtalar joint results in or is caused by lateral rotation of the tibia, and conversely, pronation of the subtalar joint results in or is caused by medial rotation of the tibia.[82,118]

Arches. The arches of the foot are visualized as a twisted osteoligamentous plate, with the metatarsal heads being the horizontally placed anterior edge of the plate, and the calcaneus being the vertically placed posterior edge. The twist causes the longitudinal and transverse arches. When the foot is bearing weight, the plate tends to untwist and flatten the arches slightly.[82]

- Primary support of the arches comes from the spring ligament, with additional support from the long plantar ligament, the plantar aponeurosis, and short plantar ligament (see Fig. 22.2). During push-off in gait, as the foot plantarflexes and supinates and the metatarsal phalangeal joints go into extension, increased tension is placed on the plantar aponeurosis, which helps increase the arch. This is called the windlass effect.
- In the normal static foot, muscles do little to support the arches, yet without muscle tension the passive support stretches, and foot pronation increases under weight-bearing loads. Muscles contribute to support during ambulation.

Effect on posture. During standing with weight equally distributed in both lower extremities, if one foot/ankle complex is more pronated than the other, the overall effect is a frontal plane asymmetry with a "short leg" on that side. All typical landmarks (crest of the ilium, greater trochanter, popliteal crease, head of the fibula, and medial malleolus) on the side of the pronated foot are slightly lower.

Abnormal foot postures. A person with a varus deformity of the calcaneus (observed nonweight-bearing) may compensate by standing with a pronated (or everted) calcaneus posture.[25] Internal rotation of the leg, valgus at the knee, and internal rotation of the femur may also be seen with the pronated foot posture. The terms *pes planus*, *pronated foot*, and *flat foot* are often used interchangeably to mean a pronated posture of the hindfoot and decreased medial longitudinal arch. Pes cavus and supinated foot describe a high-arched foot.[103]

Muscle Function in the Ankle and Foot

Plantarflexors. Plantarflexion is caused primarily by the two-joint gastrocnemius muscle and the one-joint soleus muscle; these muscles attach to the calcaneus via the Achilles tendon.

Secondary plantarflexors. Other muscles passing posteriorly to the axis of motion of plantarflexion contribute little to that motion, but they have other functions.

- Tibialis posterior is a strong *supinator* and *invertor* that supports the medial longitudinal arch during weight bearing[101] and controls and reverses pronation during the loading response of gait.
- The flexor hallucis longus and flexor digitorum longus muscles flex the toes and help support the medial longitudinal arch. To prevent clawing of the toes (MTP extension with IP flexion), intrinsic muscles must also function at the MTP joints.
- The peroneus longus and brevis muscles primarily *pronate* the foot at the subtalar joint, and the longus gives support to the transverse and lateral longitudinal arches during weight-bearing activities.

Dorsiflexors. Dorsiflexion of the ankle is caused by the tibialis anterior muscle (which also inverts the ankle), the extensor hallucis longus and extensor digitorum longus (which also extend the toes), and the peroneus tertius muscles.

Intrinsic muscles. Intrinsic muscles of the foot function similarly to those of the hand (except there is no thumb-like function in the foot). In addition, they provide support to the arches during gait.

Stability in standing. During normal standing, the gravitational line is anterior to the axis of the ankle joint, creating a dorsiflexion moment. The soleus muscle contracts to counter the gravitational moment through its pull on the tibia. Other extrinsic foot muscles help stabilize the foot during postural sway.

The Ankle/Foot Complex and Gait

During the normal gait cycle, the ankle goes through an ROM of 32° to 35°. Approximately 7° of dorsiflexion occurs at the end of midstance, as the heel begins to rise, and 25° of plantarflexion occurs at the end of stance (toe off).[105]

Function of the Ankle and Foot Joints During Gait

The shock-absorbing, terrain-conforming, and propulsion functions of the ankle and foot include the following.[82,105,107]

- During the *loading response* (heel strike to foot flat), the heel strikes the ground in neutral or slight supination. As the foot lowers to the ground, it begins to pronate to its loose-packed position. The entire lower extremity rotates inward, reinforcing the loose-packed position of the foot. With the foot in a lax position, it can conform to variations in the ground contour and absorb some of the impact forces as the foot is lowered.
- Once the foot is fixed on the ground, dorsiflexion begins as the tibia comes up over the foot. The tibia continues to rotate internally, which reinforces pronation of the subtalar joint and loose-packed position of the foot.
- During *midstance* and continuing through *terminal stance*, the tibia begins to rotate externally, initiating supination of the hindfoot and locking of the transverse tarsal joint. This brings the foot into its close-packed position, which is reinforced as the heel rises and the foot rocks up onto the toes, causing toe extension and tightening of the plantar aponeurosis (windlass effect). This stable position converts the foot into a rigid lever, ready to propel the body forward as the ankle plantarflexes from the pull of the gastrocnemius-soleus muscle group.

Muscle Control of the Ankle and Foot During Gait

Muscles of the ankle and foot function in the following manner during the gait cycle.[82,105,107]

Ankle dorsiflexors. The ankle dorsiflexors function during the initial foot contact and loading response (heel strike to foot flat) to counter the plantarflexion torque and to control the lowering of the foot to the ground. They also function during the swing phase to keep the foot from plantarflexing and dragging on the ground. With loss of the dorsiflexors, foot slap occurs at initial foot contact, and the hip and knee flex excessively during swing (otherwise the toe drags on the ground).

Ankle plantarflexors. Early in stance, the ankle plantarflexors function eccentrically to control the rate of forward movement of the tibia. Then, at around 40% of the cycle (midstance), there is a burst of concentric activity to initiate plantarflexion of the ankle for push off. Loss of function results in a slight lag of the lower extremity during terminal stance with no push-off.

Ankle evertors. Contraction of the peroneus longus muscle late in the stance phase facilitates transfer of weight from the lateral to the medial side of the foot. It also stabilizes the first ray and facilitates the pronation twist of the tarsometatarsal joints, as increased supination occurs in the hindfoot.

Ankle inverters. The tibialis anterior helps control the pronation force on the hindfoot, and the tibialis posterior helps control the pronation force on the medial longitudinal arch during the loading response of gait.

Intrinsic muscles. The intrinsic muscles support the transverse and longitudinal arches during gait.

Referred Pain and Nerve Injury

Several major nerves terminate in the foot. Injury or entrapment of the nerves may occur anywhere along their course—from the lumbosacral spine to near the nerves' termination.

For treatment to be effective, it must be directed at the source of the problem. Therefore, a thorough history is obtained, and an examination is performed when the patient reports referred pain patterns, sensory changes, or muscle weakness. For a detailed description of referred pain patterns and peripheral nerve injuries in the foot and ankle region, see Chapter 13.

Major Nerves Subject to Pressure and Trauma

Common fibular (perineal) nerve. Pressure on the common fibular nerve may occur as it courses laterally around the fibular neck and passes through an opening in the peroneus longus muscle (see Fig. 13.10 in Chapter 13).

Posterior tibial nerve. Entrapment in the tarsal tunnel, causing tarsal tunnel syndrome, may occur from a space-occupying lesion posterior to the medial malleolus.

Plantar and calcaneal nerves. These branches of the posterior tibial nerve may become entrapped as they turn under the medial aspect of the foot and pass through openings in the abductor hallucis muscle. Overpronation presses the nerves against these openings. Irritation of the nerves may elicit symptoms similar to those of acute foot strain (tenderness at the posteromedial plantar aspect of the foot), painful heel (inflamed calcaneal nerve), and pain in a pes cavus foot.

Common Sources of Segmental Sensory Reference in the Foot

The foot is the terminal point for the L4, L5, and S1 nerve roots coursing through the terminal branches of the peroneal and tibial nerves. Referred pain may occur with irritation to tissues derived from the same spinal segments, or sensory changes from irritation or damage to these nerve roots (see Fig. 13.2).

Management of Foot and Ankle Disorders and Surgeries

To make sound clinical decisions when managing patients with foot and ankle disorders, it is necessary to understand the various pathologies, surgical procedures, and associated precautions and to identify presenting impairments, activity limitations and participation restrictions (functional limitations and disabilities). In this section, common pathologies and surgeries are presented and related to corresponding preferred practice patterns (groupings of impairments) described in the *Guide to Physical Therapist Practice*[2] (Table 22.1). Conservative and postoperative management of the conditions described in this section are based on principles of tissue healing and exercise intervention.

Joint Hypomobility: Nonoperative Management

Common Joint Pathologies and Etiology of Symptoms

Pathologies, such as rheumatoid arthritis (RA); juvenile rheumatoid arthritis (JRA); degenerative joint disease (DJD); and acute joint reactions after trauma, dislocation, or fracture, affect the foot and ankle complex. Postimmobilization contractures and adhesions develop in the joint capsules and

TABLE 22.1 Foot and Ankle Pathologies/Surgical Procedures and Preferred Practice Patterns

Pathology/Surgical Procedure	Preferred Practice Patterns and Associated Impairments[2]
▪ Abnormal posture (pronated or supinated foot, tibial torsion)	Pattern 4B—Impaired posture
▪ Arthritis (osteoarthritis, rheumatoid arthritis, traumatic arthritis, gout) ▪ Postimmobilization stiffness ▪ Synovitis ▪ Joint instability, subluxation, dislocation (nontraumatic/recurrent) ▪ Leg, heel, foot pain: overuse syndromes/repetitive trauma syndromes (tendinopathy, plantar fasciitis, shin splints)	Pattern 4D—Impaired joint mobility, motor function, muscle performance, and range of motion associated with connective tissue dysfunction
▪ Arthritis—acute stage ▪ Acute capsulitis ▪ Acute plantar fasciitis, tendonitis, shin splints ▪ Acute ankle sprains ▪ Acute muscle tears	Pattern 4E—Impaired joint mobility, motor function, muscle performance, and range of motion associated with localized inflammation

Continued

TABLE 22.1 Foot and Ankle Pathologies/Surgical Procedures and Preferred Practice Patterns—cont'd

Pathology/Surgical Procedure	Preferred Practice Patterns and Associated Impairments[2]
▪ Fractures	Pattern 4G—Impaired joint mobility, muscle performance, and range of motion associated with fracture
▪ Arthroscopic débridement ▪ Osteochondral drilling, mosaicplasty, osteochondral autologous transplantation ▪ Excision arthroplasty with or without implant of the MTP or IP joints ▪ Total joint arthroplasty	Pattern 4H—Impaired joint mobility, motor function, muscle performance and range of motion associated with joint arthroplasty
▪ Fracture stabilization with internal fixation ▪ Tendon and ligament repairs ▪ Capsulorrhaphy ▪ Synovectomy ▪ Arthrodesis	Pattern 4I—Impaired joint mobility, motor function, muscle performance and range of motion associated with boney or soft tissue surgery
▪ Peripheral nerve injury (common peroneal, posterior tibial, tarsal tunnel syndrome)	Pattern 5F—Impaired peripheral nerve integrity and muscle performance associated with peripheral nerve injury

surrounding tissues any time a joint is immobilized in a cast or splint, typically after a dislocation or fracture. The reader is referred to Chapter 11 for background information on arthritis, postimmobilization stiffness, and etiology of symptoms. The following is specific to joint conditions of the ankle and foot.

RA. Pathology of the foot and ankle as the result of RA commonly affects the forefoot early in the disease process; the hindfoot later; and least frequently, the ankle.[20,54,83] Involvement may occur in the MTP, subtalar, and talocrural joints of the foot, leading to instabilities and painful deformities, such as hallux valgus and subluxation of the metatarsal heads, that increase with the stress of weight bearing. Tendon rupture of foot and ankle musculature also may occur as the result of chronic inflammation and can contribute to deformity.[54]

DJD and joint trauma. Degenerative symptoms occur in joints that are repetitively traumatized, and acute joint symptoms are often seen in conjunction with ankle sprains, chronic instability, or fracture. Posttraumatic arthritis leading to DJD is by far the most common type of arthritis that affects the ankle, accounting for approximately 70% to 80% of all ankle arthritis. In contrast, primary osteoarthritis, a common type of arthritis in the hip and knee, is rare in the ankle, even in the older adult population.[83,139]

Postimmobilization stiffness. Contractures and adhesions in the capsular tissues and the surrounding periarticular tissues may occur any time the joint is immobilized after a fracture or surgery.

Gout. Symptoms commonly affect the MTP joint of the great toe, causing pain during terminal stance, so there is a shorter stance and lack of smooth push-off.

Common Structural and Functional Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations/Disabilities)

In RA, many of the following impairments and deformities occur with progression of the disease.[54,124] With DJD and postimmobilization stiffness, only the affected joint(s) is limited.[16] Activity limitations and participation restrictions occur primarily as a result of loss of weight-bearing abilities.

- ***Restricted motion.*** When symptoms are acute, the patient experiences swelling and restricted, painful motion, particularly during weight-bearing activities. When symptoms are chronic, there is restricted motion, decreased joint play, and a firm capsular end-feel in the affected joint.
  - ***Proximal and distal tibiofibular joints.*** Restricted accessory motion in these joints usually occurs with periods of immobilization and limits ankle and subtalar joint motion.[71]
  - ***Talocrural joint.*** Passive plantarflexion is more limited than dorsiflexion (unless the gastrocnemius-soleus muscle group also is shortened, in which case dorsiflexion is limited accordingly).[22]
  - ***Subtalar, transverse tarsal, and tarsometatarsal joints.*** Progressive limitation of supination develops until eventually the joint fixes in pronation with flattening of the medial longitudinal arch.[22] The close-packed position of the tarsals (supination) becomes more and more difficult to assume during the terminal stance (push-off) phase of gait. Moderate to severe foot pain is experienced with midfoot arthritis, especially during weight bearing.[110]
  - ***MTP joint of the large toe.*** Gross limitation of extension and some limitation of flexion develop; the rest of the

MTP joints are variable. Lack of extension restricts the terminal stance phase of gait with an inability to rock up onto the metatarsal heads. This exacerbates the pronation posture and inability to supinate the foot during push-off in gait.

- ***Common deformities.*** Deformities occur due to a variety of factors including but not limited to muscle imbalances, faulty footwear, trauma, and heredity. Common deformities of the forefoot are described in Box 22.2.[80,124]
- ***Muscle weakness and decreased muscular endurance.*** Inhibition resulting from pain and decreased use of the extremities leads to impaired muscle function.
- ***Impaired balance and postural control.*** The sensory receptors in the ankle joints and ligaments, as well as in the muscle spindles, provide important information for a balance reaction, known as the *ankle strategy.* The ankle strategy is used in balance control during perturbations.[50,113] Faulty feedback and balance deficits occur when there is instability, muscle impairments, or arthritis.
- ***Increased frequency of falling.*** Impaired balance or a sense of instability (giving way) of the ankle may lead to frequent falling or fear of falling, thus restricting community outings.[83]
- ***Painful weight bearing.*** When symptoms are acute, weight-bearing activities are painful, preventing independent ambulation and causing difficulty in rising from a chair and ascending and descending stairs.
- ***Gait deviations.*** If the patient experiences pain during weight bearing, there is a short stance phase, reduced single limb support, and decreased stride length on the side of involvement. Because of the restricting motion and loss of effective plantarflexion and supination in the arthritic foot as well as pain in the forefoot area under the metatarsal heads, push-off is ineffective during terminal stance. Little or no heel rise occurs; instead, the person lifts up the involved foot.
- ***Decreased ambulation.*** Because of decreased ankle and foot mobility and resulting decreased length of stride, distance and speed of ambulation are decreased; the person may require use of assistive devices for ambulation. If pain, balance, or restricted motion is severe, the person will be unable to ambulate and will require a wheelchair for mobility.

BOX 22.2 Common Arthritis-Related Forefoot Deformities

- ***Hallux valgus.*** This deformity in the great (large) toe develops as the proximal phalanx shifts laterally toward the second toe. Eventually the flexor and extensor muscles of the great toe shift laterally and further accentuate the deformity. The bursa over the medial aspect of the metatarsal head may become inflamed and the bone may hypertrophy, causing a painful bunion.
- ***Hallux limitus/hallux rigidus.*** Narrowing and eventual obliteration of the first MTP joint space occur with progressive loss of extension. This affects terminal stance by not allowing the foot to roll over the metatarsal heads and great toe for normal push-off. Instead, the individual turns the foot outward and rolls over the medial aspect of the large toe. This faulty pattern accentuates hallux valgus and foot pronation, and usually the MTP joint is quite painful.
- ***Dorsal subluxation/dislocation of the proximal phalanges on the metatarsal heads.*** If this occurs, the fat pad, which normally is under the metatarsal heads, migrates dorsally with the phalanges, and the protective cushion during weight bearing is lost, leading to pain, callus formation, and potential ulceration.
- ***Claw toe (MTP hyperextension and IP flexion) and hammer toe (MTP hyperextension, PIP flexion, and DIP hyperextension).*** These deformities result from muscle imbalances between the intrinsic and extrinsic muscles of the toes. Friction from shoes may cause calluses to form where the toes rub.

Joint Hypomobility: Management—Protection Phase

The interventions selected for management depend on the signs and symptoms present. For acute problems, follow the general outline presented in Chapter 10 and summarized in Box 10.1. Suggested interventions for the various goals are described in this section.[60,83,124]

Educate the Patient and Provide Joint Protection

- Teach a home exercise program at the level of the patient's abilities.
- Teach the patient signs of systemic fatigue (especially in RA), local muscle fatigue, and joint stress and ways to modify exercises and activities to remain active within safe levels.
- Emphasize the importance of daily ROM, endurance activities, and joint protection, including avoidance of faulty foot and ankle postures and protection of the feet from deforming, weight-bearing forces and trauma imposed by improperly fitting footwear.
- If necessary, instruct the patient in safe use of assistive devices to decrease the effects of weight bearing and pain.

Decrease Pain

In addition to physician-prescribed medication, intra-articular injections of corticosteroids or nonsteroidal anti-inflammatory medications, and therapeutic use of modalities the following are used to manage painful symptoms.

- ***Manual therapy techniques.*** Gentle grade I or II distraction and oscillation techniques may inhibit pain and move synovial fluid for nutrition within the involved joints.
- ***Orthotic devices.*** Orthotic shoe inserts and well-constructed shoes help protect the joints by providing support and realigning forces.[60,77,86,110] Such support has been shown to decrease pain and improve functional mobility. Splinting or bracing may also be used to stabilize an arthritic joint.

FOCUS ON EVIDENCE

Kavlak and colleagues[60] reported the effects of prescribed orthotic devices in 18 patients with RA (no control group) and a variety of bilateral foot deformities, including pes planus, hallux valgus, hammer toe, subluxation of the metatarsal heads, and others. All patients in the study were community walkers with no history of foot or ankle surgery. All patients were prescribed custom-made orthotic inserts and shoe modifications, such as a medial longitudinal arch support, metatarsal pad, or heel and forefoot wedge, to meet their individual needs. Pain, temporal-distance characteristics of gait, and energy expenditure during walking were measured before and after the patients had been wearing the custom orthoses for 3 months. There was a significant reduction in pain and energy cost during ambulation and increases in step and stride length after use of the orthotic devices for 3 months. There were no significant changes in foot angle or the width of the base of support. The authors concluded that appropriately prescribed orthoses and shoe modifications were important elements of nonoperative treatment of foot pain and impaired gait in patients with RA.

Maintain Joint and Soft Tissue Mobility and Muscle Integrity

- ***Passive, active-assistive, or active ROM.*** It is important to move the joints as tolerated. If active exercises are tolerated, the benefits of the muscle action make them preferable.
- ***Aquatic therapy.*** Aquatic therapy is an effective method of combining nonstressful buoyancy-assisted exercises with therapeutic heat.
- ***Muscle setting.*** Apply gentle, multiangle, muscle-setting techniques in pain-free positions at an intensity that does not exacerbate symptoms.

Joint Hypomobility: Management—Controlled Motion and Return to Function Phases

Examine the patient for signs of decreased muscle flexibility, joint restrictions, muscle weakness, and balance impairments. Initiate exercises and mobilization procedures at a level appropriate for the condition of the patient.

PRECAUTIONS WITH RA: Modify the intensity of joint mobilization and stretching techniques used to counter any restrictions, because the disease process and use of steroid therapy weaken the tensile quality of the connective tissue. Therefore, it is more easily torn. It may be necessary to continue joint protection with orthotics, proper fitting shoes, and assistive devices for ambulation.[124] Encourage the patient to be active, but also to be aware of pain and fatigue.

Increase Joint Play and Accessory Motions

Joint mobilization techniques. Determine which articulations are restricted owing to decreased joint play, and apply grade III sustained or grade III and IV oscillation techniques to stretch the limitations. See Figures 5.55 through 5.64 and their descriptions in Chapter 5 for techniques to mobilize the leg, ankle, and foot articulations. Mobilizing the toes is the same as the fingers (see Figs. 5.42 through 5.43).

Because weight-bearing forces and joint changes with arthritis accentuate pronation, mobilizing to increase pronation usually should not be undertaken in an arthritic foot. Perform these techniques only in the stiff foot after immobilization when the foot does not pronate sufficiently during the loading response in gait.

CLINICAL TIP

Extension of the toes at the MTP joints is important during terminal stance for normal push-off and development of the windlass effect in gait. The great toe requires from 40° to 50° extension to function effectively during this phase of gait.[105,107]

Improve Joint Tracking of the Talocrural Joint

Apply mobilization with movement (MWM) techniques to increase ROM and/or decrease pain associated with movement.[97] The principles of MWM are described in Chapter 5.

MWM: Plantarflexion

Patient position and procedure: Supine with hip and knee flexed and heel on the table (Fig. 22.3). Stand at the foot of the table facing the patient and contact the patient's anterior tibia with the palm of your hand (for the right foot use the left hand). Produce a pain-free graded posterior glide of the tibia on the talus. The patient should now be unable to

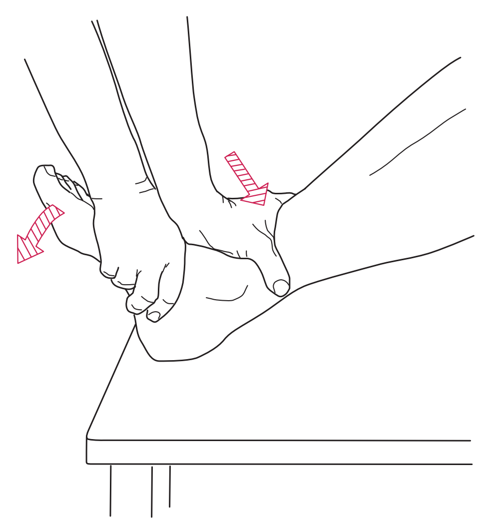

FIGURE 22.3 Mobilization with movement (MWM) to increase ankle plantarflexion. Maintain a posterior glide of the tibia while moving the talus into plantarflexion. This should not cause pain.

plantarflex. While maintaining the posterior tibial glide grip the talus with your other hand (for the right foot, use the right hand) and create a passive end-range plantarflexion movement, causing the talus to roll anteriorly.

The sustained plantarflexion must be painless. Repeat three to four times in sets of 6 to 10 and reassess to confirm improved range.

MWM: Dorsiflexion

Patient position and procedure: Standing with the affected foot placed on a chair or stool (Fig. 22.4). Kneel on the floor facing the patient with a mobilization belt around your buttocks and the patient's Achilles tendon (padded with a towel). Place the web space of both hands around the neck of the talus with the palms on the dorsum of the foot. Hold the foot down and back and the subtalar joint in neutral pronation/supination. Use the belt to produce a pain-free graded anterior gliding force to the ankle joint. While maintaining this mobilization, have the patient lunge forward, bringing the affected ankle into dorsiflexion and causing painless end-range loading. Repeat in sets of six to ten, reassessing for effect.

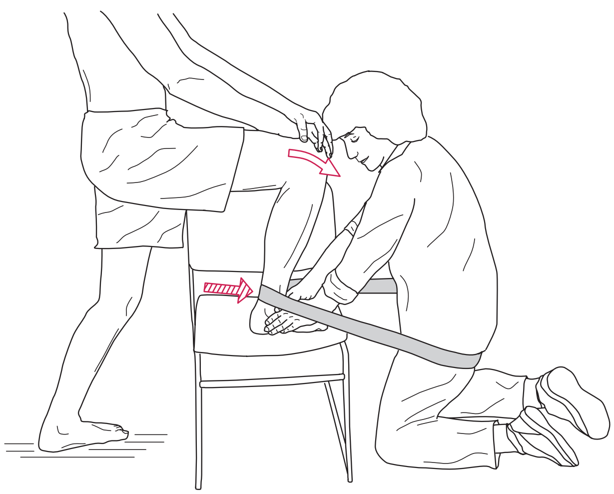

FIGURE 22.4 MWM to increase ankle dorsiflexion. Maintain an anterior glide of the tibia with the mobilization belt while the patient lunges forward to move the ankle into dorsiflexion. This should not cause pain.

Increase Mobility of Soft Tissues and Muscles

Perform stretching techniques as described in Chapter 4. Self-stretching techniques are described later in this chapter.

Regain Balance in Muscle Strength and Prepare for Functional Activities

Initiate resistive exercises at a level appropriate for the weakened muscles. Begin with isometric resistance in pain-free positions, and progress to dynamic resistance exercises through pain-free ranges using open- and closed-chain exercises. Resistive exercises are described later in this chapter.

CLINICAL TIP

Use a pool or tank to reduce stress on the foot and ankle joints for low-load, weight-bearing exercises; ambulatory activities; and for low-impact aerobic exercises.

Improve Balance and Proprioception

Initiate protected balance exercises, and progress the intensity as tolerated. Determine the level of stability and safety during ambulation and continue use of assistive devices if necessary to help prevent falls.

Develop Cardiopulmonary Fitness

Low-impact aerobic exercises should be initiated early in the treatment program and progressed as the patient is able. Water aerobics, swimming, treadmill walking, and bicycling may be within the patient's tolerance. A person with degenerative or rheumatoid arthritis should not do high-impact (jumping, hopping, and jogging) aerobic exercises.

Joint Surgery and Postoperative Management

Advanced arthritis of the ankle or the joints of the foot can cause severe pain, limitation of motion, gross instability or deformity, and significant loss of function during activities that require weight bearing through the lower extremities (Fig. 22.5). When nonoperative management no longer alleviates symptoms, surgical options for early and advanced joint disease may be necessary (Box 22.3).* The procedure(s) selected depends on the joints involved, the extent of articular damage, the severity of joint instability or deformity, and the postoperative functional goals of the patient.

Arthroscopic repair of small osteochondral lesions, débridement of a symptomatic joint, and distraction arthroplasty are used for management of early joint changes but offer little if there is significant destruction of articular cartilage.[27,83,139,145] For late-stage arthritis, arthrodesis provides pain-free weight bearing and stability of the involved joint(s) but sacrifices mobility of the operated joints, which in turn, affects functional movement. Pain-free compensatory movements must be available in adjacent joints to absorb weight-bearing forces during ambulation. Arthrodesis typically is performed in young patients with high functional demands.[17,47,62,83,139] Replacement arthroplasty of the ankle[37,48,66–68,115,116] or toes,[9,141] an option less frequently selected than arthrodesis, affords pain relief while retaining some degree of ankle mobility.

The anticipated benefits of the various types of joint surgery for the ankle and foot and postoperative rehabilitation are: (1) relief of pain with weight bearing and joint motion,

*9,27,37,66,83,115,139,141,145

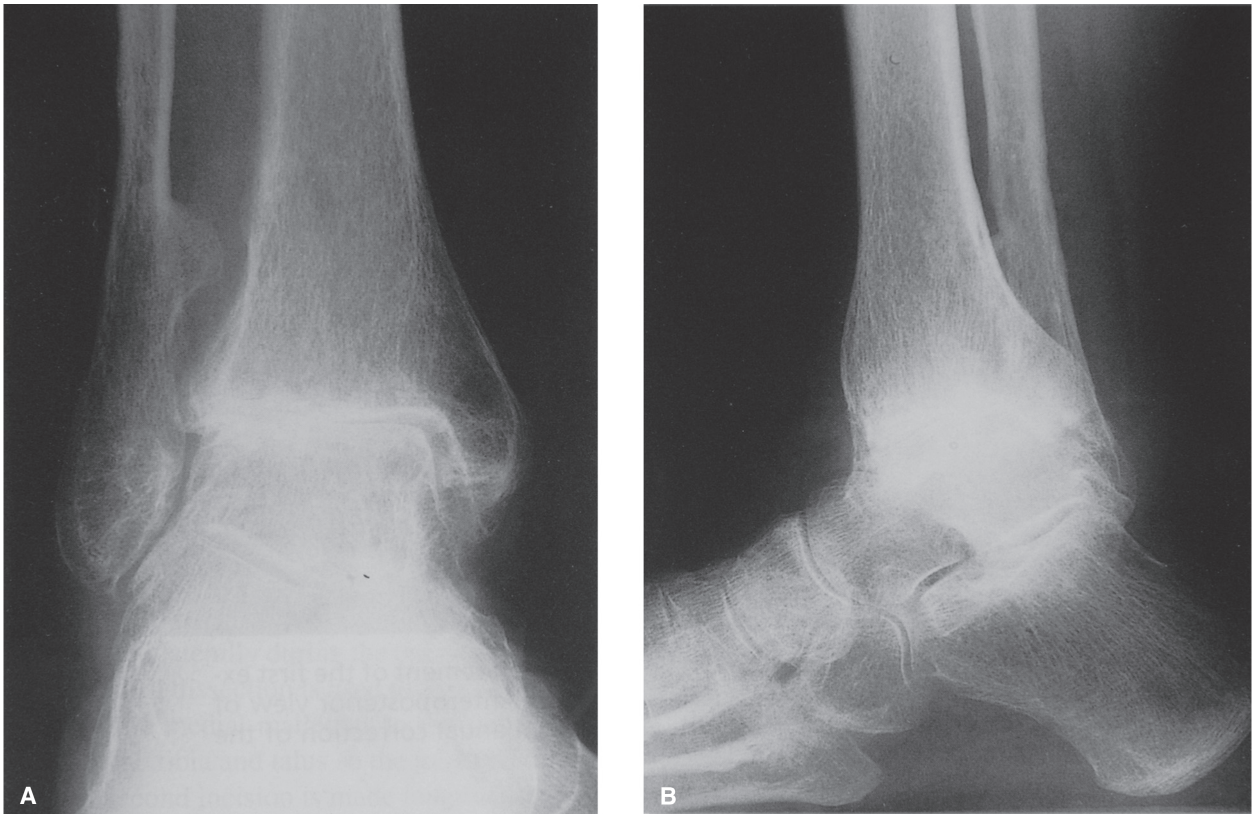

FIGURE 22.5 Late-stage arthritis of the ankle. **(A)** Mortise view of the ankle shows severe loss of the normal joint space and partial erosion of the lateral tibia. **(B)** Lateral view shows tibial erosion with mild joint space loss in the subtalar region and significant osteophyte formation in the anterior ankle. *(From Hasselman, CT, Wong, YS, and Conti, SF: Total ankle replacement. In Kitaoka, HB (ed): Master Techniques in Orthopedic Surgery: The Foot and Ankle, ed 2. Philadelphia, Lippincott Williams & Wilkins, 2002, Fig. 39.1, p 583, with permission.)*

BOX 22.3 Surgical Interventions for Early- and Late-Stage Ankle or Foot Arthritis and Joint Deformity

Early-Stage Procedures
- Arthroscopic débridement and cheilectomy (removal of osteophytes)
- Arthroscopic subchondral drilling, mosaicplasty, or osteochondral autologous implantation for small osteochondral lesions of the talus
- Articular distraction (widening of the joint space by means of a temporarily inserted external fixation device)
- Soft tissue reconstruction
- Synovectomy

Late-Stage Procedures
- Osteotomy
- Excision arthroplasty with or without implant
- Total joint arthroplasty
- Arthrodesis

(2) correction of deformity, (3) restoration of stability or mobility of the involved joints, and (4) improved strength and muscular endurance of the lower extremities for ambulation and functional activities.[9,20,37,66,83,139,141] Rehabilitation includes postoperative exercise; gait training with assistive devices; fabrication of foot orthoses; and patient education including information about shoe selection, fit, and modification and appropriate choices of recreational activities and activities of daily living (ADLs).

Total Ankle Arthroplasty

Total ankle arthroplasty (TAA) is an option for carefully selected patients who have disabling pain associated with advanced, symptomatic arthritis of the talocrural joint whose only surgical alternative is ankle arthrodesis. TAA provides pain relief while preserving functional motion of the ankle and therefore, reduces stresses on adjacent joints more effectively than arthrodesis. In the past, TAA was reserved for relatively sedentary individuals or those who do not expect to participate in moderate- to high-impact recreational activities or heavy labor after surgery.[44,66,116,139] Although the "ideal" candidate for TAA continues to be the older (> 65 years), thinner individual with minimal foot or ankle deformity and a low-demand lifestyle,[37] TAA is now being extended to younger, more active individuals (typically those with posttraumatic arthritis), who wish to continue to participate in moderately demanding activities. Improvements in implant design, instrumentation for implant alignment, and the use of cementless (bio-ingrowth) fixation are responsible for the broadening of selection criteria for TAA.[37,47,48,115]

Indications for Surgery

Although no consensus exists at this time, the following are frequently cited current-day indications for total ankle replacement.[37,44,47,54,66, 115,116,139]

- Severe, persistent pain, particularly during weight bearing, and compromised functional mobility as the result of advanced degenerative or inflammatory joint disease, including posttraumatic arthritis; primary OA, RA, or JRA; or avascular necrosis of the dome of the talus
- Sufficient integrity of ligaments for ankle stability
- A flexible deformity that can be passively corrected to neutral or no more than 5° of hindfoot valgus
- Appropriate procedure for a patient with low to moderate physical demands
- An option when both ankles are involved and bilateral ankle fusions are impractical and would dramatically compromise functional mobility, such as ascending or descending stairs or rising from a chair
- Persistent pain during weight bearing and long-term, unsatisfactory functional results following ankle arthrodesis

Contraindications

There are a number of absolute and relative contraindications to current-day TAA.[37,44,116] Absolute contraindications include active or chronic infection of the ankle, severe osteoporosis, avascular necrosis of a significant portion of the body of the talus, peripheral neuropathy leading to decreased sensation or paralysis, impaired lower extremity vascular supply, and long-term use of corticosteroids. As with replacement of other joints, TAA is contraindicated for the individual who has not yet reached skeletal maturity.

Relative contraindications include a remote history of infection, presence of marked ankle instability, a varus or valgus deformity of the hindfoot greater than 20°, less than a 20° total arc of dorsi- and plantarflexion, obesity, and the need to return to high-demand, high-impact physical activities.

Procedure

Implant Design, Materials, and Fixation

Introduced in the 1970s, the first total ankle replacement designs were two-component, metal-to-polyethylene implants, requiring significant bone resection and held in place with cement fixation.[37] Although quite variable, short-term results of these "first generation" implants seemed to hold promise. The early designs, however, proved to have limited durability, because many had highly constrained tibial and talar components and did not replicate the complex biomechanical characteristics of the ankle's articulating surfaces.[37] Functional ROM of the ankle also was difficult to achieve with the more constrained designs. Other early designs were totally unconstrained, allowing multiplanar movements but providing no ankle stability. Consequently, a high rate of complications occurred, such as loosening at the bone-cement interface and premature component wear with the constrained implants, and ankle dislocation with the unconstrained designs, leading to unsatisfactory long-term results.[37,44,66,116]

Since the early designs, changes in prosthetic design, based on a more thorough understanding of the biomechanics of the ankle and foot, have led to refinement of two-component, fixed-bearing designs and development of three-component, mobile-bearing designs, which incorporate sliding and rotational motions into the implant systems. Because contemporary prosthetic designs more closely mimic the characteristics of a normal ankle joint, ROM available in several of these systems now approaches that of a normal ankle.[142] Advances in design and the availability of new implant materials combined with improved surgical techniques, such as better soft tissue balancing and ligament reconstruction, have led to current-day TAA (Fig. 22.6). These newer implant designs are minimally constrained or semiconstrained and completely resurface the tibial, fibular, and talar articulating surfaces. Contemporary TAA also requires far less resection of bone than early replacements and typically employs cementless (bio-ingrowth) fixation.[3,7,37,44,47,48,67,116,121] A hydroxyapatite coating on the outer surfaces of the metal implants is used to increase the rate of bone ingrowth.[123] However, cement fixation continues to be used for patients with poor bone stock.[69]

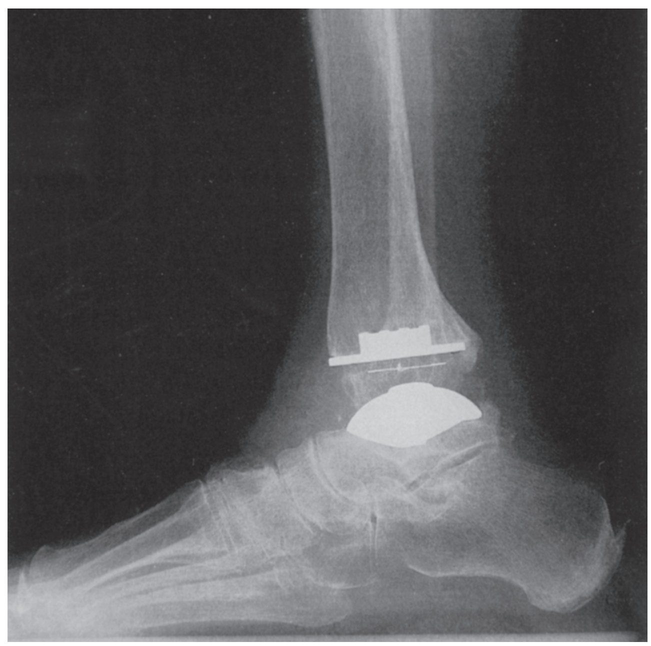

FIGURE 22.6 Total ankle arthroplasty. Lateral view of a total ankle replacement in a 78-year-old woman, one year after surgery for post-traumatic arthritis. *(From Kitaoka, HB, and Claridge, RJ: Ankle replacement arthroplasty. In Morrey, BF (ed): Joint Replacement Arthroplasty, ed. 3, p. 1148, 2003, with permission from The Mayo Clinic Foundation.)*

With a two-component, fixed bearing system, a porous or beaded metal-backed, high-density polyethylene tibial surface articulates with a metal talar component that also has a beaded outer surface.[67,83,121] A three-component, mobile-bearing design, sometimes referred to as a meniscal-bearing design, employs a flat (table-top) tibial component made of metal and a metal talar dome distally with a mobile, polyethylene bearing

interposed between the two metal components.[3,7,37,47,48] All of these contemporary designs allow at least 5° to 10° of dorsiflexion and 20° to 25° of plantarflexion, sufficient for functional activities, and a small degree of rotation of the foot on the tibia to reduce stresses on the implants.

Operative Overview

Although there are numerous variations of operative techniques involved in a TAA, the following represent key components.[3,7,44,47,66,123] An anterior longitudinal incision between the tibialis anterior and extensor hallucis longus tendons is the most widely used approach. The extensor retinaculum and capsule are incised to expose the joint. The joint is débrided and osteophytes are removed. An external distraction device is used to separate the joint surfaces and facilitate bone resection. Small portions of the distal tibia and talar dome are excised, followed by preparation of the joint surfaces. In some cases, the medial and lateral malleolar recesses also are resurfaced. Trial implants are inserted to evaluate their alignment and the range of dorsiflexion available. If there is less than 5° of dorsiflexion because of a contracture of the gastrocnemius-soleus muscle group, a percutaneous lengthening of the Achilles tendon is performed.

Sometimes a second incision is made along the distal fibula for fusion of the tibiofibular syndesmosis with screw fixation to provide a larger surface for fixation of the tibial prosthesis.[37,66,67] If there is a significant varus or valgus hindfoot deformity, a subtalar arthrodesis may also be performed.[47,123] After the permanent implants are inserted, soft tissues are balanced and repaired. Ligament reconstruction may be necessary if there is inadequate stability of the ankle and hindfoot. After the wound is closed, a bulky compression dressing and well-padded, short-leg cast or posterior splint are placed on the foot and ankle to control joint swelling and peripheral edema.

BOX 22.4 Complications of Total Ankle Arthroplasty

Intraoperative Complications

- Fracture of the medial or lateral malleolus during implant insertion → the necessity for fracture stabilization with internal fixation and a longer period of ankle immobilization and restricted weight bearing
- Malpositioning of an implant → chronic ankle instability, subluxation, dislocation, early mechanical loosening, or premature implant wear
- Laceration of the posterior tibialis or flexor hallucis longus tendon during bone resection due to their proximity to the medial malleolus → necessity for tendon repair
- Nerve injury, usually the superficial or deep peroneal → impaired sensory or motor function
- Insufficient soft tissue balancing or reconstruction → chronic ankle instability or deformity

Postoperative: Early and Long-Term Complications

- Delayed wound healing → an extended period of restricted ankle motion
- Delayed union or nonunion of a tibiofibular syndesmosis fusion → an extended immobilization and restricted weight-bearing period
- Tarsal tunnel syndrome or complex regional pain syndrome
- Component migration or impaction → malalignment and premature component wear
- Mechanical (aseptic) loosening (most often the talar component) → pain and impaired functional mobility
- Hindfoot arthritis (most often the subtalar joint) → pain and impaired weight-bearing abilities.
- Heterotopic bone formation → restricted motion

Complications

The incidence of complications after contemporary ankle replacements appears to be lower than after the early implant designs and surgical techniques. Only a limited number of long-term follow-up studies have been reported, and the full picture is not yet available. In addition, whether current-day TAA will prove to be as successful as total hip or knee arthroplasty remains unclear.[65] When complications following TAA versus ankle arthrodesis are compared, the overall rate of complications is higher with TAA than with arthrodesis.[115]

As with all types of joint arthroplasty, postoperative infection is a potential complication. Postoperative edema in the ankle and foot also increases the risk of delayed wound healing, which in turn, often prolongs the immobilization period, delaying early ankle motion and potentially leading to poor ROM outcomes.[44,65,99] Tarsal tunnel syndrome or complex regional pain syndrome occasionally develop and causes chronic foot or ankle pain.[7] (Complex regional pain syndromes and interventions are described in Chapter 13.) A summary of intraoperative, early postoperative, and long-term complications unique to TAA is noted in Box 22.4.[3,7,37,44,47,65,99,115] Any of these complications can adversely affect the progression of rehabilitation and short-term and long-term outcomes of ankle replacement. Persistent or severe complications may necessitate revision arthroplasty or ankle arthrodesis.

Postoperative Management

There are few guidelines in the literature for postoperative management of patients who have undergone TAA. Those that are available vary considerably with regard to the duration of immobilization, weight-bearing restrictions, and the initiation and progression of exercise. There is a lack of evidence to support whether ROM exercises should be initiated a few days postoperatively or delayed several weeks until there is evidence of bone ingrowth into the implants. It also is unclear whether early protected motion has a positive impact on ROM outcomes or if it is detrimental to implant fixation or wound healing.[116]

Therefore, the guidelines and precautions in the following sections for postoperative management are a summary of those cited by several authors based on their experience and training.[3,7,20,44,47,83,99,115,116]

Immobilization and Weight-Bearing Considerations

Immobilization. The ankle is placed in a compression dressing and immobilized in a neutral position in a well-padded, short-leg cast or posterior splint, which is later replaced with a short-leg walking cast, a removable splint, or ankle-foot orthosis. The duration of continuous immobilization and initiation of ROM exercises vary depending on the type of implant fixation used, the types of concomitant surgical procedures performed during the arthroplasty and the surgeon's recommendations. For example, if a tibiofibular syndesmosis or subtalar fusion was performed, no motion is allowed for 6 weeks or until there is evidence of boney union.[66,67] If a soft tissue procedure, such as an Achilles tendon lengthening or ligament repair, was required, the period of immobilization may be extended. If there was no boney fusion or soft tissue repair, as little as 2 to 3 weeks or as many as 6 weeks of immobilization after cementless fixation is recommended.[3,83,115,116]

Weight-bearing considerations. A patient must always wear an ankle immobilizer when initiating weight bearing after TAA. Recommendations for the initiation and extent of weight bearing after cementless fixation range from minimal weight bearing to weight bearing as tolerated immediately—or by 2 weeks—after surgery[3,7,44,47] to nonweight-bearing for 3 weeks to 6 weeks.[83,115,116] If a tibiofibular syndesmosis or hindfoot fusion was performed or a malleolar fracture requiring stabilization occurred during surgery, weight bearing is not permitted for at least 6 weeks.[66,67] After a period of restricted weight bearing, a patient gradually progresses to full weight bearing over several weeks while still wearing the immobilizer. This is followed by a gradual return to weight bearing without the immobilizer after 6 weeks.[47,83]

Exercise: Maximum Protection Phase

The first phase of postoperative rehabilitation, which extends for about 6 weeks, focuses on the patient becoming functionally mobile immediately after surgery with attention to protecting the operated ankle and controlling postoperative edema. During this phase, beginning ROM exercises of the operated ankle may be permissible.

Goal and interventions. In addition to elevating the operated foot and ankle for edema control, maintaining mobility proximal to the operated ankle or other arthritic joints, and improving strength of the upper extremities and nonoperated lower extremity, goals and interventions include the following.[3,20,83,116]

- ***Re-establish independent ambulation and functional mobility.***
  - Gait training with assistive devices and transfers, adhering to weight-bearing restrictions.
- ***Minimize atrophy of the ankle and foot muscles of the operated limb.***
  - Low-intensity, isometric (muscle-setting) exercises of the ankle musculature while in the immobilizer.
- ***Prevent stiffness of the operated ankle and foot and loss of extensibility of surrounding soft tissues and regain ROM.***
  - Active ROM of the toes.
  - Gentle, active ROM exercises if removal of the immobilization is allowed and wound healing is sufficient. Initially, include ankle dorsiflexion and plantarflexion, but postpone active inversion, eversion, and circumduction until after 6 weeks.

NOTE: ROM of the operated ankle may be permitted as early as 4 weeks after surgery but often is postponed until after postoperative week 6.

Exercise: Moderate and Minimum Protection Phases

Except in cases of poor soft tissue healing or delayed bone ingrowth, use of the immobilizer is gradually discontinued and weight-bearing restrictions are removed about 6 weeks after surgery. During the intermediate and advanced phases of postoperative rehabilitation after TAA, which may last as long as 6 months, emphasis is placed on increasing the range of ankle dorsiflexion and strength of the ankle plantarflexors.[83] Improving standing balance and ankle proprioception also are important for a gradual return to functional activities.

CLINICAL TIP

The level of physical activity possible after TAA depends on many factors, including the type of arthritis (DJD versus RA), other joint involvement, the patient's overall health status, and his or her goals for recovery.

Goals and interventions. During the final phases of rehabilitation, the goals and interventions include[116]:

- ***Achieve 100% of the ROM obtained intraoperatively.***
  - Active, pain-free ROM exercises first in nonweight-bearing and then in weight-bearing positions. Include dorsiflexion/plantarflexion, inversion/eversion, and circumduction.
  - Stretching of the gastrocnemius-soleus muscle group if dorsiflexion is limited. Begin with a towel stretch in a long-sitting position; progress to standing on a wedge for an extended period of time.
- ***Restore strength, muscular endurance, and balance in the lower extremities for functional activities.***
  - Low-intensity, high-repetition, open-chain, resisted exercises against elastic resistance and closed-chain exercises, such as squats, lunges, and heel raises.
  - A progression of bilateral and unilateral balance activities on stable and unstable surfaces. (Refer to Chapters 8 and 23 for examples.)
- ***Improve aerobic capacity and cardiopulmonary endurance.***
  - Swimming, stationary cycling, treadmill walking.

CLINICAL TIP

The amount of ankle dorsiflexion required while pedaling a bicycle can be adjusted by raising or lowering the seat height. A lower seat height requires greater dorsiflexion.

- ***Resume a safe level of work-related and recreational activities.***
  - Integration of strength and balance training into simulated functional activities.
  - Activity modification for joint protection and patient education to help the patient return to safe and appropriate activities.

PRECAUTIONS: Plyometric training and other activities that involve high-impact and quick stop-and-go motions are not appropriate after TAA.[143]

Return to fitness and sports activities. With advances in TAA design and surgical techniques and increasing knowledge of long-term outcomes and the eventual need for revision arthroplasty, it is now possible for selected patients—typically younger patients (< 50 to 60 years of age) who were physically active prior to surgery and underwent unilateral TAA for posttraumatic arthritis—to return to low-demand (and some moderately demanding) athletic and fitness activities.[143] Unlike the consensus documents describing activities that are and are not recommended by surgeons following total hip and knee replacement (see Table 20.5 and Box 21.5), a consensus of recommendations has not yet been published for physical activity after TAA. Typically, low-impact activities, such as swimming, cycling, and walking, are advocated to reduce the risk of ankle dislocation and implant loosening or wear. Participation in such activities is advisable only after completion of an individualized rehabilitation program and if the patient is free of complications.[100,143] Results of two studies of patient-reported sports and fitness activities after TAA are summarized in the following section on outcomes.

Outcomes

As discussed previously, although early total ankle arthroplasty afforded pain relief for a period of time,[37] there were unacceptably high rates of complications, leading to poor functional outcomes and patient dissatisfaction.[37,66,115,116] Now that intermediate results of second and third generation implant systems and refined surgical techniques combined with more judiciously selected surgical candidates are becoming available, contemporary TAA is encouraging. Long-term success, however, is still in question.[3,37,44,66,115,116] It is important to note that there have been no studies to date that have compared rehabilitation conditions, such as early versus delayed weight-bearing or ROM exercises following TAA.

Measurements of pain, ROM, general level of function, patient satisfaction, and postoperative complications are outcomes most often reported in follow-up studies. A variety of quantitative assessment instruments are used to measure pain relief, postoperative function, and patient satisfaction. Descriptors of outcomes, from "excellent" to "poor," are based on data from these scales. Two examples of assessment instruments are the Ankle Osteoarthritis Scale and the American Orthopedic Foot and Ankle Society Questionnaire.

Pain relief, functional improvement, and patient satisfaction in different populations. Evidence from prospective studies suggests the survival rates of implants are similar for patients with OA (primary or posttraumatic arthritis) and RA at a median follow-up of 14 years[69] and for patients older or younger than 50 years of age, at a median follow-up of 6 years.[67] Survival rates (the percentage of prostheses not requiring removal) in the former study were 72.7% and 75.5% respectively in the patients with OA and RA and in the latter study were 75% and 80.6% respectively in the younger and older patients.

Bai and colleagues[3] conducted a prospective study to compare outcomes following mobile-bearing ankle replacement in patients with posttraumatic arthritis versus primary OA. At a mean follow-up of 38 months, no significant differences between groups were found in ankle ROM, radiographic findings, and an ankle-hindfoot assessment scale. Survival rates of the implants were comparable between the posttraumatic and primary OA groups (97% and 100% respectively) at the conclusion of the study. However, the rate of complications was significantly higher (38% versus 27%) in the group of patients with posttraumatic arthritis compared with the primary OA group.

Outcomes for a frequently used second generation, two-component system and more recently developed third generation, three-component (mobile-bearing) designs have been reported but not directly compared. Knecht[67] reported positive outcomes (reduced pain and increased function) in 66 patients who had undergone a two-component ankle replacement a mean of 9 years earlier. The mean total arc of dorsi- and plantarflexion measured in 33 patients was 18°.

Buechel and colleagues[7] followed 50 patients (mean age 49 years), who had received a mobile-bearing replacement with cementless fixation. They reported 48% excellent and 40% good results at a mean follow-up of 5 years (range 2 to 10 years). Of the 50 patients who participated in the study, 26% reported no pain after TAA; 60% reported slight or mild pain; and 14% reported moderate or severe pain that interfered with functional activities. The mean total arc of dorsi- and plantarflexion was 28°. In a short-term follow-up study of 116 patients who had a different mobile-bearing prosthesis implanted in 122 ankles, 84% of patients were satisfied, with 82% reporting good or excellent results at an average of 19.9 months.[48] The mean total arc of ankle dorsi- and plantarflexion was 39°. Although postoperative gains in ROM reported in these studies were small (often as little as 5° to 10°), gains of even a few degrees have been reported to improve functional mobility.[116]

Participation in physical activities. Although most outcome studies of TAA focus on prosthetic survival rates and

changes in clinical measurements, the ability to return to a physically active lifestyle is also of interest. Valderrabano and co-investigators[143] studied147 patients (mean age 59.6 years, range 28 to 86 years) who participated in sports and recreational activities before and after TAA. Of these patients, 89% had a preoperative diagnosis of posttraumatic arthritis or primary OA, and only 11% had a diagnosis of RA. A combined total of 83% of all patients in the study reported excellent or good results and 69% were pain-free postoperatively. Just prior to surgery, 36% of patients were active in sports/recreational activities, and 56% were active at a mean of 2.8 years after surgery. This change reflected an increase in the activity level of the patients with posttraumatic arthritis and primary OA, not of the patients with RA. The most frequently reported preoperative activities (in descending order) were cycling, swimming, hiking, and low-impact aerobics. After surgery, hiking was most frequently reported followed by cycling, swimming, and aerobics. The only significant change in activity before and after surgery was an increase in hiking (partipation spiked from 25.5% to 52.8%). The authors recommended that before initiating any sport activity after ankle replacement, a patient should complete postoperative rehabilitation and be free of complications.

In a subsequent investigation, Naal and colleagues[100] reported the results of a study comparing the preoperative and postoperative activity levels of 101 patients who had undergone ankle replacement. The diagnoses of the study participants were posttraumatic arthritis (46.5 %), primary OA (34.7%), and RA (18.8%). One year prior to surgery, 62.4% were active in sports and fitness activities, whereas 66.3% were active at an average of 3.7 years after surgery. The types of activities and the frequency of participation before and after surgery were essentially unchanged. However, 65% of those surveyed indicated that performance during their preferred activities had improved. Swimming, cycling, and weight training for fitness were the most frequently performed activities before and after surgery. Although some patients participated in high-impact sports, such as jogging, soccer, and tennis, before surgery, few or none participated in these activities at follow-up, perhaps because of postoperative patient education. Interestingly, sports participation after TAA decreased in the group of patients with posttraumatic arthritis. Consequently, of the three groups, these patients were least satisfied with their postoperative ability to participate in sports.

It is important to note that the long-term impact of sports participation following TAA has yet to be determined.

Arthrodesis of the Ankle and Foot

Arthrodesis (fusion) is the most frequently used surgery for late-stage arthritis of the ankle or one or more of the joints of the foot and toes. It typically is the procedure of choice for relatively young, active patients with posttraumatic arthritis and gross instability of the ankle and hindfoot.[125,139] Arthrodesis also is an option for patients with hindfoot or forefoot involvement as the result of RA or JRA.[9,20] Deformities of the forefoot, such as hallux valgus or hallux rigidus, and severe deterioration of the MTP joint of the first toe also are managed with arthrodesis.[1,9,20,23]

Indications for Surgery

The following are frequently cited indications for surgical fusion of selected joints of the ankle and foot.[1,9,20,37,62,125,139]

- Debilitating pain, particularly during weight bearing, and severe articular degeneration secondary to posttraumatic arthritis, primary OA, RA, infection, or other inflammatory arthropathies
- Marked instability of one or more joints
- Deformity of the toes, foot, or ankle associated with chronic joint malalignment as the result of congenital anomalies, neuromuscular disorders, or arthritis
- Patients with high functional demands and pain-free compensatory movements in adjacent joints
- A salvage procedure after failed TAA when revision arthroplasty is not an option

NOTE: For patients with RA or primary OA of both ankles, bilateral arthrodesis is rarely performed, because loss of dorsiflexion bilaterally makes it difficult to get up from a chair or ascend or descend stairs.

Procedures

There are many types of arthrodesis; however, all involve the use of bone grafts coupled with internal fixation devices (see Fig. 12.2) or occasionally external skeletal fixation for boney ankylosis. Internal fixation can be achieved via multiple compression screws, pins, an intramedullary nail, or a plate. The type of fixation selected depends on the joint(s) to be fused and the types of deformity. For correction of severe deformity or tendon rupture, concomitant soft tissue procedures are required.

Arthrodesis of the ankle or foot almost always is performed through an open approach. Over the past decade, however, arthroscopic or arthroscopically assisted arthrodesis of the ankle has become an option for select patients with severe pain at the tibiotalar joint but without significant fixed deformity.[10,104,106,122,131] Specifically, an arthroscopic approach cannot be used if a varus or valgus deformity is greater than 5° to 10°.[131] The most consistently suggested benefit of an arthroscopic approach is a reduced rate of wound healing complications because of less disruption of soft tissues during surgery.[122,139]

There have been reports of a more rapid rate of fusion with an arthroscopic approach compared to an open approach. However, this potential benefit is based largely on data from nonrandomized, retrospective studies and therefore, cannot be substantiated.[104,106,131,139]

Common Types of Arthrodesis

Arthrodesis of the ankle. When the tibiotalar joint is fused, it is positioned in 0° of dorsiflexion, 5° of hindfoot valgus, and 5° to 10° of external rotation of the foot on the tibia to match

the rotation of the opposite lower extremity.[17,62,115,125,139] Although ankle arthrodesis provides pain relief and ankle stability, dorsiflexion and plantarflexion are lost, thus altering the biomechanics and speed of gait and increasing energy expenditure during ambulation.[139] The hindfoot and forefoot compensate to a great extent for the loss of motion at the ankle. Despite this, an asymmetrical gait pattern is detectable in most patients after ankle arthrodesis.[17]

FOCUS ON EVIDENCE

When the gait of 27 patients, who had undergone tibiotalar arthrodesis at a mean duration of 44 months, was analyzed and compared with the gait of 27 age-matched normal individuals, investigators found significant differences between groups. Cadence and stride length were significantly decreased in the arthrodesis group as were motions of the hindfoot and midfoot during the swing and stance phases of gait. In addition, radiographic evaluation demonstrated evidence of severe hindfoot arthritis in 15% of the arthrodesis group.[138]

Arthrodesis of the hindfoot. Severe instability or chronic malalignment and deformity of the hindfoot, such as pes valgus or pes planus, and pain as the result of advanced hindfoot arthritis may require a triple arthrodesis or a single-joint fusion, such as talonavicular or talocalcaneal (subtalar) arthrodesis. A triple arthrodesis—often indicated for a rigid hindfoot deformity—involves fusion of the talocalcaneal, talonavicular, and calcaneocuboid joints.[91] A single-joint fusion, such as a talonavicular arthrodesis, may be sufficient to correct a chronic but flexible hindfoot deformity.[30,64,117] In most instances, the hindfoot is positioned in 5° of valgus in each of these fusions.

Talonavicular, subtalar, or triple arthrodesis provides permanent medial-lateral stability and relief of pain in the hindfoot, but pronation and supination of the ankle are eliminated or substantially diminished. It is interesting to note that fusion of the talonavicular joint alone indirectly reduces motion at the subtalar and calcaneocuboid joints, providing added frontal plane stability without fusing additional joints.[30,117]

Arthrodesis of the first toe. Fusion of the first MTP joint for hallux rigidus and hallux valgus provides relief of pain, most notably during ambulation.[1,23,54] The position of fusion is neutral rotation, 10° to 15° of valgus, and 15° to 30° of MTP extension. This allows adequate push-off during ambulation but also enables a patient to wear some types of commercially available shoes.[20,23,54] If the lateral MTP joints also are involved, fusion of the great toe is performed after—not before—excision or implant arthroplasty of the lateral joints.[9,20,141]

Arthrodesis of the IP joints of the toes. Fusion of the IP joints of the toes in a neutral position for hammer toes, which usually occur in the second and third toes, provides relief of pain for ambulation and correction of deformities of the toes to improve shoe fit.[54]

Complications

The overall rate of complications associated with arthrodesis is relatively low but varies with patient population, the joints involved, and surgical techniques.[139] The most common complication is nonunion, occurring in up to 10% of arthrodesis procedures and typically requiring revision arthroplasty.[38,117,139]

The smaller the area of the boney surfaces and the poorer their vascular supply, the higher the rate of nonunion. Factors that contribute to nonunion include postoperative infection, malalignment of the fused joint, and a patient's use of tobacco before and after surgery.[64,91] Delayed wound healing is a particular problem in patients with poor vascularity of the foot and ankle. Furthermore, nerve damage can occur during surgery, or a neuroma can develop postoperatively, causing pain and limiting function. Occasionally, a postoperative stress fracture of one of the fused bones or adjacent bones occurs.

Postoperative Management

Immobilization. The method and duration of immobilization of the fused joint(s) are determined by the surgeon and are based on the site of the fusion, the type of fixation used, the quality of fixation achieved, the patient's bone quality, and the presence of factors that affect bone healing, such as systemic inflammatory disease and preoperative use of corticosteroids.

At the close of surgery, a compression dressing and splint are applied and worn for 48 to 72 hours for edema control. For an ankle or hindfoot arthrodesis, after the compression dressing has been removed, a short-leg cast is applied for an extended period of time, usually 4 to 8 weeks. During the first 6 weeks, frequent cast changes are necessary as swelling subsides. A short-leg walking cast or rigid boot is applied at about 4 to 8 weeks, and immobilization continues for an additional 6 to 8 weeks.[30,64,91,106,115,117,125] After arthrodesis of the first MTP joint, a short-leg cast or surgical shoe with a flat, rigid sole is worn to protect the joint as it heals.[1,23]

When there is evidence of fusion, the patient is weaned from the immobilizer over several weeks. After splint use is discontinued, the patient should be advised of proper shoe selection, modification, and fit. The use of a custom-made foot orthosis may be necessary for support, relief of pressure, or shock absorption.[20]

Weight-bearing considerations. As with postoperative immobilization, published guidelines for the timing and extent of weight bearing permissible after arthrodesis vary considerably. The same considerations that influence decisions about immobilization also influence the progression of postoperative weight bearing on the operated extremity. The most prevalent practice is to substantially restrict weight bearing for many weeks after open or arthroscopic arthrodesis. Initially, a patient must ambulate with crutches or a walker and is not allowed to bear weight on the operated side for 4 to 8 weeks.[1,64,91,106,115,117,125,131] When there is radiographic evidence of boney healing, partial weight bearing is permitted, while the patient wears a rigid short-leg boot or shoe. Full weight bearing without an immobilizer usually is permitted by 12 to 16 weeks postoperatively.

In an effort to reduce recovery time and improve a patient's quality of life during this time, the safety of early weight bearing is being investigated. To date, most studies have assessed the effects of early weight bearing only after arthroscopic ankle arthrodesis. In select patient populations, early results are encouraging. However, randomized, prospective studies have not yet been done.

FOCUS ON EVIDENCE

Cannon and co-investigators[10] conducted a nonrandomized, retrospective study of two comparable groups of patients who had undergone arthroscopic ankle arthrodesis. One group (*n*=16; mean age 48) wore a short-leg cast and was not permitted to bear weight on the operated limb for 8 weeks. In contrast, the other group (*n*=23; mean age 51) was encouraged to bear as much weight as was comfortable on the operated limb within the first few days after surgery while wearing a rigid boot that immobilized the ankle and foot.

At 8 weeks, all patients in both groups had radiographic evidence of boney union, and by 4 months, all had achieved ankle fusion. There were no significant differences between groups in the rate of postoperative complications. The investigators concluded that an early weight-bearing regimen is safe after arthroscopic ankle arthrodesis provided the ankle is protected by a rigid splint. However, the investigators cautioned that early weight bearing after arthrodesis is not appropriate for patients with reduced sensation in the foot and ankle.

Postoperative exercises. Initially, postoperative exercises focus on ROM of the nonoperated joints proximal or distal to the joints that are immobilized. If the patient is wearing a removable splint, ROM exercises of the nonoperated joints confined by the immobilizer may be permissible early in the rehabilitation program as well.[10] For example, after ankle or hindfoot arthrodesis, exercises to maintain toe mobility are indicated in addition to knee ROM. For a patient with RA, active ROM is essential in all involved joints not controlled by the immobilization device.

When boney fusion has occurred and use of the immobilizer has been discontinued, there are often signs of postimmobilization muscle weakness, hypomobility of joints adjacent to the arthrodesis, and impaired balance. In such instances, exercises described previously in this chapter for nonoperative management of chronic joint hypomobility are appropriate.

Return to physical activities. Unlike TAA, no studies investigating patients' level of participation in recreational and sport activities after arthrodesis of the ankle or foot have been published to date. However, surgeons and athletic trainers have been surveyed and their opinions reported.[146] In general, participation in low-impact, but not high-impact, sports is permitted. However, some low-impact activities, such as cycling, can be difficult after tibiotalar arthrodesis because of loss of dorsiflexion, which is necessary for pedaling.

Outcomes

Short-term and intermediate outcomes. Following arthrodesis, boney union is achieved in the ankle, more than 90% of the time[37,38] but varies with the number and location of joint(s) fused, the extent of preoperative deformity, and the underlying pathology. When healing is complete after arthrodesis, pain relief and joint stability are predictable outcomes, resulting in improved functional mobility. However, after tibiotalar arthrodesis, in particular, patients continue to face functional challenges, such as difficulty walking on uneven surfaces and inclines and ascending and descending stairs.

Long-term outcomes. Although arthrodesis provides pain relief in the fused joint(s), it also imposes increased stresses on contiguous joints, leading to excessive compensatory motion and eventual degeneration of these joints.[37] Consequently, there can be long-term adverse functional outcomes after arthrodesis. For example, Coester and colleagues[17] carried out a long-term follow-up study of 23 patients who had undergone isolated ankle arthrodesis for posttraumatic arthritis a mean duration of 22 years earlier. They found a significantly higher rate of arthritis in the joints distal (subtalar, talonavicular, naviculocuneiform, tarsometatarsal, and first MTP) but not proximal to the fused tibiotalar joint compared with the same joints of the contralateral lower limb. In addition, based on information from standardized, self-report functional assessment instruments, ipsilateral foot pain interfered with the functional mobility of almost all patients.

Leg, Heel, and Foot Pain: Nonoperative Management

The cause of pain in the leg, heel, or foot is multifactorial, but most commonly occurs from biomechanical stress or overload. It is often described as an overuse syndrome from repetitive microtrauma, but is also described as degenerative without inflammation.[137] The biomechanical stress may be from obesity, work habits, faulty alignment of the lower extremity, muscle imbalances or fatigue, changes in exercise or functional routines, training errors, improper footwear for the ground, functional demands placed on the feet, or a combination of several of these factors.[36,87,137] The symptoms occur because continued demand is placed on the tissue before it has adequately healed. A common cause predisposing this region to painful syndromes is excessive pronation of the subtalar joint during weight-bearing activities. The pronation could be related to a variety of causes including excessive joint mobility, leg-length discrepancy, femoral anteversion, external tibial torsion, genu valgum, or muscle flexibility and strength imbalances in the lower extremity. Often, there is a hypomobile gastrocnemius-soleus complex related to the abnormal foot pronation.

Related Pathologies and Etiology of Symptoms

The extrinsic foot musculature may develop symptoms either at or near its proximal attachment in the leg (shin splints), or where coursing around boney prominences in the ankle, or at its distal attachment in the foot (tendonitis/tenosynovitis). Symptoms also may develop in the intrinsic muscles of the foot as well as in the plantar fascia (plantar fasciitis). Several common syndromes are described in this section.

Heel Pain

The Heel Pain Committee of the American College of Foot and Ankle Surgeons (ACFAS) published a revised clinical practice guideline (CPG)[137] that categorizes mechanical heel pain as: plantar heel pain (including plantar fasciitis, plantar fasciosis, and heel spurs) and posterior heel pain (including insertional Achilles tendinopathy, and bursitis). The Orthopaedic Section of the American Physical Therapy Association has published two separate CPGs, one for heel pain (plantar fasciitis)[87] and one for Achilles pain, stiffness, and muscle power deficits (Achilles tendinitis).[12] Recommendations from these CPGs are included in the following information.

Plantar fasciitis. Pain is usually experienced along the plantar aspect of the heel, where the plantar fascia inserts on the medial tubercle of the calcaneus. The site is very tender to palpation. Pain occurs on initial weight bearing after periods of rest, then decreases, but returns as weight-bearing activity increases.[87,137] Associated impairments include hypomobile gastrocnemius-soleus muscles and plantar fascia pain or restriction when extending the toes creating the windlass effect. A high body-mass index, inappropriate footwear, and a flexible flat foot (pes planus) may be predisposing factors. Conversely, stress forces on the fascia also may occur with an excessively high arch (cavus foot). Pressure transmitted to the irritated site with weight bearing or stretch forces to the fascia, as when extending the toes during push-off, causes pain.

A heel spur may develop at the site of irritation on the calcaneus, causing pain whenever the heel is on the ground. The individual usually avoids heel-strike during the loading response of gait.

Achilles tendinopathy (Achilles tendinitis/Achilles bursitis). Pain is experienced at the midportion of the tendon (2 to 6 cm proximal to the insertion on the calcaneus) or at the calcaneal insertion. Associated impairments include decreased ankle dorsiflexion, decreased strength in ankle plantarflexion, and increased foot pronation.[36,75,112] Reported risk factors include obesity, hypertension, and diabetes.[12] Pain and stiffness in the tendon occur following a period of inactivity and initially decrease with a return to activity but then increase with additional activity. Symptoms may develop when the person switches from high-heeled to low-heeled shoes followed by a lot of walking.

Tendinosis, Tendonitis, and Tenosynovitis

Any of the tendons of the extrinsic muscles of the foot may become irritated as they approach and cross behind or over the ankle or where they attach in the foot. Pain occurs during or after repetitive activity. When the foot and ankle are tested, pain is experienced at the site of the lesion as resistance is applied to the muscle action and also when the involved tendon is placed on a stretch or when palpated.[13,36,98] A common site for symptoms is proximal to the calcaneus in the Achilles tendon or its sheath (Achilles tendonitis or peritendinitis) as described in the heel pain section. Tendon degeneration in the posterior tibial tendon is a common source of pain and leads to impaired walking and acquired flatfoot deformity.[73] Symptoms in the anterior or posterior tibialis tendons or peroneus tendons are also associated with athletic activities, such as running, tennis, and basketball.[98]

Shin Splints

This term is used to describe activity-induced leg pain along the posterior medial or anterior lateral aspects of the proximal two-thirds of the tibia. It may include different pathological conditions such as musculotendinitis, stress fractures of the tibia, periosteitis, increased pressure in a muscular compartment, or irritation of the interosseous membrane.

Anterior shin splints. Overuse of the anterior tibialis muscle is the most common type of shin splint. A hypomobile gastrocnemius-soleus complex and a weak anterior tibialis muscle as well as foot pronation are associated with anterior shin splints. Pain increases with active dorsiflexion and when the muscle is stretched into plantarflexion.

Posterior shin splints. A tight gastrocnemius-soleus complex and a weak or inflamed posterior tibialis muscle, along with foot pronation, are associated with posterior medial shin splints. Pain is experienced when the foot is passively dorsiflexed with eversion and with active supination. Muscle fatigue with vigorous exercise, such as running or aerobic dancing, may precipitate the problem.

Common Structural and Functional Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations/Disabilities)

- Pain with repetitive activity, on palpation of the involved site, when the involved musculotendinous unit is stretched, and with resistance to the involved muscle
- Pain on initial weight bearing and with repetitive weight-bearing activities and gait
- Muscle length-strength imbalances, especially tight gastrocnemius-soleus muscle group
- Abnormal foot posture (may be from faulty footwear)
- Decreased length of time the individual can stand and decreased distance or speed of ambulation, which may restrict associated community and work activities and recreational and sports activities

Leg, Heel, Foot Pain: Management—Protection Phase

If signs of inflammation are present, treat as an acute condition, with rest and appropriate modalities. (See Chapter 10 for general principles and guidelines.) Immobilization in a cast or splint with the foot slightly plantarflexed or use of a heel lift or custom orthotic inside the shoe may relieve stress.[26,75,112]

- Apply cross-friction massage to the site of the lesion.
- Initiate gentle muscle-setting contractions or electrical stimulation to the involved muscle in pain-free positions.
- Teach active ROM within the pain-free ranges.
- Instruct the patient to avoid activity that provokes pain.
- Use supportive taping or orthotic shoe insert to provide relief of symptoms.[12,53,73,87,101,137]

Leg, Heel, Foot Pain: Management—Controlled Motion and Return to Function Phases

When symptoms become subacute, the entire lower extremity as well as the foot should be examined for impaired alignment or muscle flexibility and strength imbalances. Eliminating or modifying the cause is important to improve outcomes and prevent recurrences.[16,152] Orthotic devices may be necessary to correct alignment.[75,77,112] Therapeutic exercises may be helpful to increase flexibility and improve general muscle performance. Detailed descriptions of stretching and strengthening exercises for the ankle and foot are in the last section of this chapter.

FOCUS ON EVIDENCE

A multicenter, randomized study of 60 subjects with plantar heel pain compared two treatment groups, one receiving electrophysical agents and exercise, and the other treated with manual interventions (vigorous soft tissue techniques and joint mobilization directed at the hip, knee, and ankle/foot as needed) and exercise. There was a significant improvement in both groups in functional measures and pain, with those receiving the specific manual interventions and exercise showing greater differences at 4-week and 6-month follow-up.[16]

Educate the Patient and Provide Home Exercises

- Help the patient incorporate home exercises and soft tissue and joint mobilization into his or her daily routine.
- If the patient experiences pain when first bearing weight, especially in the morning and after prolonged sitting, teach the patient to do ROM exercises (especially dorsiflexion) or alphabet writing with the foot for several minutes before standing.
- Teach prevention, including the following principles.
  - Before intense exercise, use gentle repetitive warm-up activities followed by stretching of tight muscles.
  - Use proper foot support for the ground conditions (this cannot be overemphasized).
  - Allow time for recovery from microtrauma after high-intensity workouts

Stretch Range-Limiting Structures

- The gastrocnemius-soleus muscle complex is frequently hypomobile in cases of foot problems and should be stretched if limiting dorsiflexion. Restricted mobility causes the foot to pronate when the ankle dorsiflexes.

CLINICAL TIP

Instruct patients with pes planus to wear supportive shoes with medial arch support when performing standing gastrocnemius-soleus stretches to protect the foot.[56]

- With heel pain (fasciitis, heel spurs), apply joint and soft tissue mobilization techniques.[16]
  - Deep massage to the insertion of the plantar fascia at the medial calcaneal tubercle and the gastrocnemius-soleus tendon.
  - Joint mobilization directed to specific limitations such as lateral glide to the subtalar joint to improve rearfoot inversion and posterior glide to the talus to improve ankle dorsiflexion.
  - Stretching exercises to the plantar fascia
- Stretching exercises to any lower extremity region that may affect alignment and function of the foot and ankle.

Improve Muscle Performance

- Begin with resistive isometric and progress to resistive dynamic exercises to the foot and ankle in open- and closed-chain activities.
- For medial and lateral support, develop a balance in strength between the muscle groups, especially the invertors and evertors.
- Emphasize muscular endurance, and train the muscles to respond to eccentric loading.[12,73]
- With plantar fasciitis, the intrinsic muscles need to be strengthened. Include exercises that require toe control, such as scrunching tissue paper or a towel and picking up marbles and other small objects with the toes.

Ligamentous Injuries: Nonoperative Management

After trauma, the ligaments of the ankle may be stressed or torn. First- and second-degree (grades I and II) sprains are usually treated conservatively. The most common type of ankle sprain is caused by an *inversion stress* and can result in a partial or complete tear of the anterior talofibular (ATF) ligament and often the calcaneofibular (CF) ligament (see Fig. 22.2).[51,114] The posterior talofibular (PTF) ligament, the strongest of the

lateral ligaments, is torn only with *massive* inversion stresses. If the inferior tibiofibular ligaments are torn after stress to the ankle, the mortise becomes unstable. Rarely do the components of the deltoid ligament become stressed; there is greater likelihood of an avulsion from or fracture of the medial malleolus with an eversion stress. Depending on the severity of injury, the joint capsule also may be involved, and intra-articular pathology, including articular cartilage lesions, may occur,[70] resulting in symptoms of acute (traumatic) arthritis.

Common Structural and Functional Impairments, Activity Limitations, and Participation Restrictions (Functional Limitations/Disabilities)

- Pain when the injured tissue is stressed in mild to moderate injuries.
- Excessive motion or instability of the related joint in the case of complete tears.
- Proprioceptive deficit manifested as decreased ability to perceive passive motion and development of balance impairments.[32]
- Related joint symptoms and reflex muscle inhibition.
- Possible decreased ROM of the talocrural joint in recurrent lateral ankle sprains due to anterior subluxation and impaired tracking of the talus in the mortise.[147]
- Postural control deficits following an acute lateral ankle sprain in both the injured and uninjured limb.[84]
- Restricted ambulation (requiring an assistive device) during the acute and subacute phases. With chronic instability, the individual may have difficulty walking or running on uneven surfaces or making quick changes in direction. He or she may be unable to land safely when jumping or hopping or may fall more frequently.

FOCUS ON EVIDENCE

A study of recreational athletes with chronic ankle instability (n=15) and matched healthy athletes without instability (n=15) tested single limb postural stability on a moving surface while simultaneously performing a cognitive activity. Results showed when the cognitive activity was performed, there was significantly poorer postural stability in those with chronic instability than in those without instability. The authors suggest that this demonstrated decreased automaticity of postural control in the group with ankle instability.[109]

Acute Ankle Sprain: Management—Protection Phase

See Chapter 10 for principles of treatment during stages of inflammation and repair.

- If possible, examine the ankle before joint effusion occurs. To minimize the swelling, use compression, elevation, and ice. The ankle should be immobilized in neutral or in slight dorsiflexion and eversion.
- Use gentle joint mobilization techniques to maintain mobility and inhibit pain.
- Educate the patient.
  - Teach the patient the importance of RICE (rest, ice, compression, and elevation), and instruct the patient to apply ice every 2 hours during the first 24 to 48 hours.
  - Teach partial weight bearing with crutches to decrease the stress of ambulation.[34]
  - Teach muscle-setting techniques and active toe curls to help maintain muscle integrity and assist with circulation.

FOCUS ON EVIDENCE

Green and associates[35] studied 38 individuals following acute ankle sprain (within 72 hours of injury and requiring partial weight bearing). All subjects received RICE intervention. Those randomly assigned to the experimental group (n=19) also received gentle anterior-posterior (AP) joint mobilization techniques to the talocrural joint with the foot positioned in dorsiflexion. Range of pain-free ankle dorsiflexion, gait speed, step length, and single support time were measured. The majority of those in the experimental group were discharged after fewer treatments (13 of 19 subjects by the fourth treatment), having gained full range of dorsiflexion, whereas only three subjects in the control group met this criterion and required additional treatment. Also, subjects in the experimental group demonstrated improved stride speed compared to the control group.

Ankle Sprain: Management—Controlled Motion Phase

- As the acute symptoms subside, continue to provide protection for the involved ligament with a splint during weight bearing. Fabricating a stirrup out of thermoplastic material and holding it in place with an elastic wrap or Velcro straps provides stability to the joint structures while allowing for the stimulus of weight bearing for proprioceptive feedback and proper healing. Commercial splints, such as an air splint, are also available to provide medial-lateral stability while allowing dorsiflexion and plantarflexion.[40,63]
- Apply cross-fiber massage to the ligaments as tolerated.
- Use grade II joint mobilization techniques to maintain mobility of the joint.
- Teach the patient exercises to be done within tissue tolerance at least three times per day. Suggestions include:
  - Nonweight-bearing AROM into dorsiflexion and plantarflexion, inversion and eversion, toe curls, and writing the alphabet in the air with the foot.
  - Sitting with the heel on floor and scrunching paper or a towel and picking up marbles with the toes.

- If adhesions are developing in the healing ligament, have the patient actively move the foot in the direction opposite the line of pull of the ligament. For the anterior talofibular ligament, the motion is plantarflexion and inversion. Also, stretch the gastrocnemius-soleus muscle group for adequate dorsiflexion. Progress to weight-bearing stretches when the patient's recovery allows.
- As swelling decreases and weight-bearing tolerance increases, progress to strengthening, endurance, and stabilization exercises; include isometric resistance to the peroneals, bicycle ergometry, and partial to full weight-bearing balance board exercises. Have the patient wear a brace or splint that restricts end-range motion to control the range and prevent excessive stress on the healing ligament.[34]

Ankle Sprain: Management—Return to Function Phase

- Progress strengthening exercises by adding elastic resistance to foot movements in long-sitting (open-chain) and sitting with the heel on the floor for partial weight bearing. Use isokinetic resistance if a unit is available.
- Progress postural/stabilization and proprioceptive/balance training for ankle stability, coordination, and neuromuscular response with full weight-bearing activities.
  - Incorporate movement patterns, such as forward/backward walking and cross-over side stepping with elastic resistance secured around the unaffected lower extremity.[43]
  - Utilize an unstable surface, such as a BOSU® or BAPS® board.[33,113,150]
  - Depending on the final goals of rehabilitation, train the ankle with weight-bearing activities, such as walking, jogging, jumping, hopping, and running, and with agility activities, such as controlled twisting, turning, and lateral weight shifting.
- When the patient is involved in sports activities, the ankle should be splinted, taped, or wrapped, and proper shoes should be worn to protect the ligament from reinjury.[23]

FOCUS ON EVIDENCE

Twenty-five individuals with postacute (3 to 4 weeks) lateral ankle sprain (unilateral grade I or II), who exhibited postural sway instability in the sprained ankle (modified Romberg Test), were tested under two conditions (with a commercial air splint and nonbraced control) with two dependent variables (shuttle-run and vertical-jump). The tests were repeated after 5 to 7 days of wearing the splint during ADLs to determine if acclimation to the brace affected performance. Results demonstrated immediate performance enhancement, while wearing the air splint for the shuttle-run test (mean 9.43 ± 0.72 seconds) compared with the nonbraced condition (mean 9.57 ±pm 0.75 seconds) in sessions 1 and 2, demonstrating that an acclimation period was not necessary for the stabilizing benefit. The vertical jump did not show improvement when the splint was worn.[40]

A systematic review of the literature was carried out to determine the effectiveness of balance and coordination training for lateral ankle instability and revealed the following.[85] Prophylactic balance and coordination training is effective in reducing the risk of ankle sprains; the effect is greater in those with a history of sprains (strong evidence) than for those without prior injury. There was inadequate evidence to show that training prevented ankle sprains in those without prior injury. The review also demonstrated that balance and coordination training substantially improved treatment outcomes after acute ankle sprains, but the evidence is inconclusive regarding improved postural control. The authors suggested that self-reported function is improved (limited, but promising evidence) in those with chronic ankle instability who complete balance and coordination training.[85]

Traumatic Soft Tissue Injuries: Surgical and Postoperative Management

Repair of Complete Lateral Ankle Ligament Tears

A third-degree (grade 3) sprain of the lateral ankle, which usually occurs as the result of a severe inversion injury, causes a complete tear or rupture of the anterior talofibular (ATF) ligament, often the calcaneofibular (CF) ligament, and only occasionally, the posterior tibiofibular (PTF) ligament (Fig. 22.7).[31,128] Tearing of both the ATF and CF ligaments leads to combined instability of the tibiotalar and subtalar joints. The ATF ligament is most likely to tear when forceful inversion occurs while the ankle is plantarflexed.[130] Associated

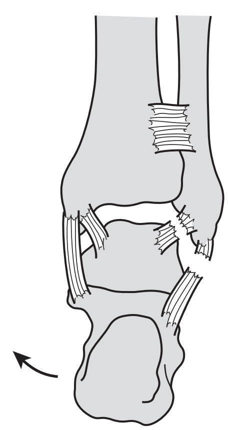

FIGURE 22.7 A complete tear of the lateral collateral ligament complex as the result of a severe (grade 3) inversion injury of the ankle. *(From McKinnis, LN: Fundamentals of Musculoskeletal Imaging, ed. 3. FA Davis, Philadelphia, 2010, p. 432, with permission.)*

injuries that occur include articular cartilage lesions, a transverse fracture of the lateral malleolus, or an avulsion fracture of the base of the fifth metatarsal.[29,31,114,145]

In addition to significant swelling, tenderness, and often times pain, a complete tear of one or more lateral ligaments causes marked mechanical instability and functional instability of the ankle during weight-bearing activities. Mechanical instability is defined as ankle mobility beyond the physiological ROM, increased talar tilt, and an anterior drawer sign indicative of joint laxity, whereas functional instability is characterized by the patient's sensation of the ankle "giving way."[49,132] The severity of functional ankle instability does not appear to be directly related to the magnitude of anterior joint displacement or talar tilt.[49] This may be why as many as 20% of patients without evidence of mechanical instability complain of the ankle "giving way" after a severe lateral ankle sprain, thus significantly impairing functional activities.[18]

After an acute, grade 3 inversion injury, nonoperative treatment is successful for most patients. However, some patients continue to have pain and a "giving way" sensation and sustain recurrent inversion injuries after the acute injury has healed, leading to chronic, symptomatic instability. For patients with demonstrated mechanical instability who do not respond to nonoperative management and for select patients with acute lateral ankle injuries who regularly engage in high-impact activities, surgical repair or reconstruction may be required to manage the instability and return the patient to a desired level of function.[18,31] The overall goal of surgery and postoperative management is to restore joint stability while retaining pain-free, functional ROM of the ankle and subtalar joints.[18,31,41,42,128]

Indications for Surgery

The following are frequently cited indications for surgical repair or reconstruction of the soft tissues of the lateral aspect of the ankle.[29,31,41,128,136]

- Chronic mechanical and functional instability of the ankle during activity, which remains unresolved after conservative management.
- Acute, third-degree lateral ankle sprain resulting in a complete tear of the ATF and/or CF ligaments.

Procedures

Types of Stabilization Procedures

There are numerous surgical procedures that may be used for repair and reconstruction of the lateral ligaments and associated structures of the ankle (Fig. 22.8).[11,19,29,31,52,128,136] Arthroscopy, for the most part, is reserved for perioperative examination to assist the surgeon in identifying pathologies associated with ankle instability that may not be readily evident through physical examination or during the ligament surgery.[11,29] The various procedures for ligament repair, however, are performed almost exclusively through an open approach, although arthroscopic repair of ATF ligament tears by means of staples or bone anchors has been reported.[127]

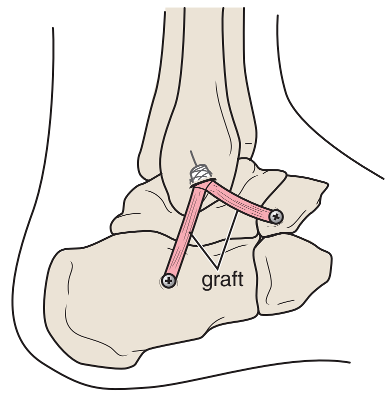

FIGURE 22.8 Lateral view of the ankle depicting reconstruction of torn ATF and CF ligaments using a tendon graft to augment stability. Proximal advancement and suturing of the extensor retinaculum (not shown) over the reconstructed ligaments to the distal fibula provide additional stability.

Open procedures are classified into two broad categories: those that primarily involve a direct (anatomic) repair of the torn or attenuated (overstretched) ligaments and those that involve tenodesis (tendon graft and transposition) to reconstruct the lateral ankle complex and augment joint stability.[72] During the last decade an arthroscopic, thermally assisted capsular shift was introduced as an alternative to open repair for select patients.[52]

The type of procedure selected depends on the severity and chronicity of the instability, the presence of co-morbidities, the age of the patient, and the patient's anticipated postoperative activity level. Some procedures are used predominantly for a primary repair, whereas others are reserved for revision surgery.

Direct repair. The surgery used most commonly for a primary repair is an open procedure called the *modified Broström procedure*, also known as the *Broström-Gould procedure*.[29,41,42,46] This procedure involves an anatomic repair with direct suturing of the torn ATF and/or CF ligament ends, imbrication (reefing) of lax ligaments in a pants-and-vest manner to tighten the ligament and provide a double layer of reinforcement or reinsertion of an avulsed ligament to bone. The lateral aspect of the ankle is reinforced by advancing the lateral portion of the extensor retinaculum proximally over the repaired structures and suturing it to the anterior aspect of the distal fibula.

The advantages of the modified Broström procedure are that it provides stability (without the need to harvest a soft tissue graft) while retaining full ROM of the tibiotalar and subtalar joints, an outcome particularly important to individuals who wish to return to activities that require full ankle mobility, such as gymnastics and ballet.

Reconstruction with augmentation. The other broad grouping of procedures are those that use a tenodesis, usually a tendon autograft and transposition of the peroneus brevis tendon, to reinforce the lateral ankle complex with or without ligament repair. Examples of early procedures, classified as

nonanatomic, include various modifications of the *Evans, Chrisman-Snook,* and *Watson-Jones procedures*.[18,31,46] These early procedures, all of which provided additional reinforcement to the joint to augment stability but sacrificed a portion of the ankle evertors and often limited the range of inversion available after surgery, also were associated with increased risk of osteoarthritis of the subtalar and talocrural joints.[72]

To preserve the integrity of the peroneal tendons, anatomic reconstruction procedures using a gracilis tendon autograft[19,136] or a bone-patellar tendon allograft[134] have been developed as alternatives to a peroneal tendon autograft. Reconstruction procedures, in general, are employed when primary repair is not an option because of deterioration of the torn ligament(s) or as a revision procedure when previous direct repair has failed to prevent recurrence of lateral instability. Reconstruction with augmentation also is used occasionally during a primary repair for large patients, specifically those weighing more than 200 to 250 pounds.[41]

Arthroscopic thermally assisted capsular shift. Similar to its use for glenohumeral joint instability, arthroscopic, thermally assisted capsular shift (capsulorrhaphy) is a relatively new type of procedure for the chronically unstable ankle. The procedure shrinks and tightens attenuated lateral ligaments and the joint capsule by means of radiofrequency or laser energy for the purpose of improving joint stability. The long-term success of this procedure at the ankle has not yet been determined. (Refer to Chapters 12 and 17 for additional discussions of thermally assisted capsular shift.)

Operative Overview

Prior to an open repair or reconstruction for lateral ankle instability, arthroscopy is performed to assess the extent of intra-articular pathology, because a high percentage (reported as 77%[135] in one study and 93%[70] and 95%[29] in two other studies) of chronically unstable ankles exhibit associated intra-articular pathology, specifically small articular cartilage lesions, which are thought to be a precursor to osteoarthritis of the ankle. If a chondral lesion is identified, arthroscopic subchondral drilling typically is carried out to manage the lesion.

After arthroscopy, an oblique or vertical incision is made beginning at the anterior aspect of the distal fibula and extending distally along the lateral aspect of the ankle and foot. If a direct repair is used, torn or ruptured structures are identified and sutured in a pants-and-vest manner. If a peroneus brevis tendon graft is to be used to provide additional reinforcement of the lateral ankle, the tendon is split longitudinally. One-half of the tendon is harvested by detaching it proximally at its musculotendinous junction and weaving it through prepared drill holes in the fibula, talus, and/or calcaneus. Then it is doubled back and sutured to itself. The extensor retinaculum is advanced proximally and sutured over the ligament repair to the distal fibula for additional reinforcement.

Prior to wound closure, the stability and ROM of the ankle are checked. The foot and ankle are placed in a compression dressing and well-padded, short-leg, bivalved cast or posterior splint with the ankle in 0° of dorsiflexion and slight eversion. The leg is elevated for control of joint swelling and peripheral edema.

Postoperative Management

In the past decade, there has been a trend to allow early postoperative weight bearing while the ankle is immobilized and in select patients, early but protected ROM after lateral ligament reconstruction. The exercise progression after surgery is similar to that used for nonoperative management of lateral ankle sprains. Postoperative management is geared toward not only returning a patient to a pre-injury level of function, but also toward preventing re-injury.

NOTE: After an arthroscopic thermally assisted capsular shift, the period of continuous immobilization and nonweight-bearing is longer than after an open repair or reconstruction, because the thermally treated ligaments are vulnerable to excessive stress.[52]

Immobilization and Weight-Bearing Considerations

Immobilization. After some degree of swelling has subsided, usually within 3 to 5 postoperative days or as late as a week to 10 days, the compression dressing and protective cast is removed and reapplied or replaced with a short-leg walking cast that continues to immobilize the ankle in a neutral position. If a short-leg cast is used initially, it may be removed at 4 to 6 weeks and replaced with an air-stirrup-type splint,[41] a removable cast-boot, or a controlled active motion (CAM) walking brace, which is worn for several additional weeks.[19,29,31,98,130,132,136]

By 8 to 12 weeks, the patient gradually discontinues use of the immobilizer during ambulation. However, patients returning to athletic activities that involve jumping, running, and quick changes of direction are advised to wear a protective orthotic device or to tape the ankle for at least 3 to 6 months or even indefinitely to prevent re-injury.

Weight-bearing considerations. Immediately after surgery the patient must remain nonweight-bearing on the operated extremity while the ankle is in the compression dressing and protective cast or posterior splint. When the compression dressing is removed and the short-leg walking cast applied, protected weight bearing is initiated as early as 3 to 4 weeks. Weight bearing is gradually progressed to full weight bearing by 6 weeks.[19,29,31,41,130,132,136] Full weight bearing without the immobilizer during ambulation usually is postponed until about 3 months after surgery.

Exercise: Maximum Protection Phase

The focus of the first phase of rehabilitation, which lasts from 4 to 6 weeks, is to regain independent mobility for functional activities while protecting the repaired or reconstructed lateral ankle structures. Ambulation with crutches, nonweight-bearing on the operated extremity, is initiated directly after surgery. Elevation of the operated foot is essential when the patient is resting to control peripheral edema and reduce pain. ROM of the operated ankle is not permitted during this period.

Goals and interventions. The following exercise-related goals and interventions are appropriate during the first postoperative phase.[31,41,130,132]

- ***Maintain strength of nonimmobilized muscle groups.*** Perform active or gentle resisted exercises of the hip and knee of the operated lower extremity and resistance exercises of the upper extremities and sound lower extremity. When partial weight bearing is permissible and if the immobilizer, such as a boot or posterior splint, allows a small degree of dorsi- and plantarflexion, perform mini-squats in bilateral stance while using a walker for support.
- ***Prevent reflex inhibition of immobilized muscle groups.*** While the ankle is immobilized, begin gentle, pain-free muscle-setting exercises of the ankle musculature including isometric contractions of the peroneal muscles.

Exercise: Moderate and Minimum Protection Phases

By the intermediate phase of rehabilitation, which begins at approximately 4 to 6 weeks and continues to about 12 weeks postoperatively, healing structures are able to sustain progressive but controlled levels of stress. Ankle ROM typically is limited and painful with end-range overpressure. Lower extremity strength and balance are impaired from weeks of restricted weight bearing as well.

This phase is characterized by a gradual weaning from the immobilizer and restoring pain-free ankle mobility and neuromuscular control during weight bearing without jeopardizing stability of the ankle joint. Because most patients are allowed to bear full weight on the operated extremity by 6 weeks after surgery while wearing the immobilizer, improvement of lower extremity strength and balance is now possible.

The focus of the final phase of rehabilitation is to restore strength and muscular endurance of the operated lower extremity equal to that of the sound side, re-establish a normal, pain-free gait pattern, and prepare the patient to safely return to necessary and desired work-related and recreational activities while preventing reinjury of the ankle.[31,98,130,132]

CLINICAL TIP

With proper precautions, a return to functional activities, including select sports, may be possible by 16 weeks postoperatively[41,132] or when peroneal muscle strength is normal (compared to the contralateral ankle) and when multiple, pain-free single-leg hops on the operated lower extremity are possible.[130]

Goals and interventions. The following exercise-related goals and interventions are appropriate during the intermediate and final phases of rehabilitation.

- ***Restore pain-free ROM of the operated ankle.*** It is not unusual for a patient to have just a few degrees of ankle dorsiflexion beyond neutral after weeks of immobilization. To increase ankle ROM:
  - Begin assisted or active dorsiflexion and plantarflexion within the limits of pain as soon as the immobilizer may be removed for exercise as determined by the surgeon.
  - Postpone inversion and supination movements until 6 to 8 weeks postoperatively.
  - Progress to multiplanar active motions, such as figure-of-eight movements.
  - Perform grade II or III joint mobilization techniques to the tibiotalar and tibiofibular joint if joint restriction limits dorsi- or plantarflexion. Avoid stretch mobilization of the subtalar joint.
  - Add gentle self-stretching exercises to improve flexibility of specific muscle groups, most frequently the gastrocnemius-soleus complex.

PRECAUTION: It is advisable to begin with stretching in a nonweight-bearing position, such as a towel stretch or closed-chain stretching in a *seated* position with the foot resting on the floor, because stretching in a standing position imposes significant ground reaction forces on the repaired ligaments.

- ***Increase isometric and dynamic strength of ankle and foot musculature and throughout both lower extremities.***

CLINICAL TIP

Functional ankle instability has been shown to be associated with decreased strength (peak torque) of the ankle evertors of the involved ankle when compared with the contralateral ankle in individuals who have not undergone a surgical stabilization procedure.[119] In addition, the extent of strength loss in the ankle musculature has been shown to be associated with the *chronicity* of the instability.[57] Therefore, after surgical repair or reconstruction of the lateral ligaments, improving strength of the evertors is particularly important for developing dynamic stability of the ankle.

  - Perform low-intensity, pain-free resistance exercises of all ankle muscles, first in nonweight-bearing and then in weight-bearing positions.

PRECAUTION: Postpone unilateral heel raises in standing to strengthen the plantarflexors on the operated side until late in the rehabilitation process. The risk of reinjury by overstressing the repaired ligament(s) is high if loss of balance and excessive inversion occur during plantarflexion.

  - Emphasize strengthening of the ankle evertors. For isometric strengthening, have the patient cross the ankles and press the lateral borders of the feet together. For dynamic strengthening, perform eversion against elastic resistance (see Fig. 22.13).
  - Include bilateral hip and knee strengthening in nonweight-bearing and weight-bearing positions for proximal control (see Chapters 20 and 21).

- Progress to plyometric training if weight bearing is pain free. Include jumping, then hopping forward, diagonally, backward, and side-to-side on the floor or a mini-trampoline. (Refer to Chapter 23 for descriptions and illustrations of advanced balance activities and plyometric training.)

- ***Improve muscular endurance and cardiopulmonary fitness.*** Begin with pool walking, swimming, stationary bicycling, treadmill walking, or using a cross-country ski machine. Progress to deep-water running and outdoor walking, jogging, or running, being certain the ankle is appropriately supported for land-based activities.
- ***Improve neuromuscular control, balance reactions, dynamic stability, and agility.***
  - Initiate proprioceptive/balance training at about 6 weeks postoperatively or when weight bearing on the operated lower extremity without ankle pain is possible.
  - Include a progression of bilateral to unilateral balance activities first on a level, firm surface, then on a soft surface, such as dense foam, and then on a balance board or BOSU®.
  - Progress to activities to improve agility, such as grapevine walking (carioca), lateral shuffles, use of a slide board, and pivoting and cutting activities.
  - Refer to Chapter 23 for a sequence of balance and agility activities.

FOCUS ON EVIDENCE

For patients with a functionally unstable ankle, proprioceptive/balance training, using rocker or wobble boards has been shown to be an effective method of improving joint proprioception (joint position sense) and single-leg standing ability and reducing postural sway and muscle reaction times during balance activities.[28,33,43,113,150]

In a prospective study by Verhagen and co-investigators,[144] 1,127 male and female professional volleyball players from 116 teams were randomly assigned by team to a training group or a control group. Throughout the 36-week volleyball season, the training groups participated in a proprioceptive training program consisting of a variety of balance activities, some on balance boards. The control groups were not given any training program. The training and control groups kept track of injuries sustained during the season. Among players who had a history of lateral ankle sprains prior to the beginning of the study, those who participated in the balance training program had a significantly lower incidence of acute lateral ankle sprains during the season than those in the control group. Among training and control group players who did not have a history of lateral ankle sprains, there was no significant difference in the incidence of ankle injury during the season. The authors concluded that proprioceptive training was effective in preventing recurrence of lateral ankle injury in adult volleyball players.

Although this and other studies have not involved patients undergoing rehabilitation after repair or reconstruction of the lateral ankle ligaments, proprioceptive training programs such as these may be beneficial for the postoperative patient.

- ***Re-establish pain-free, symmetrical weight bearing during gait and related activities.***
  - Begin gait training in a pool or land-based training on level surfaces as soon as ambulation in a controlled ankle motion brace (which allows dorsi- and plantarflexion) is permitted.
  - Emphasize symmetrical weight bearing during sit-to stand movements and eventually ascending and descending stairs.
  - Progress to ambulation and functional activities without the brace.
- ***Safely return to functional activities and prevent re-injury.*** Sport-specific training, beginning with low-intensity, simulated movements, usually is permissible by 8 to 12 weeks postoperatively.[41,130,132] Precautions to reduce the risk of re-injury when returning to sports or high-demand activities after repair or reconstruction of lateral ankle ligaments are summarized in Box 22.5.

Outcomes

An optimal postoperative outcome after lateral ankle repair or reconstruction is an ankle that has full mobility but remains stable and pain-free during functional activities. At this time, an open approach for primary repair or reconstruction provides more predictable long-term results than an arthroscopic stabilization procedure.[18,29] Although not an optimal result, a slight loss of ankle motion, possibly 5° to 10° of eversion, occurs most often after nonanatomic reconstruction (tenodesis) procedures.[136]

BOX 22.5 Activity-Related Precautions to Reduce the Risk of Re-injury After Lateral Ligament Reconstruction of the Ankle

- Modify activities, if possible, by participating in low-impact sports, such as swimming, cycling, low-impact aerobics, or cross country skiing.
- Minimize or avoid participation in activities that involve high-impact (basketball, volleyball), rapid stopping and starting and changes of direction (tennis, soccer), or traversing uneven surfaces.
- If involved in activities associated with high risk of ankle injury:
  - Participate in a pre-season injury prevention program that includes progressive proprioceptive and plyometric training and continue the program throughout a sport season.[144]
  - Wear a prescribed orthotic device, such as a functional stirrup brace or splint, to provide medial-lateral stability of the ankle.[130]
  - Tape the ankle or insert a slight lateral lift in the shoe.[86,98]

Current and past reviews of studies involving patients with chronic lateral ankle instability indicated that 87% to 95% of patients report excellent or good results after surgery.[29,108,136] (Based on a variety of clinical and functional assessment instruments, an "excellent" result is the absence of symptoms with full activity, and a "good" result is the ability to participate in full activity with some symptoms.[29]) Similar results were reported in a postoperative follow-up study of ballet dancers who had undergone a modified Broström procedure a mean of 64.3 months earlier.[42] Results of a subsequent retrospective study[29] revealed that 100% of 21 patients who underwent the same surgical procedure for chronic ankle instability demonstrated excellent and good results 60 months after surgery.

Several studies have compared the results of a direct anatomic repair with reconstruction with a tendon graft (tenodesis). Hennrikus and associates[46] compared two types of lateral ankle reconstruction, one using anatomic repair (modified Broström procedure) and the other involving augmentation with a peroneus brevis tendon graft (Chrisman-Snook procedure). Both procedures yielded good to excellent results in 80% of patients, but the latter was associated with a higher rate of complications.

In a multicenter, retrospective, nonrandomized study, Krips and colleagues[72] evaluated two groups of athletes (n=77) who had undergone either direct anatomic repair or a reconstruction with a tenodesis procedure for chronic lateral ankle instability 2 to 10 (mean 5.4) years earlier. There were no significant differences in preoperative characteristics of the athletes in the two groups. All had participated in a nonoperative treatment program for at least 6 months before surgery. Physical examination at follow-up revealed significantly more patients (15 of 36) in the tenodesis group had limited ankle ROM than patients (3 of 41) in the anatomic repair group. Functional abilities reported by patients on a quantitative questionnaire were rated as excellent and good by 21 of 36 subjects in the tenodesis group and by 36 of 41 in the anatomic repair group. Those in the tenodesis group reported a noticeably diminished push-off power on the operated side during running. They also reported a lower activity level and a perception of less ankle stability than those in the anatomic repair group. The authors concluded that an anatomic repair was a better choice than tenodesis for primary repair of chronic ankle instability in an athletic population.[72] However, current-day *anatomic* reconstruction methods, which more closely restore normal ankle kinematics, do not appear to be associated with restricted postoperative ROM or increased incidence of arthritis.[120]

In summary, primary anatomic repair or reconstruction of the lateral ligaments effectively stabilizes the ankle joint and enables patients to return to functional activities. That said, successful outcomes may be compromised for some patients due to continued or late onset of ankle or foot pain if intra-articular pathology associated with the acute injury or chronic instability, such as a bone spur or chondral lesion, is not identified and treated in conjunction with the stabilization procedure.[136]

Repair of a Ruptured Achilles Tendon

Acute rupture of the Achilles tendon is a common soft tissue injury, occurring more frequently in men than in women, 30 to 50 years old, who intermittently participate in exercise or athletic activities.[4,61,151] The rupture usually is associated with a forceful concentric or eccentric contraction of the gastrocnemius-soleus muscles (triceps surae) during sudden acceleration or abrupt deceleration, such as jumping or landing.[8] Degenerative and mechanical factors appear to increase the risk of acute rupture, including decreased strength or flexibility of the plantarflexors, excessive body weight, preexisting tendinosis, corticosteroid injections into the tendon, and decreased vascularity of the tendon.[8]

The tendon often ruptures proximal to the distal insertion of the tendon on the calcaneus.[45] At the time of injury, a complete rupture leads to pain, swelling, a palpable defect, and significant weakness in plantarflexion. It also is associated with a positive Thompson test (absence of reflexive plantarflexion when the patient is prone-lying with the knee flexed or the knee extended and the foot over the edge of a table and the calf squeezed).[90,140]

Historically, an acute rupture of the Achilles tendon has been managed nonoperatively or surgically with an extended period of cast immobilization or functional bracing combined with restricted weight bearing with both approaches to treatment. There is general agreement in the literature and in clinical practice that surgical intervention is recommended for the elite athlete wishing to return to a high-demand sport as quickly as possible[78] and for the young, regularly active individual, but nonoperative management is the better option for the relatively sedentary individual, older than 50 to 60 years of age.[4,61,151] Furthermore, surgery is considered the only option for the symptomatic patient with a chronic rupture in which the diagnosis or treatment was delayed 4 weeks or more.[90,96,148]

Several systematic reviews and meta-analyses of the literature that included only prospective, randomized, and quasi-randomized studies have revealed there is insufficient evidence to indicate whether the nonoperative or operative option is the better treatment strategy or yields better outcomes.[4,61,151] Both options have their advantages and disadvantages. With surgical repair followed by postoperative rehabilitation, there is a lower rate of rerupture of the tendon than with nonoperative management, but there also is a risk of wound closure problems, infection, and nerve injury with surgery. Nonoperative management typically requires a longer immobilization and recuperative time and is associated with a higher rate of deep vein thrombosis (DVT).[4,15,61,62,151] There is a trend, however, to minimize the duration of immobilization and restricted weight bearing with surgical as well as nonoperative management. Consequently, evidence is emerging to suggest that when either approach to management includes accelerated rehabilitation, outcomes, including rerupture rates, are similar.[89,149] Both patient and surgeon, therefore, must weigh the different advantages and disadvantages of surgery and nonoperative treatment in the decision-making process.

Indications for Surgery

The following are frequently cited indications for surgical repair or reconstruction of an acute or chronic rupture of the Achilles tendon.

- Acute, complete rupture of the Achilles tendon[8,14,15]
- Typically indicated for the elite athlete or active individual who wishes to return to high-demand functional activities[4,15,78,151]
- Chronic, previously undiagnosed or untreated complete rupture in which end-to-end apposition cannot be achieved by conservative means[96,148]

Procedures

Primary versus Delayed Repair

There are a considerable number of surgical procedures and techniques for repair or reconstruction of a ruptured Achilles tendon.[8,14,15,94,95,148,151] An open, minimally invasive, or percutaneous surgical approach can be used for a primary repair.[5,21,76,78,129] However, only an open approach is used for a delayed repair requiring reconstruction of the torn tendon.

Primary repair of an acute rupture is performed within the first few days after the injury and usually is carried out with a direct, end-to-end repair in which the ends of the torn tendon are re-opposed and sutured together.[8] The repair site may or may not be reinforced by some method of tissue augmentation. Delayed repair of a chronic rupture requires reconstruction and augmentation of the tendon most often by an autograft, or tendon transfer, or possibly an allograft.[96,148] Structures that may serve as a donor graft are the flexor hallucis longus, plantaris, or peroneus brevis tendons or a flap of fascia from the gastrocnemius muscle.

Operative Overview

Primary repair. With a percutaneous repair, the tendon ends are located and sutured together through several small puncture wounds that are made along the medial and lateral aspects of the Achilles tendon or through several small transverse incisions made directly over the tendon.[39,78] In an open primary repair, a posterior incision is made at the distal leg just medial to the Achilles tendon. Placing the incision medial of the tendon avoids possible damage to the sural nerve. The tendon ends are identified; frayed fibers are removed; and the ends re-opposed and sutured together.[8] A minimally invasive approach uses a less lengthy skin incision but provides the surgeon with a smaller visual field than with a fully open approach. The tendon end is identified and sutured and then guided subcutaneously to a boney drill hole for the repair.[5,88] In each of these approaches, the tendon is repaired while the ankle is maintained in a slightly plantarflexed or neutral position.

Delayed repair/reconstruction. With a tendon reconstruction, a second incision is made to harvest the donor graft. If, for example, the flexor hallucis longus (FHL) tendon is selected, an incision is made along the medial aspect of the sole of the foot at the midmetatarsal level. A sufficient portion of the FHL tendon is left distally, so the remaining portion can be sutured to the flexor digitorum longus tendon to retain active flexion of the first toe.[148] The harvested portion of the FHL tendon then is woven into and sutured to bridge the gap of the Achilles tendon ends.

Before closure, the ankle is moved through the ROM to assess the stability of the repair or reconstruction. A compression dressing and below-knee posterior splint are applied after closure with the ankle usually positioned in 15° to 20° of plantarflexion.[8,148] If immediate or very early postoperative weight bearing is to be allowed by the surgeon, the ankle is placed in a neutral position (0° of dorsiflexion), if possible, and stabilized with a rigid anterior splint.[58]

NOTE: An above-knee cast is applied (and later replaced with a below-knee cast) if the rupture occurred at the myotendinous junction or the quality of the repair is tenuous.[8]

Complications

Complications associated with surgical repair or reconstruction of a ruptured Achilles tendon that may negatively affect postoperative outcomes are summarized in Box 22.6.[15,61,88,92,93,149,151] A meta-analysis of randomized controlled trials revealed that one-third of patients experience some type of complication following open repair of a ruptured Achilles tendon.[61] The risk of complications associated with operative management decreases with minimally invasive and percutaneous approaches compared with an open approach for repair.[88]

Of the complications noted in Box 22.6, rerupture and severe wound infection have the greatest negative impact on long-term postoperative outcomes. For example, patients who experience reruptures after repair are most likely to discontinue or change postrehabilitation sports activities.[88] It is important to note that some complications, including tendon rerupture, DVT, decreased ankle ROM, and impaired strength or endurance of the plantarflexors, also occur with nonoperative treatment of Achilles tendon ruptures, particularly when

BOX 22.6 Complications Following Primary Repair of a Ruptured Achilles Tendon

- Tendon rerupture or failure of the tendon to heal (palpable gap)
- Wound complications: infection, delayed healing of the incision
- Sural nerve injury leading to altered sensitivity of the lateral border of the foot
- Adherent or hypertrophic scarring
- Deep vein thrombosis or pulmonary embolism
- Restricted ankle ROM as the result of joint hypomobility or soft tissue adhesions or contractures, leading to impaired function, such as difficulty ascending or descending stairs due to limited dorsiflexion
- Strength and muscular endurance deficits, typically of the plantarflexors
- Pain at the site of a suture knot
- Complex regional pain syndrome (rare)

the injury is managed with an extended period of cast or brace immobilization in plantarflexion and restricted weight bearing.[15,61,92,93,151]

Postoperative Management

Guidelines for postoperative rehabilitation after a primary open repair of an acute Achilles tendon rupture vary considerably in the literature and clinical practice. These guidelines tend to fall within two categories: (1) use of a traditional (conventional) management strategy or an early remobilization and/or (2) weight-bearing approach, sometimes referred to as accelerated functional rehabilitation.[149] The duration of continuous immobilization and the initiation of weight bearing distinguish one approach from the other.

Guidelines for management after percutaneous repair vary as well and are often quite similar to postoperative guidelines following open repair or reconstruction. Therefore, specific guidelines for percutaneous repair are not addressed in the following sections but can be found in other resources.[21,39,76,78,129]

Immobilization and Weight-Bearing Considerations: Conventional versus Early Remobilization Approaches

Conventional approach. After an open primary repair of an acute Achilles tendon rupture, conventional postoperative management, a widely used practice for many years, involves approximately 6 weeks of continuous immobilization with the ankle held in plantarflexion at least a portion of that time.[4,8,15,39,90,92] The patient remains nonweight-bearing on the operated extremity during most or all of this time. After a delayed tendon reconstruction with graft augmentation for a chronic rupture, the duration of time before motion and weight bearing are initiated is longer, usually an additional 2 weeks or more.[148]

Table 22.2 summarizes immobilization and weight-bearing guidelines associated with conventional management

TABLE 22.2 Conventional Postoperative Management After Achilles Tendon Repair or Reconstruction with Graft*

Postoperative Time Period	Type and Position of Ankle Immobilization	Weight-bearing Guidelines
From 0–4 weeks		
	■ Compression dressing and posterior splint set in equinus removed a few days to a week postoperatively ■ Compression dressing replaced with a below-knee cast or fixed hinge boot/brace; foot held in 15° to 30° plantarflexion ■ At 2–3 weeks, new cast applied or boot adjusted in less plantarflexion	■ Nonweight-bearing ■ Ambulation with crutches
At 4 weeks		
	■ If an equinus cast was used, it is removed and replaced with a walking cast with ankle positioned in neutral ■ Alternative: a controlled ankle motion (CAM) brace, which may or may not allow active plantarflexion but limits dorsiflexion to 0° ■ Continuous immobilization in cast or very limited motion in brace for an additional 2–4 weeks	■ Nonweight-bearing continued or touch-down weight bearing initiated while wearing immobilizer ■ Weight bearing progressed as tolerated
At 6–8 weeks		
	■ If walking cast used previously, replaced with CAM brace allowing dorsiflexion beyond neutral ■ Active ROM exercises initiated while in brace	■ Full weight bearing wearing functional brace; transition to shoe with 1.0- to 1.5-cm heel lift for an additional 2–4 weeks or more
Beyond 12 weeks		
	■ Functional brace gradually discontinued by 12 weeks** ■ Brace use or ankle taping may be necessary for return to high-demand sports	■ Full weight bearing in regular shoes without lift, if ankle is pain-free and 10° dorsiflexion beyond neutral attained

*All time periods are approximately 2 weeks longer after reconstruction with tendon graft.
** Immobilizer may be worn during ambulation for a longer period of time if wound healing is delayed or the quality of the repair is tenuous.

after primary Achilles tendon repair.[4,8,15,92,133] Although this approach is safe and associated with a low risk of rerupture, extended immobilization, traditionally thought to be necessary to protect the healing tendon, has been shown in some studies to lead to deficits in strength, particularly in the plantarflexors, and loss of ROM of the ankle.[13,90,94,129]

Early remobilization and weight-bearing approach. For the past two decades or more, there has been a trend to decrease the period of continuous postoperative immobilization and to initiate early ankle ROM in a protected range and early weight bearing in a functional orthosis.[13,45,58,79,81,89,94,95,111,126,133,149] An accelerated rehabilitation approach is an option after primary repair of an acute rupture—but not after a delayed reconstruction. Early motion and weight bearing are possible because of advances in surgical procedures, such as stronger suturing techniques and materials and sometimes the use of soft tissue augmentation to reinforce the primary repair.[14,58,79,81,89,94,95,126,133,149]

Although published recommendations for accelerated functional rehabilitation following open repair vary widely, hallmarks of this approach include a very brief period (1 to 2 weeks) of continuous immobilization in a cast or splint followed by early ankle and weight bearing in a below-knee (boot-like) functional brace or dorsal or posterior splint. If bracing is prescribed, it often is a hinged, controlled ankle motion (CAM) orthosis that can be locked in various positions.[111] The orthosis is adjusted to allow movement but only in a protected range, typically limiting dorsiflexion beyond neutral.[13,45,92] If a rigid dorsal splint is used, its configuration limits dorsiflexion to 0° but allows plantarflexion.[58,79]

Initially, the brace or splint holds the ankle in plantarflexion but is adjusted (or refabricated in the case of a splint) to neutral or less plantarflexion by 2 weeks postoperatively.[45,79,89,133,149] During the first 6 weeks of rehabilitation, the protective orthosis is worn during ambulation with progressive weight bearing and at all other times except when removed for wound care and select exercises.

When the patient is able to ambulate on level surfaces without pain while bearing full weight on the operated extremity, the protective boot or splint is gradually discontinued (usually by 8 to 10 weeks postoperatively). As with a conventional approach, after discontinuing the functional brace or splint, many surgeons prescribe a 1.0- or 1.5-cm heel lift for both shoes. The lifts are worn for several weeks to decrease ground reaction forces during functional activities.[94]

The guidelines for initiating and progressing weight bearing and ankle ROM recommended in published programs differ from study to study. A summary of these guidelines is presented in Box 22.7.[58,79,89,111,133,149] Common to all early remobilization programs is the use of safe levels of applied stress while protecting the healing tendon. Close communication among the surgeon, therapist, and patient is essential for success with this approach to postoperative management.

BOX 22.7 Features of Early Weight-bearing and Remobilization Programs After Repair of Acute Achilles Tendon Rupture*

Weight-bearing Guidelines

- Initiated as tolerated while using crutches immediately after surgery[58,79] or after 1 or 2 weeks[89,92,111,133,149] in a below-knee orthosis with the ankle immobilized most often in plantarflexion or possibly neutral
- Progress gradually to full weight-bearing status between 3 to 6 weeks postoperatively[58,111,133,149]
- Orthosis worn during all weight-bearing activities for 6 to 8 weeks after surgery[111,133]
- Full weight bearing without the functional orthosis but wearing regular shoes with bilateral heel lifts when orthosis discontinued beginning at about 6 to 8 weeks postoperatively[58,130,133]

ROM Exercises

- Immediately[58,79,81,126] or by 1 to 2 weeks[92,111,130,133,149] after surgery, active plantarflexion and dorsiflexion of the operated ankle initiated while wearing a functional brace or splint to prevent dorsiflexion beyond 15° to 20° of equinus or to no more than a neutral position
- During the first 4 to 6 weeks and with the orthosis removed, ankle inversion and eversion while maintaining the ankle in plantarflexion[149]
- By 6 to 8 weeks, dorsiflexion to 10° beyond neutral permitted in the orthosis and inversion/eversion out of the orthosis[58,92]

* During the first 6 postoperative weeks, all ankle ROM exercises are performed while seated or supine. Beyond 6 to 8 weeks postoperatively, guidelines are similar for early remobilization and conventional (traditional) programs.

FOCUS ON EVIDENCE

Although there have been few randomized studies directly comparing a functional bracing or splinting and early motion and weight-bearing program after acute Achilles tendon repair with a program of extended cast immobilization (usually 6 weeks) followed by ROM exercises, a recent meta-analysis of these studies demonstrated that patients managed with an early motion/functional bracing program had a significantly lower rate of adhesion formation and limited ankle ROM. However, the investigators noted that the pooled data from the available studies must be interpreted with caution because of the variety of postoperative regimens used.[61]

After that review was published, Suchak and colleagues[133] reported results of a randomized controlled trial in which 110 patients were assigned to one of two groups following open primary repair for acute Achilles tendon rupture. All patients wore a posterior splint set in plantarflexion and ambulated nonweight-bearing with crutches for 2 weeks after surgery. Then, all patients wore a fixed-angle, hinged

ankle-foot orthosis until 6 weeks after surgery. One group was allowed to begin weight bearing (as tolerated) in the orthosis at 2 weeks after surgery; the other group remained nonweight-bearing through the sixth postoperative week and then was permitted to begin weight bearing as tolerated in the orthosis. Both groups gradually discontinued use of the orthosis after 6 weeks and then began a progressive home exercise program.

In addition to a baseline assessment, follow-up evaluations were carried out at 6 weeks, 3 months, and 6 months postoperatively. Outcomes assessed were physical activity level and health-related quality of life (by means of a self-report assessment tool), ankle ROM, calf muscle strength and endurance, return to work, and complications. At 6 weeks, the early weight-bearing group reported significantly better levels of physical and social functioning and patient satisfaction than the nonweight-bearing group based on the quality of life questionnaire. At 6 months, there were no significant differences between groups for any of the outcomes measured. Rerupture did not occur in either group. However, at 6 months, both groups continued to exhibit decreased calf muscle endurance compared with the contralateral side. This study demonstrated that weight bearing initiated during the early postoperative period after tendon repair contributes to a better quality of life and daily activity level without adverse consequences.

Exercise Progression

After open, primary repair of an acute Achilles tendon rupture, the types of exercise included in a postoperative program are similar regardless of whether an early motion/early weight-bearing approach or a conventional (extended immobilization/delayed motion and weight bearing) approach is employed. What is different is the timing and progression of the exercises based on when ROM and weight bearing are permissible.

In the phases of rehabilitation that follow, a progression of exercises designed to help a patient achieve a number of treatment goals and ultimately function at the pre-injury level is presented. The time frame for the initiation of weight bearing on the operated extremity and ankle ROM and the resumption of pre-injury work-related and sports activities must be determined by the surgeon.

Exercise: Maximum Protection Phase

Achilles tendon repair frequently is performed on an outpatient basis. Therefore, patient education is essential before surgery or prior to discharge. It focuses on wound care (if the immobilizer is removable), controlling peripheral edema by elevating the operated leg, gait training, and a home exercise program.

Goals and interventions. The following treatment goals and exercise interventions are appropriate during the first 4 to 6 weeks after surgery.

- ***Maintain ROM of nonimmobilized joints.*** In a seated, supine, or prone position, perform active ROM of the hip, knee, and toes of the operated side while wearing the immobilizer.
- ***Prevent reflex inhibition of immobilized muscle groups.*** If early ROM is not permitted, begin submaximal, pain-free, muscle-setting exercises of the ankle in the immobilizer within the first few days after surgery. Start with setting exercises of the dorsiflexors, invertors, and evertors. At 2 weeks, add setting exercises of the plantarflexors.
- ***Prevent joint stiffness and soft tissue adhesions in the operated ankle and foot.*** If an early motion and weight-bearing approach was planned, begin the ROM exercises within a few days to 2 weeks after surgery as determined by the surgeon (see Box 22.7).
- ***Begin to restore balance reactions in standing.*** If partial weight bearing on the operated limb is permitted, perform weight-shifting activities in *bilateral* stance *while wearing the orthosis*. Use the parallel bars or another stable surface (countertop, table) for upper extremity support as needed.
- ***Maintain cardiopulmonary fitness.*** Use an upper extremity ergometry for endurance training, if available.

Exercise: Moderate Protection Phase

At the end of 4 weeks or more often after 6 weeks postoperatively, the patient typically is permitted to bear weight as tolerated on the operated extremity regardless of whether an early weight-bearing program or conventional program was implemented. However, a functional CAM orthosis or another type of ankle-foot orthosis is worn during progressive weight-bearing activities. Weaning from the orthosis begins at about 6 to 8 weeks and is discontinued by 12 weeks after surgery.[133,149] As the patient is weaned from the orthosis, it may be necessary to resume using a cane or crutches for a period of time even if the patient had been ambulating without an assistive device while wearing the orthosis.

During this phase of rehabilitation, which begins at about 4 to 6 weeks and extends to 12 weeks after surgery, the stress placed on the operated tendon and surrounding structures is gradually increased. Patients typically begin a supervised exercise program at this time. Precautions for progressing exercises and functional activities are noted in Box 22.8.[133,149]

Goals and interventions. The following goals and exercises are implemented during the intermediate phase of rehabilitation.

- ***Increase ROM of the operated ankle with joint mobilization and stretching techniques.***
  - Grade III joint mobilization techniques if ankle or foot joints are restricted.
  - Gentle self-stretching exercises, such as a towel stretch in a sitting position, to increase ankle dorsiflexion with the knee extended and slightly flexed.
  - Gentle manual self-stretching to increase inversion/eversion and dorsiflexion/plantarflexion and toe extension.
  - Gentle active ankle ROM with patient seated and foot on a wobble or rocker board.
  - Self-stretching to increase dorsiflexion by standing on a wedge in bilateral stance with knees flexed and extended.

BOX 22.8 Precautions and Guidelines for Exercise and Functional Activities Following Achilles Tendon Repair*

General Precautions
- Progress all exercises very cautiously that place resistance or a stretch on the gastrocnemius-soleus muscle group.
- Postpone all *unilateral* weight-bearing exercises on the operated side until full weight bearing *without pain* is possible.

Stretching to Increase Ankle Dorsiflexion
- Begin with nonweight-bearing stretches, such as a towel stretch
- Limit dorsiflexion to no more than 10° beyond neutral until 8–12 weeks after surgery
- Initiate weight-bearing stretches in *sitting* with feet on the floor or a rocker board
- Begin standing stretches in *bilateral* stance, such as standing on a wedge, only if pain-free
- Postpone *unilateral* standing stretches or bilateral standing stretches with heels over the edge of a step until advanced activities are permitted (after 12 to 16 weeks) postoperatively.

Resistance Exercises
- Begin strengthening exercises for ankle and foot musculature in nonweight-bearing positions against low-loads (light-grade elastic resistance) before progressing to closed-chain exercises against body weight.
- Cautiously progress heel raising/lowering exercises for closed-chain calf muscle strengthening. (See suggested sequence in Box 22.9.)
- Postpone *unilateral* heel raising/lowering against full body weight until about 12 weeks postoperatively.

Advanced Training (Plyometric, Agility, Sport-Specific Training)
- Begin plyometric training in a pool (chest-deep progressing to waist-deep immersion).
- Postpone land-based plyometric training and activities that involve high-impact and quick acceleration/deceleration and changes of direction until about 16 weeks postoperatively.
- Teach the patient correct landing technique for proper alignment during jumping and hopping exercises.
- Wear a prescribed functional ankle-foot orthosis or tape the ankle during high-impact, high-velocity activities to minimize the risk of rerupture of the repaired tendon.

* Precautions are applicable to conventional and early ROM/weight-bearing approaches to rehabilitation.

- Postpone *unilateral* standing stretches of plantarflexors until the end of this phase of rehabilitation (about 10 to 12 weeks postoperatively).

- ***Improve strength and muscular endurance of the operated lower extremity.*** Initiate a progression of open- and closed-chain, *low-load, high repetition* resistance exercises at 6 to 8 weeks. Emphasize controlled, *eccentric* loading of the plantarflexors. Perform closed-chain exercises without the orthosis as its use is gradually discontinued. Examples of resistance exercises include:
  - Open-chain resistance exercises for the hip, knee, and ankle musculature against a light grade of elastic resistance.
  - Closed-chain exercises, such as bilateral progressing to unilateral heel raising and lowering *while seated*.
  - *Standing* heel raising/lowering in bilateral stance against the resistance of body weight. (See Box 22.9 for a suggested sequence of heel raising/lowering exercises.) Postpone heel raises in unilateral stance until about 12 weeks after surgery.[133]
  - Partial lunges with the involved leg forward, bilateral mini-squats, and toe raises.
  - Using handheld weights, a weighted backpack, or a weight belt to add resistance to standing exercises.

CLINICAL TIP

A resistance training program should focus on improving muscular endurance as well as strength. Substantial deficits in muscular endurance of the calf muscles of the operated limb compared with the contralateral limb (as determined by the number of unilateral heel raises performed in standing) have been identified in men more than women and have been shown to persist for at least a year after surgical repair of Achilles tendon ruptures. It has been suggested that the presence of *resting* pain in the Achilles tendon at 3 months postoperatively may be an early indicator of delayed muscular endurance at one year.[6]

- ***Improve balance reactions.*** While wearing the functional orthosis, initiate or continue proprioceptive/balance training in bilateral stance on a firm surface. Progress to soft surfaces and narrow the base of support.
  - While continuing to wear the orthosis, progress to balance training in *unilateral* stance when full weight bearing is tolerated on the operated side.
  - Transition to a sequence of more advanced balance exercises in supportive shoes (usually with a heel lift inserted) after use of the functional bracing has been discontinued.
- ***Reestablish a symmetrical gait pattern.*** When full weight bearing is comfortable and as the patient is weaned from the orthosis, begin gait training, emphasizing symmetrical alignment and weight shifting as well as equal step lengths and timing, paying particular attention to push-off on the operated side.
- ***Improve cardiopulmonary endurance.*** Begin and gradually progress level-surface treadmill walking or stationary cycling (recumbent or upright) while wearing the functional,

hinged orthosis, if required, or regular shoes with a heel lift. Raise the seat height of the upright bicycle to accommodate for limited dorsiflexion. Progress to treadmill walking on an incline.

Exercise: Minimum Protection/Return to Function Phase

The final phase of rehabilitation, which begins around 12 to 16 weeks postoperatively, is directed toward returning a patient to a pre-injury level of function for expected work-related demands and desired recreational/athletic activities. Stretching exercises continue until full ROM is achieved, and then the patient transitions to a maintenance program.

Strength and muscular endurance training is continued, emphasizing eccentric loading of the gastrocnemius-soleus muscle group with heel-lowering exercises in *unilateral* stance (see Fig. 22.17) or with resistance equipment. Descending stairs step over step also imposes eccentric loading. Depending on the patient's pre-injury activity level, plyometric training can be initiated in a pool, if available, at the beginning of this phase (see Chapter 23). A variety of activities on a level surface can now be used for cardiopulmonary conditioning as well.

After 16 weeks postoperatively,[89,149] begin land-based plyometric training and treadmill walking on an incline. Advance to jogging, running, agility drills (cutting, pivoting), and sport-specific training. Patient education is a priority and focuses on ways to reduce the risk of rerupture of the repaired tendon, such as warming up before strenuous activity and daily stretching. If the strength of the operated extremity is relatively comparable to that of the contralateral extremity, most patients are permitted to resume athletic activities gradually by 5 to 6 months.[8,79,92]

Outcomes

The ideal outcome is for a patient to return to a pre-injury level of physical activity without pain or rerupture of the repaired Achilles tendon. Patients undergoing primary repair of an acute rupture have consistently better outcomes than those who undergo a delayed repair for a chronic rupture. The longer the delay between injury and repair, the poorer the results.[148] The patient population with the highest risk of rerupture after primary repair of an acute rupture is active individuals 30 years of age or younger.[111]

The results of numerous studies comparing methods of management of acute tendon ruptures have been reported. Methods compared include operative and nonoperative management, open and percutaneous procedures, and conventional (traditional) and "accelerated rehabilitation" (early motion/early weight bearing) approaches to postoperative treatment. Outcomes typically reported are rate of rerupture, ROM, strength, functional or sport-related activity level, and patient satisfaction. Some generalizations can be drawn from systematic reviews of the literature and individual studies.

Nonoperative versus operative management. When comparing outcomes of nonoperative (cast immobilization) with operative management of acute ruptures, three systematic reviews and meta-analyses of the literature have revealed that there is a significantly higher rate of rerupture associated with nonoperative management than with surgical repair.[4,61,151] The authors of one of these reviews of randomized trials concluded that there is a three times higher risk of rerupture after nonoperative treatment than after surgery. However, excluding rerupture, operative management is associated with a substantially higher rate of complications than nonoperative treatment, including infection, adhesions, and nerve injury.[61] The authors of another one of the reviews noted that when patients who sustain a rerupture are excluded from an analysis of outcomes of nonoperative and operative management, long-term results, including activity level, ROM, and strength, are similar.[4]

Two recent randomized, controlled trials[89,149] directly compared outcomes of surgical and nonoperative approaches to treatment of acute Achilles tendon ruptures with all groups participating in accelerated functional rehabilitation programs postoperatively. Results of these two studies demonstrated no significant differences in outcomes (rerupture rates, ankle ROM, calf muscle strength, or overall functional assessment) between treatment groups in either study. Moreover, there were significantly fewer complications in the nonoperative groups in both studies.

Open versus percutaneous repair. A systematic review of the literature demonstrated that, overall, fewer complications occur with percutaneous versus open repairs. More specifically, complications develop in 10% of patients following percutaneous repair compared with approximately one-third of patients after open repair.[61] However, there is no significant difference in the rate of rerupture between the two techniques. A higher rate of wound complications occurs with open repair.[39,76] The cosmetic result, not surprisingly, is better with a percutaneous approach, but a higher rate of sural nerve damage occurs when compared with an open approach.[151] Postoperative ankle ROM and calf muscle strength are comparable between the two approaches, but return to work typically occurs more quickly when a percutaneous approach is used.

Traditional versus accelerated rehabilitation. Post-injury management that includes "accelerated rehabilitation" (early but protected motion and/or weight bearing) appears to be as safe as management with prolonged cast or fixed-hinge brace immobilization and delayed weight bearing. Follow-up studies have demonstrated that accelerated rehabilitation does not increase the incidence of tendon rerupture.[13,59,79,81,89,94,149] In addition, the complications associated with prolonged immobilization, such as DVT and decreased ankle ROM and calf muscle strength, occur less often with accelerated rehabilitation. It remains unclear, however, whether early motion and weight bearing enable a patient to return to a full, pre-injury level of functional activity sooner than if managed with a conventional postoperative approach.[59,81,94]

In summary, there continues to be controversy as to whether surgical or nonoperative treatment is the better

option for management of acute Achilles tendon ruptures. Regardless of which treatment option is selected, it is apparent from the literature that early but protected ankle motion and weight bearing are becoming the standard of care for rehabilitation.[90]

Exercise Interventions for the Ankle and Foot

Exercise Techniques to Increase Flexibility and Range of Motion

Loss of flexibility in the ankle and foot can result from a variety of causes. Restoration of motion may be necessary to correct alignment or for normal biomechanics during walking and running. Joint mobilization techniques are used to increase accessory motion of the joint surfaces. These techniques are described in detail in Chapter 5. Manual passive stretching and PNF stretching techniques are described in Chapter 4. Self-stretching techniques to improve flexibility and ROM are the emphasis of this section.

Flexibility Exercises for the Ankle Region

Increase Dorsiflexion of the Ankle

The muscles that restrict dorsiflexion of the ankle are the one-joint soleus and the two-joint gastrocnemius. To effectively stretch the gastrocnemius, the knee must be extended while dorsiflexing the ankle. To isolate stretch to the soleus, the knee must be flexed during dorsiflexion to take tension off the gastrocnemius. Most of the following stretching exercises can be adapted with the knee in flexion or extension, so both of the plantarflexor muscles can be stretched.

PRECAUTION: When a patient uses weight-bearing exercises to stretch the plantarflexor muscles, shoes with arch supports should be worn or a folded washcloth placed under the medial border of the foot to minimize the stress to the arches of the foot.

FOCUS ON EVIDENCE

In a study of 30 subjects, 15 with pes planus and 15 with neutral foot alignment, the effects of weight-bearing dorsiflexion stretches on the displacement of the myotendinous junction of the medial gastrocnemius, rearfoot angle, and navicular height were measured. Results showed a significantly greater displacement (elongation) at the myotendinous junction when the arch was supported in both groups, with a greater displacement occurring in subjects with pes planus. When the subjects with pes planus stretched without arch support, there was a significant increased rearfoot angle and drop in navicular height.[56]

- *Patient position and procedure:* Long-sitting (knees extended) or with the knees partially flexed. Have the patient strongly dorsiflex the feet, attempting to keep the toes relaxed.
- *Patient position and procedure:* Long-sitting or with the knee partially flexed and with a towel or belt looped under the forefoot. Have the patient pull with equal force on both ends of the towel to move the foot into dorsiflexion.
- *Patient position and procedure:* Sitting with the foot flat on the floor. Have the patient slide the foot backward, keeping the heel on the floor.
- *Patient position and procedure:* Standing. Have the patient stride forward with one foot, keeping the heel of the back foot flat on the floor (the back foot is the one being stretched). If necessary, have the patient brace his or her hands against a wall. To provide stability to the foot, the patient partially rotates the back leg inward so the foot assumes a supinated position and locks the joints. The patient then shifts body weight forward onto the front foot. To stretch the gastrocnemius muscle, the knee of the back leg is kept extended; to stretch the soleus, the knee of the back leg is flexed.
- *Patient position and procedure:* Standing on an inclined board with feet pointing upward and heels downward (Fig. 22.9). Greater stretch occurs if the patient leans forward. Because the body weight is on the heels, there is little stretch on the long arches of the feet. Little effort is required to maintain this position for extended periods.
- *Patient position and procedure:* Standing, with the forefoot on the edge of a step or stool and heel over the edge. Have the patient slowly lower the heel over the edge (heel drop).

FIGURE 22.9 Self-stretching the ankle to increase dorsiflexion (stretching the gastrocnemius muscle).

PRECAUTION: This stretch may create muscle soreness, because it requires that the patient control an eccentric contraction of the plantarflexors.

Increase Inversion

- *Patient position and procedure:* Sitting, with the foot to be stretched placed across the opposite knee. Have the patient grasp the mid- and hindfoot with the opposite hand and lift the foot into inversion. Emphasize turning the heel inward, not just twisting the forefoot.
- *Patient position and procedure:* Long-sitting with a towel or belt looped under the foot. Have the patient pull on the medial side of the towel to cause the heel and foot to turn inward (Fig. 22.10). This technique also can be used to turn the foot outward by pulling on the lateral side of the towel. It is important that the motion includes the heel, not just the forefoot.

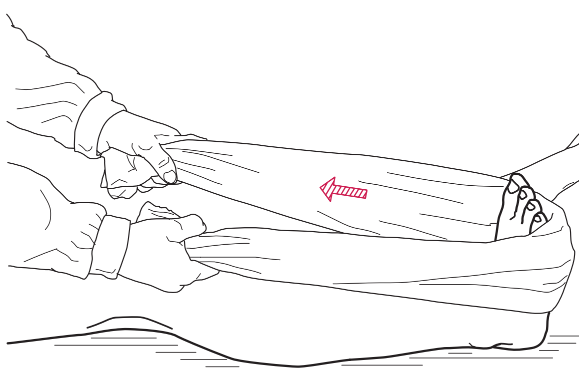

FIGURE 22.10 Self-stretching the foot into inversion by pulling on the towel on the medial side of the foot.

- *Patient position and procedure:* Sitting or standing, with feet pointing forward. Have the patient roll to the lateral border of each foot so the soles are turned inward.
- *Patient position and procedure:* Standing or walking, with the involved foot on a slanted board, placing the lateral aspect of the foot to be stretched on the lower side of the board. Bilateral stretching can be accomplished if hinged planks are placed in an inverted-V position and the patient stands or walks on them.

Increase Ankle Plantarflexion and Eversion

It is uncommon for plantarflexion and eversion to be restricted, because gravity plantarflexes the foot in the supine position, and the body's weight everts the foot in the standing position. Eversion, which is a component of pronation, is the loose-packed position of the foot and is perpetuated with weight bearing. The exception for restricted talocrural plantarflexion is when there is a capsular pattern at the joint as a result of arthritis. If the restriction is from joint hypomobility, it is treated with joint mobilization techniques.

Increase Eversion and Ankle Dorsiflexion

Patient position and procedure: Long-sitting with a towel or belt looped under the foot. Have the patient pull on the lateral side of the towel to cause the heel and foot to turn outward.

Flexibility Exercises for Limited Mobility of the Toes

Tight extrinsic muscles of the toes occur with claw toes and hammer toes, causing the MTP joints to extend and the IP joints to flex. There is often weakness of the intrinsic muscles. To stretch the intrinsic muscles, emphasize *MTP flexion* and *IP extension.*

Passive MTP Flexion

Patient position and procedure: Sitting with the foot crossed onto the opposite knee. Show the patient how to stabilize the foot under the metatarsal heads (MTP joints) with the thumbs, and passively flex the MTP joints by applying pressure against the proximal phalanges. Or, have the patient attempt active flexion of the MTP joints, assisting the motion if necessary.

Passive IP Extension

Patient position and procedure: Sitting with the foot crossed onto the opposite knee. Teach the patient to stabilize the proximal phalanx of the involved toe and passively stretch the long flexors across each joint by moving the middle and/or distal phalanx into extension.

Active MTP Flexion

Patient position and procedure: Standing with the toes over the edge of a stool or book and the MTP joints at the edge. Have the patient attempt to flex the MTP joints over the edge of the stool. Ideally, the patient should try to keep the IP joints of the toes extended, but many individuals cannot do this.

Great Toe Extension

Extension of the great toe at the MTP joint is critical during the push-off phase of gait. In addition to joint mobilization techniques, passive stretching and self-stretching techniques should be used.

- *Patient position and procedure:* Sitting with the foot resting on the opposite knee. Show the patient how to stabilize the foot around the head of the first metatarsal with one hand and passively *extend* the MTP joint by applying pressure against the proximal phalanx.
- *Patient position and procedure:* Sitting with the feet placed on the floor. Have the patient slide the foot to be stretched backward by flexing the knee while keeping the toes on the floor and raising the heel off the floor.
- *Patient position and procedure:* Standing with the involved foot in a backward stride position. The patient may lean his or her hands against a wall for support. Have the patient keep the toes on the floor and rock forward lifting the heel until a stretch is felt under the first toe. A sustained stretch or a gentle rocking stretch can be used.

Stretching the Plantar Fascia of the Foot

- *Patient position and procedure:* Sitting with the foot placed across the opposite knee. Teach the patient to use his or her thumbs to apply deep massage horizontally and longitudinally across the plantar surface of the foot.
- *Patient position and procedure:* Sitting with a ball, small roller, or plastic bottle under the foot. Have the patient roll the foot forward and backward across the curved surface, using as much pressure as is comfortable. Pressing down on the knee with one or both hands can exert additional force.

Exercises to Develop and Improve Muscle Performance and Functional Control

Causes of strength and flexibility imbalances of the ankle and foot include disuse, immobilization, nerve injury, and progressive joint degeneration. In addition, imbalances occur from the weight-bearing stresses that are imposed on the feet. Imbalances can be the cause or the effect of faulty lower extremity mechanics. Because the lower extremities bear weight, realignment by strengthening exercises alone is of limited value. Strengthening exercises undertaken in conjunction with conscious correction, appropriate stretching, balance training, and other necessary measures (such as using orthotic inserts or adaptations for shoes, bracing, splinting, or surgery) improve alignment, so structurally safe weight bearing is possible. In addition, knowledge of the types of shoes used or surfaces encountered during walking or sports activities may be a lead to the source of faulty mechanics, which then can be adjusted. (Techniques of orthopedic adaptations for shoes, bracing, and splinting are beyond the scope of this text.)

Most functional demands on the ankle and foot occur in weight-bearing postures. Kinesthetic input from skin, joint, and muscle receptors and the resulting joint and muscle responses are different in open- and closed-chain activities.[32,74] Therefore, whenever possible, use of progressive weight-bearing exercises is important to simulate functional activities. In addition to the exercises described in this section, refer to Chapter 23 for total lower extremity functional exercises performed in the standing position that influence muscle control at the hip, knee, and ankle.

Exercises to Develop Dynamic Neuromuscular Control

- *Patient position and procedure:* Long-sitting or with the knees partially flexed. Have the patient practice contracting each of the major muscles while concentrating on his or her actions—for example, dorsiflexion with inversion (anterior tibialis), plantarflexion with inversion (posterior tibialis), and eversion (peroneus muscles).
- *Patient position and procedure:* Long-sitting or with the knee partially flexed. Instruct the patient to “draw” the alphabet in space, leading with the toes but moving at the ankle. For variety, have the patient “print” using capital letters, then with lower case letters, or “write” words such as his or her name or address.
- *Patient position and procedure:* Sitting on a chair or low mat table with feet on the floor. Place a number of small objects, such as marbles or dice, to one side of the involved foot. Have the patient pick up one object at a time by curling the toes around it and then place the object in a container on the other side of the foot. This exercise emphasizes the plantar muscles as well as inversion and eversion.
- *Patient position and procedure:* Sitting with feet on the floor or standing. Have the patient curl the toes against the resistance of the floor. Place a towel or tissue paper under the feet, and have the patient attempt to wrinkle it up by keeping the heel on the floor and flexing the toes.
- *Patient position and procedure:* Sitting, with the feet on the floor. Have the patient attempt to raise the medial longitudinal arch while keeping the forefoot and hindfoot on the floor. External rotation of the tibia—but not abduction of the hips—should occur. The activity is repeated until the patient has consistent control; then it is performed while standing as a progression.
- *Patient position and procedure:* Sitting with a tennis ball placed between the soles of the feet. Instruct the patient to roll the tennis ball back and forth from heel to forefoot.
- *Patient position and procedure:* Sitting with both feet or just the involved foot on a rocker or balance board. Have patient perform controlled ankle and foot motions (with or without the assistance of the normal foot) into dorsiflexion and plantarflexion and inversion and eversion (Fig. 22.11). If the equipment permits, the patient also

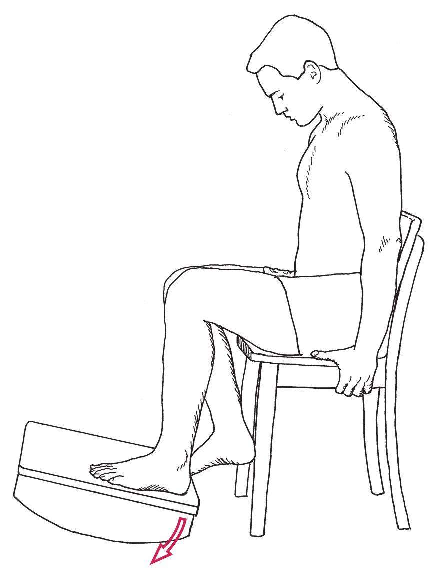

FIGURE 22.11 Using a rocker board to develop control of ankle motions with the patient sitting. When both feet are on the board, the normal foot can assist the involved side. With only the involved foot on the board, the activity is more difficult.

can perform circumduction in each direction. Progress this activity to the standing position to further develop control and balance.

- *Patient position and procedure:* Standing. Have the patient practice walking while concentrating on placement of the feet and shifting body weight with each step. The patient begins by accepting body weight on the heel, then shifting the weight along the lateral border of the foot to the fifth metatarsal head and across to the first metatarsal head and great toe for push-off.

Open-Chain (Nonweight-Bearing) Strengthening Exercises

Plantarflexion

Patient position and procedure: Long-sitting with the leg resting on a rolled towel to slightly elevate the heel off the treatment table. Have the patient hold both ends of an elastic band that is looped under the forefoot, then plantarflex the foot against the resistance (Fig. 22.12).

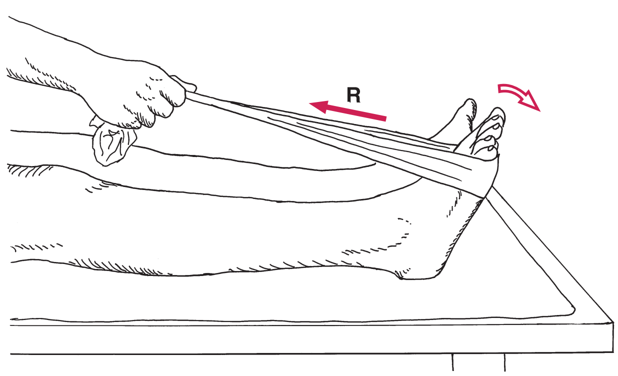

FIGURE 22.12 Resisting the ankle plantarflexor muscles with an elasticized material.

Isometric Eversion and Inversion

Patient position and procedure: Long-sitting or sitting in a chair with knees flexed.

- To resist *eversion*, the ankles are crossed; instruct the patient to press the lateral borders of both feet together against each other.
- To resist *inversion*, the medial borders of the feet are placed beside each other; instruct the patient to press the medial borders of the feet against each other.

Eversion and Inversion with Elastic Resistance

Patient position and procedure: Long-sitting, supine, or sitting with the feet resting on the floor.

- To resist *eversion*, place a loop of elastic tubing around both feet and have the patient evert one or both feet against the resistance (Fig. 22.13). Instruct the patient to keep the knees still and turn the foot outward, not allowing the thigh and leg to abduct or externally rotate.

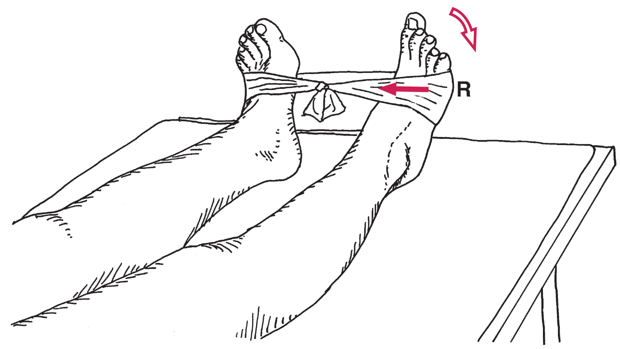

FIGURE 22.13 Resisting the evertor muscles of the foot with an elasticized material.

- To resist *inversion*, tie the elastic band or tubing to a structure on the lateral side of the foot. Again, have the patient keep the legs stationary and only turn the foot inward without allowing the hip to adduct and internally rotate.

Adduction with Inversion and Abduction with Eversion Using Weights

Patient position and procedure: Sitting with the foot on the floor. Place a towel under the forefoot and a weight on the end of the towel (Fig. 22.14). Have the patient pull the weighted towel along the floor with the forefoot by keeping the heel fixed on the floor and swinging the foot either inward or outward.

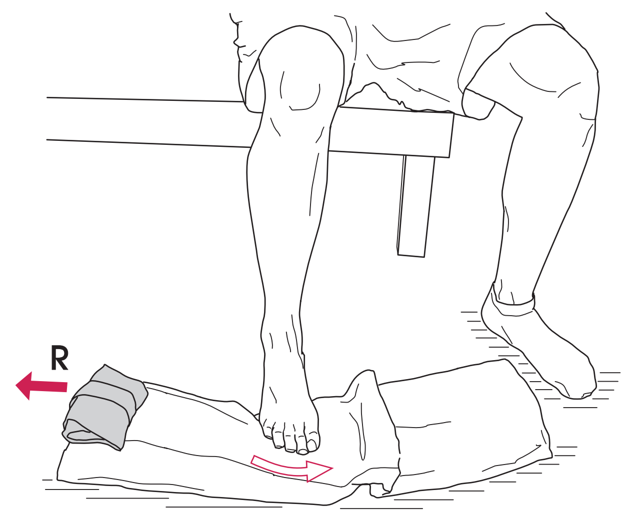

FIGURE 22.14 Resisting adduction and inversion with a weight on the end of the towel. The heel is kept stationary while a windshield wiper motion of the foot is used to pull the towel along the floor. Abduction with eversion is resisted by placing the weight on the towel on the medial side of the foot.

Dorsiflexion

Patient position and procedure: Long-sitting or supine with a rolled towel under the distal leg to elevate the heel slightly. Tie both ends of an elastic band or tubing to the foot board of a bed (or other object), and loop the elastic over the dorsum of the foot. Have the patient dorsiflex the ankle against the resistance (Fig. 22.15).

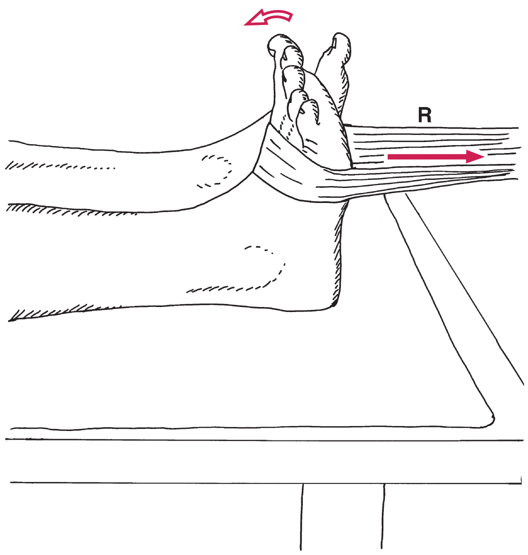

FIGURE 22.15 Resisting the ankle dorsiflexor muscles with an elasticized material.

All Ankle Motions

Patient position and procedure: Sitting in a chair or standing with one or both feet in a box filled with sand, foam, dry peas, dry beans, or other similar type material to offer resistance to various foot motions. Have the patient plantarflex, dorsiflex, invert, and evert the foot and ankle, and curl the toes with the foot on top or with the foot dug into the medium.

Closed-Chain (Weight-Bearing) Exercises

For these exercises, the patient position is standing. If the patient does not initially tolerate full weight bearing without reproduction of symptoms, begin with the patient standing in parallel bars using both hands for support, holding onto a stable object, harnessed into a body weight support system, or exercising in a pool to reduce weight-bearing forces. Progress from bilateral to unilateral stance. Refer to Table 6.9 for general guidelines for progression of closed-chain exercises.

Stabilization Exercises

Begin stabilization exercises for the ankle and foot in bilateral stance, progressing to unilateral stance and by standing on a flat, stable surface and later on less stable surfaces.

- Apply resistance to the patient's pelvis in various directions while he or she attempts to maintain control. At first, use verbal cues, then resist without warning. Also, increase the speed and intensity of the perturbation forces.
- Have the patient hold onto a wooden dowel rod or cane with both hands. Apply the resistance through the rod in various directions and with varying intensities and speeds as the patient attempts to remain stable (Fig. 22.16).
- Progress to standing only on the involved foot.

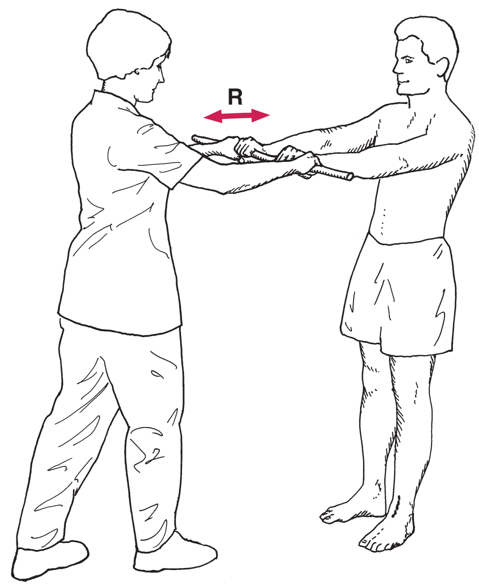

FIGURE 22.16 Stabilization exercises with the patient standing and maintaining balance against the alternating resistance forces from the therapist. The therapist applies force through the rod in backward/forward, side-to-side, and rotational directions.

- Have the patient stand on the involved leg and maintain a stable position of the ankle and foot while moving the opposite leg forward, backward, and to the side against the resistance of an elastic band or tubing secured around the ankle of the moving limb and a table leg (similar to Fig. 20.22).

Dynamic Strength Training

- Have the patient perform bilateral toe and heel raises and rock outward to the lateral borders of the feet. Progress to performing these exercises unilaterally. When tolerated, add resistance with a weighted backpack, weight belt, or handheld weights. A sequence for progressing heel raising and lowering exercises to strengthen the plantarflexors is noted in Box 22.9.

BOX 22.9 A Progression of Heel-Raising/Lowering Exercises for Calf Muscle Strengthening

- Begin in a *sitting* position with feet on the floor or a rocker board.
- Add resistance by crossing the thigh of one leg over the other thigh.
- Perform *standing* heel raising/lowering on a level surface in bilateral stance before progressing to unilateral stance.
- Perform heel raising/lowering exercises starting with heels over edge of a step.
- For additional challenge, use hand-held weights, a weighted backpack, or weight belt during standing heel raising/lowering.
- Progress to jumping, then hopping on level surfaces and then on and off a platform for explosive concentric and eccentric loading.

- For *eccentric loading* of the gastrocnemius-soleus muscle group without concentric loading of the affected ankle, have the patient perform the following sequence.[55] While positioned next to a stable surface (wall, countertop) using one hand for balance, have the patient stand on a low platform on the *sound* lower extremity; transfer body weight onto the ball of the foot of the *affected* side; and then slowly lower the foot to the floor (Fig. 22.17) using a lengthening contraction of the gastrocnemius-soleus muscle group. Repeat the sequence by stepping back onto the platform with the sound limb.

FIGURE 22.17 Eccentric loading of the gastrocnemius-soleus muscle group by performing heel lowering of the affected ankle.

CLINICAL TIP

A resistance training regimen that emphasizes eccentric loading of the ankle plantarflexors has been shown to decrease pain and increase physical functioning in patients with mid-position Achilles tendinopathy.[12] Eccentric loading, emphasizing heel-lowering exercises, has been investigated for management of insertional Achilles tendinopathy as well with promising results.[55]

Resisted Walking

- Have the patient walk on heels and on toes against resistance.
- Apply manual resistance against the patient's pelvis, or have the patient walk against a weight-pulley system or elastic resistance secured around the pelvis.
- Apply an elastic band around the ankle of the sound lower extremity and secure the band to a stable object.[43] While bearing weight on the involved lower extremity:
  - Bring the sound leg one step forward against the resistance of the elastic band to strengthen the ankle dorsiflexors of the weight-bearing limb (Fig. 22.18 A and B).

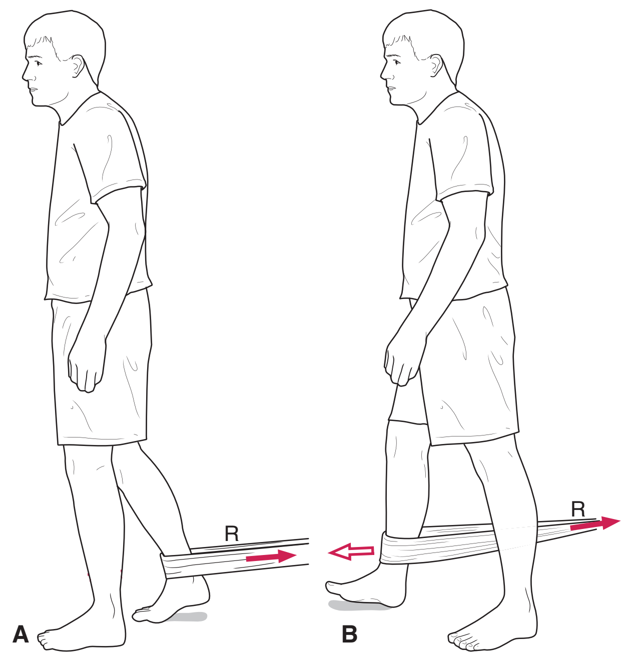

FIGURE 22.18 **(A)** Starting position for activation of the ankle dorsiflexors of the *weight-bearing limb* by moving opposite limb forward against resistance of an elastic band; **(B)** ending position.

  - Move the sound leg one step backward against the resistance of the elastic band to strengthen the ankle plantarflexors of the weight-bearing limb (Fig. 22.19 A and B).

Functional Progression for the Ankle and Foot

As with functional training for the hip and knee, implement a progression of exercises that prepares a patient recovering from structural or functional impairments of the ankle to return safely to as many necessary and desired occupational and

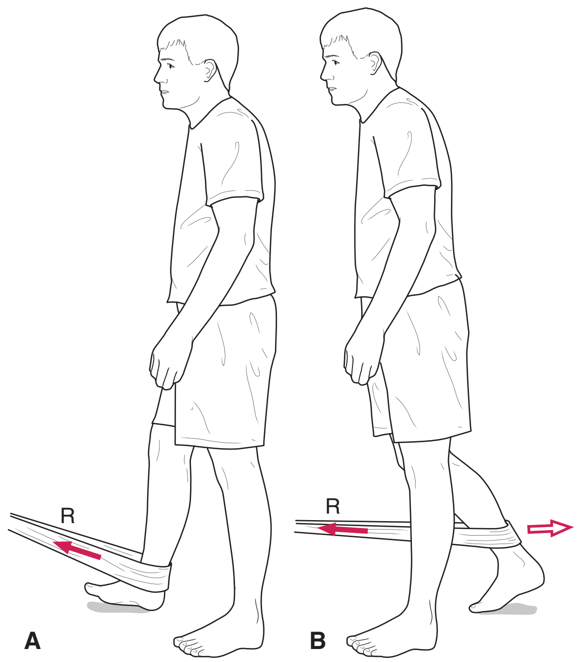

FIGURE 22.19 **(A)** Starting position for activation of the ankle plantarflexors of the *weight-bearing limb* by moving opposite limb backward against resistance of an elastic band; **(B)** ending position.

recreational activities as possible. To meet these challenges, a patient must develop sufficient strength, endurance, and flexibility as well as power, balance, coordination, agility, aerobic fitness, and task-specific skills. Refer to Chapters 7 and 8 respectively for principles of aerobic conditioning and balance training.

A functional progression of exercises for the ankle and foot must involve the entire body—lower extremities, trunk, and upper extremities. A variety of advanced stability, balance, strengthening, plyometric, and agility exercises that could be used for the patient with dysfunction of the ankle and/or foot are described and illustrated in Chapter 23. Some of the closed-chain strengthening exercises and functional progressions described in Chapters 20 and 21 are applicable as well (see Box 20.11).

Selected equipment also is valuable for improving function of the ankle and foot. Training on a stationary bicycle, treadmill, cross-country ski machine, or mini-trampoline is useful for developing endurance of ankle musculature. A slide board can be used to develop coordination, control, and dynamic ankle stability. Use of balance equipment, such as a rocker or wobble board or BOSU®, imposes a significant challenge on dynamic stabilizers of the ankle as does walking or running on uneven surfaces.

Independent Learning Activities

Critical Thinking and Discussion

1. Observe how the foot and ankle function as a unit in several activities, such as walking up steps, walking on uneven surfaces, and walking in high-heeled shoes versus low-heeled shoes.
   - What motions occur in the talocrural, subtalar, transverse tarsal, and metatarsophalangeal joints? Describe the mechanics.
   - What muscles are functioning, and what level of strength is needed to move or control each joint?
2. Describe the role of the ankle and foot during the gait cycle.
   - What ROM is needed at the ankle, and what muscles are acting to cause or control the motion? What other forces are causing or controlling motion at the ankle?
   - What gait deviations occur if there is muscle shortening or weakness at the ankle?
   - After a unilateral arthrodesis of the talocrural joint (ankle fused in neutral), what deviations will occur in the gait cycle?
   - Describe the mechanics and function of pronation and supination in the foot during the gait cycle. Explain how the gait cycle would be affected if a patient had flexible flat feet versus rigid supinated feet.
3. Compare and contrast an exercise program for a patient who has had a repair or reconstruction of torn lateral ligaments of the ankle versus a patient who has had a repair of a ruptured Achilles tendon. How will precautions and selection of exercises differ after these two types of surgical repairs?
4. Discuss the benefits and limitations of total ankle arthroplasty versus arthrodesis of the ankle.

Laboratory Practice

1. Review all the joint mobilization techniques for the leg, ankle, and foot; include basic glides, accessory motions, and mobilization with movement techniques.
   - Identify and practice techniques that you could use to increase ankle plantarflexion; begin with the ankle at zero, and progress at 15° increments until full plantarflexion is reached.
   - Do the same for ankle dorsiflexion, subtalar inversion and subtalar eversion, and metatarsophalangeal extension.

2. Set up a circuit-training course for the foot and ankle musculature to increase strength, muscular endurance, stability, balance, and neuromuscular reactions. Sequence the activities from basic to advanced, and observe accuracy and safety with each exercise. Identify other muscles in the lower extremity, trunk, or arms that are also being affected by the exercises.

Case Studies

1. Mr. C. has a 10-year history of rheumatoid arthritis. Currently, medication is managing his acute symptoms, so he is able to walk with a cane. His complaints are increased pain after walking 15 minutes and considerable stiffness along with generalized weakness. You observe his gait: he walks with a short step and has no push-off. Ankle ROM: dorsiflexion 10°, plantarflexion 15°, inversion 0°, eversion 8°. He stands with a pronated foot, has dorsal migration of the first phalanges and moderate hammer toes. He tolerates moderate resistance in all his musculature within the limited range, although he is unable to demonstrate toe walking or do bilateral toe raises even one time.
   - List his impairments and activity limitations and state his goals.
   - Develop a program of intervention to meet the goals. How will you initiate the intervention? What techniques will you use and how will you progress them?
   - Describe the rationale for each manual technique you would use and for each exercise you would teach the patient.
   - Identify any precautions you will use and that you will teach the patient.
2. Sally S., a college student, sustained a boot-top fracture of the tibia and fibula as the result of a fall while snow skiing. She was immobilized in a long-leg cast for 6 weeks, followed by a short-leg cast for 4 weeks. She was allowed partial weight bearing while wearing the short-leg cast. The cast was removed this morning. She described significant stiffness and discomfort when attempting to move her foot. Observation reveals atrophy in the calf, but no edema or joint swelling. ROM in the ankle and foot is minimal, and there is no gliding of the fibula at the proximal or distal tibiofibular joints. Strength could not be tested, although the patient can activate all muscles.
   - Answer the same questions posed in Case 1.
   - Even though both patients have restricted motion and demonstrate weakness, what are the differences in your intervention strategies and in the precautions you will follow?
   - How will you determine the progression of weight-bearing activities?
3. Ron W. is a 35-year-old computer programmer who plays basketball at the local recreation center. He sustained a massive inversion strain of his right ankle when landing on the foot of an opponent after jumping to rebound the basketball. He wrapped the ankle and iced it for 2 days. On the third day, he went for a radiograph. No fracture was detected, but he does have a grade II instability of the ATF ligament. Observation reveals swelling and discoloration of the anterior and lateral ankle region. He experiences a marked increase in pain with inversion and plantarflexion tests, anterior gliding of the talus, and palpation over the involved ligament. Because of muscle guarding, strength was not tested.
   - Identify structural and functional impairments, activity limitations, and participation restrictions; then determine goals and an intervention strategy for this patient.
   - Describe how his program will be progressed.
   - Ron wants to know how soon he can return to playing his favorite sport. What criteria will you use to make this judgment, and how will you protect his ankle when he does return?
4. Dr. A is a 43 year-old dentist with a relatively active lifestyle, who ruptured his (L) Achilles tendon during a weekend tennis match. At the time of the injury, he experienced acute pain above his heel which persisted for a brief period of time. After the pain subsided, he was able to ambulate and returned home, where he rested for the remainder of the day and applied ice to the posterior aspect of the lower leg. Dr. A decided to go to an urgent care facility the next day, because he was having some difficulty walking and ascending and descending stairs. Physical examination suggested a ruptured Achilles tendon, which was confirmed by an MRI. An open primary repair of the tendon was performed two days later on an outpatient basis. Following surgery, the involved ankle was immobilized in a short-leg cast with the ankle positioned in plantarflexion for two weeks. The patient has been ambulating nonweight-bearing with crutches since surgery. At the 2-week postoperative visit to the surgeon, the cast was removed and replaced with an ankle-foot orthosis, which was set in slight plantarflexion. The patient is now permitted to bear partial weight on the involved foot within pain tolerance while wearing the orthosis. The patient has been referred to physical therapy to begin rehabilitation, using an early remobilization and weight-bearing approach. The patient is allowed to remove the orthosis for ankle ROM exercises.
   - Identify the components of your initial examination.
   - Describe a sequence of exercises and criteria for progression that you would teach Dr. A consistent with this accelerated functional approach to management.
   - What precautions would you include in your treatment plan?

CHAPTER

23

Advanced Functional Training

Functional training involves developing and progressing exercise programs that improve a patient's muscle performance in order for the individual to regain his or her pre-injury level of function. For those individuals whose goal it is to return to high-level work, leisure, recreational, or athletic activities, rehabilitation must progress to meet the anticipated demands. The process requires that multiple steps be taken that utilize the individual's readiness to progress. For the therapist, it requires a continued process of decision-making that involves:

- A thorough knowledge of the anatomy, biomechanics, and function of the human body.
- An understanding of tissue healing, the effect of time on healing, and the response of tissues to imposed stresses.
- An understanding of neuromuscular responses to various forms of exercise.
- The ability to examine and evaluate the structural and functional impairments that restrict activity and full functional participation within the context of personal and societal expectations.
- Knowledge of diagnoses, surgical and therapeutic exercise interventions, special precautions, and each patient's potential for achieving the projected outcomes.

Rehabilitation begins as early as possible with specific muscle activation and training techniques designed to develop a balance in strength and timing of contractions between synergists and antagonists. Proximal stability is critical for coordinated functioning of the extremities, and therefore, exercises to develop stability and balance are incorporated early into the program as well.

As muscle strength, endurance, and control of the involved region improve (and other goals are met, such as increasing joint mobility and muscle flexibility), greater emphasis is placed on strengthening muscle groups in functional patterns, using both weight-bearing and nonweight-bearing exercises. Care is taken to ensure that stronger muscles do not dominate the pattern in preference to weaker, impaired muscles. As function improves, exercises become more activity specific.

Functional motor skills are composed of an array of movements carried out in various positions, at varying speeds, and for varying repetitions or durations of time. The cornerstone of a functionally relevant therapeutic exercise program is the inclusion of task-specific movements that are superimposed on sufficient stability, balance, and muscle strength, endurance, and power to meet the necessary, expected, and desired functional demands in a patient's life.

It is the purpose of this chapter to describe a variety of advanced exercises for functional training that involve the total body and may be appropriate for the final phase of rehabilitation. The chapter is divided into two sections. The first section focuses on advanced exercises for stability and balance and the second on advanced exercises for strength and power. The choice of exercises to be implemented and progressed is based on the desired outcome for the patient, so the motor skills needed for that outcome are the ones emphasized in the program.

CLINICAL TIP

For all exercises, always stay within the healing constraints of the impaired tissues. Be aware of the stresses imposed on the tissues from the position, the motion, the intensity, and the speed of each exercise. Initially, emphasize correct exercise form. Then, when increasing the intensity of an exercise, decrease the repetitions (or time) until the patient is able to perform the activity safely and effectively.

Exercises for Stability and Balance

Guidelines Revisited

Stability requires the ability to fixate a unit while external forces are imposed on it. The concept of proximal stability for controlled distal mobility can be applied not only to general postural stability but also to individual joints for effective and safe function.

Joint stability. Stability of each joint in the body is necessary for effective function. Examples of joint stability include the ability to maintain a scapular posture and glenohumeral joint alignment so the humeral muscles can safely coordinate movement of the upper extremity (see Chapter 17). It also includes coordinated segmental and global stability of the spine for postural alignment and safe body mechanics (see Chapters 14 and 16) and stability of the hips, knees, and ankles for control during functional weight-bearing activities (see Chapters 20 through 22). Because specific exercises for joint stability are described in detail in the respective chapters, the reader is referred to those chapters for study before progressing to the advanced exercises described in this chapter.

Postural stability and balance. For an individual to be able to execute functional activities, balance—or postural stability—is necessary to maintain the position of the body in equilibrium within the environment. These concepts are described in detail in Chapter 8. In addition, stability and balance exercises in upright postures that are appropriate early in a rehabilitation program are described in each of the lower extremity chapters. Parameters for progressing balance exercises are summarized in Table 23.1.

CLINICAL TIP

As patients progress through advanced rehabilitative exercises, remind them frequently to maintain the spine in a neutral position and to activate the trunk muscles in order to stabilize the spine against imposed forces. If at any time the patient shows signs of insufficient trunk stability (such as lack of control of spinal posture or increased painful symptoms), review the spinal stabilization exercises as described in Chapter 16.

TABLE 23.1 Parameters for Progressing Balance Exercises

Parameters	Progression
Upright posture	
	▪ Sitting→kneeling→standing
Base of support	
	▪ Sitting: feet on floor→feet off floor ▪ Standing: wide→narrow base ▪ Standing: Double leg stance →tandem stance→single-leg stance
Support surface	
	▪ Stationary, firm, or flat surface →moving, soft, uneven surface (ball, wobble board, slide board, sand, gravel, grass) ▪ Wide surface→narrow (balance beam, half foam roll)
Superimposed movements	
	▪ Head, trunk, extremity movements ▪ Small→large-range extremity movements ▪ Unresisted→resisted (free weights, elastic resistance)
Perturbations	
	▪ Anticipated→unanticipated ▪ Low magnitude→high magnitude ▪ Slow speed→high speed
Environment	
	▪ Surroundings nonmoving (closed)→moving(open)
Functional tasks	
	▪ Simple→complex tasks ▪ Single→multiple tasks

Advanced Stabilization and Balance Exercises

Sitting

Once the individual can sit on a firm, stable surface and maintain balance while reaching in all directions and under various loads, progress to sitting on an unstable surface. Suggestions include a foam cushion, rocker board, BOSU®, or large gym ball.

Sitting and Reaching

Have the patient balance on an unstable surface and reach in various directions, first with one extremity, then with both. Add weights as the patient is able (Fig. 23.1).

Sitting with External Perturbations

While the patient maintains sitting balance on an unstable surface:

- Move the surface in various directions, first slowly, then more quickly.
- Pull on a length of elastic resistance held by the patient. Alter the speed and direction of pull.
- Toss a ball to the patient, requiring him or her to reach out in various directions and return the toss (Fig. 23.2).

FIGURE 23.1 Resisted reaching movements while maintaining sitting balance on an unstable surface.

FIGURE 23.2 Maintaining sitting balance while catching and returning a ball.

- Increase the challenge by integrating a plyometric component into the balance activity, such as catching and tossing a weighted ball.

NOTE: Refer to the next section of this chapter for examples of plyometric exercises that also improve a patient's balance.

Kneeling

Kneeling activities can be performed in the *half-kneeling* (balancing on one knee with the other extremity forward and foot planted on the floor) or *high-kneeling* (tall-kneeling) positions and include reaching in various directions under loaded and unloaded conditions and responding to perturbations on stable and unstable surfaces.

Kneeling on a Stable Surface

- In the half-kneeling position, loop an exercise band under the forward foot and have the patient perform diagonal upper extremity patterns against the resistance (Fig. 23.3 A).
- While in a half-kneeling or high-kneeling position, have the patient reach and lift a weighted object from the floor with one or both hands, and then move the weighted object upward and outward in various patterns of motion and return (Fig. 23.3 B).

FIGURE 23.3 Balancing in half-kneeling position **(A)** while performing diagonal patterns against elastic resistance; and **(B)** while moving a weighted object from a chair to the floor.

- While in a half-kneeling or high-kneeling position, toss a ball and have the patient reach outward to catch and then return it.

Kneeling on an Unstable Surface

- Have the patient kneel on a foam roller, balance board, BOSU®, or partially deflated large therapy ball and perform arm motions in various directions; progress the activity by having the patient move the arms against resistance (weights or elastic resistance).
- While kneeling on an unstable surface, have the patient catch and return a ball. Progress by using a weighted ball (Fig. 23.4).

a neutral spine and contract the abdominals when reaching upward to stabilize the spine or to rotate at the hips, not the spine, when reaching outward or downward.

  - Perform various arm motions against elastic resistance, with free weights, or while controlling a BodyBlade®.
- Progress to balancing in *tandem stance*. Have the patient stand on a stable, narrow surface, such as a line on the floor or a balance beam. Apply quick alternating resistance against the patient's pelvis (Fig. 23.5), or apply quick pulling motions to elastic resistance held by the patient.
- Progress to *tandem walking* on a narrow but stable surface.

FIGURE 23.4 Balancing in high-kneeling position on a BOSU® while catching and tossing a ball.

FIGURE 23.5 Balancing in tandem stance on a balance beam with quick alternating resistance applied against the pelvis.

Bilateral Stance

Once the individual can stand upright and maintain balance while reaching in all directions and under various imposed loads (using free weights, pulley system, or elastic resistance), the patient is ready to progress to exercises that provide a greater challenge to stability and balance, first in bilateral stance and progressing to unilateral stance.

Bilateral Stance on a Stable Surface VIDEO 23.1

- Begin with the patient standing with both feet on the floor, shoulder width apart, or in a stride position.
  - Toss a ball (unweighted or weighted) that requires the patient to reach outward, upward, or downward to catch and return it. Remind the patient to maintain

Bilateral Stance on an Unstable Surface VIDEO 23.2

- While on a balance board or BOSU®, have patient gain balance, then rock the feet forward and backward and side-to-side while attempting to control the motion and maintain balance. Instruct the patient to not let the edges of the board hit the floor.
- Have the patient stand on a foam half-roller (curved side down), a balance board, or BOSU®; add the following perturbations as the patient is able.
  - Apply quick alternating resistance against the patient's pelvis.
  - Have the patient perform various arm motions against elastic resistance, with free weights (Fig. 23.6), or while controlling a BodyBlade® (see Fig. 6.50).

- Toss a ball (unweighted or weighted) back and forth to the patient (Fig. 23.7).
- Have the patient perform partial squats (Fig. 23.8).

FIGURE 23.6 Balancing in bilateral stance on a balance board while performing arm movements.

FIGURE 23.7 Balancing in bilateral stance on a BOSU® while catching and tossing a ball.

FIGURE 23.8 Balancing on an unstable surface while performing partial squats.

Unilateral Stance

Begin by having the patient practice standing in unilateral stance on a stable surface, progressing to an unstable surface and adding perturbations as described in the bilateral stance exercises.

Unilateral Stance on a Stable Surface VIDEO 23.3

- Have the patient perform upper extremity diagonal patterns, unilaterally or bilaterally, using free weights or elastic bands (tubing) while balancing on one lower extremity (Fig. 23.9). When using elastic resistance, change the angle of pull to vary the challenge and balance response.
- Have the patient, while balancing on one lower extremity, practice various lower extremity patterns that replicate functional activities. The following are suggestions.
  - Place a star pattern (such as four intersecting lines) on the floor. Have the patient place one foot on the center of the pattern and then touch the opposite foot on each of the lines of the pattern: directly forward, diagonally forward, sideways, diagonally backward (Fig. 23.10 A), straight backward, and crossed behind (Fig. 23.10 B). Then switch feet and repeat the pattern on the opposite side.
  - Perform an alternating PNF pattern such as D_1 flexion (flexion, adduction, and external rotation)/extension (extension, abduction, internal rotation) with one leg while holding a weight and flexing/extending the opposite elbow (Fig. 23.11).
  - Have the patient walk sideways, then progress to braiding or carioca motions using forward and backward

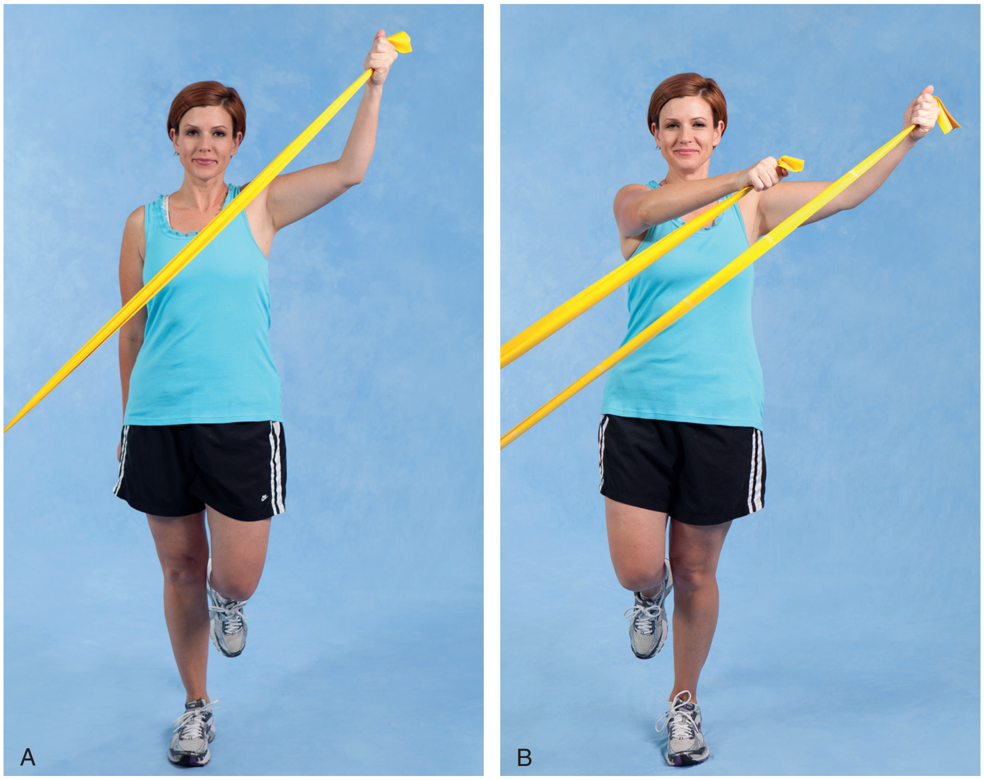

FIGURE 23.9 Balancing in unilateral stance while performing upper extremity diagonal patterns against elastic resistance: **(A)** unilaterally; and **(B)** bilaterally.

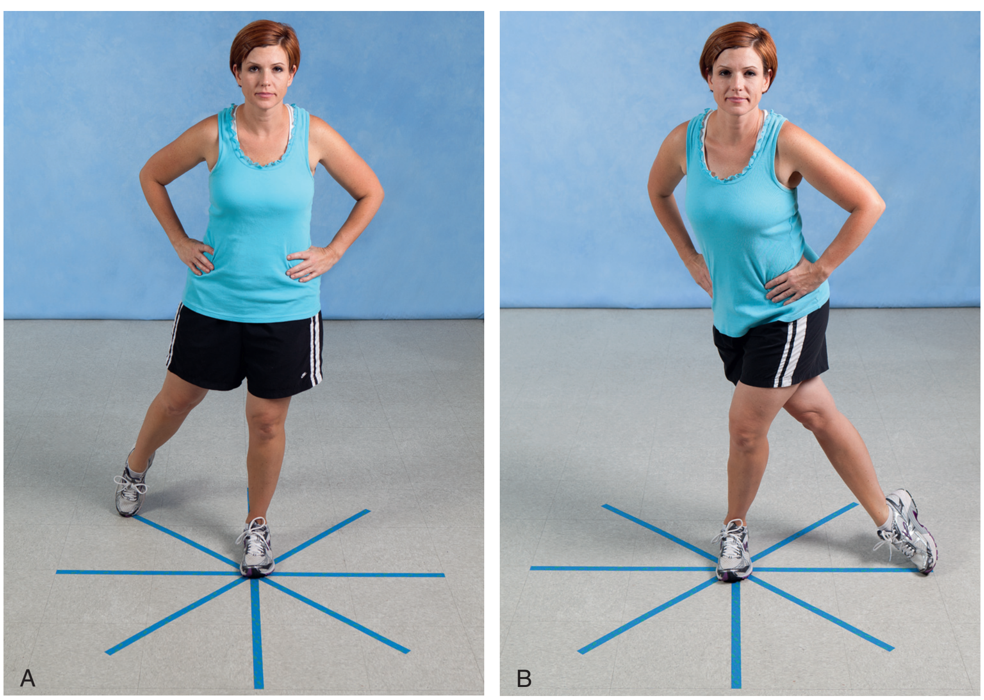

FIGURE 23.10 Maintaining balance while touching one foot on each of the lines of a star pattern on the floor and returning to the center; **(A)** diagonally backward and **(B)** crossed behind stationary leg.

FIGURE 23.11 Balancing in unilateral stance while performing a diagonal pattern with one lower extremity. Upper extremity motions add additional challenges to balance.

cross-over steps. This requires alternating balance reactions from one lower extremity to the other.

- Bend to one side while performing a partial squat to lift an object from a chair or the floor (Fig. 23.12).

FIGURE 23.12 Partial squatting in unilateral stance, leaning to one side and picking up an object.

- Reach outward with arms while bending forward and extending one leg as in a "skater" position (Fig. 23.13 A). Increase the challenge by picking up a weight from the floor or by alternately moving the arms in a windmill manner (without or with weights in each hand) (Fig. 23.13 B).

A

B

FIGURE 23.13 Maintaining balance in unilateral stance: **(A)** while bending forward at the hips and reaching out with both arms; and **(B)** while performing a windmill motion using handheld weights.

Unilateral Stance on an Unstable Surface

- Have the patient stand on the round and then flat side of a BOSU® or on a balance board or disc, and apply resistance against the patient's trunk or to upper extremity patterns using elastic resistance (Fig. 23.14).
- While balancing on an unstable surface, have the patient swing one leg forward and backward, first slowly, then with increasing speeds.

FIGURE 23.14 Perturbations in unilateral stance using elastic resistance while on a balance disc.

Moving and Planting Activities VIDEO 23.4

Movement followed by a "plant" not only requires a coordinated movement but also a rapid balance response to keep from falling. These activities also prepare the individual for skills that involve rapid reversals of direction and agility drills.

Jump and "Freeze"

- Have the patient jump down from a platform or low step and hold the end position (Fig. 23.15 A). Progress to jumping up onto the platform.
- When the patient has learned one-legged balance and demonstrates control in the jump-and-freeze exercise, progress to having him or her hop down from a step and hold the end position then have the patient hop up onto the step and hold (Fig. 23.15 B).

Side Shuffle and "Freeze"

- Have the patient perform two to three side shuffles and hold the end position, then shuffle in the opposite direction and "freeze" (Fig. 23.16).
- Vary the pattern to include shuffling in various directions, such as moving diagonally forward then backward or in a curved pattern, freezing and then reversing the direction.

Run and "Freeze"

Have the patient run forward, sideways, and backwards and "freeze" when you call out "freeze" or blow a whistle.

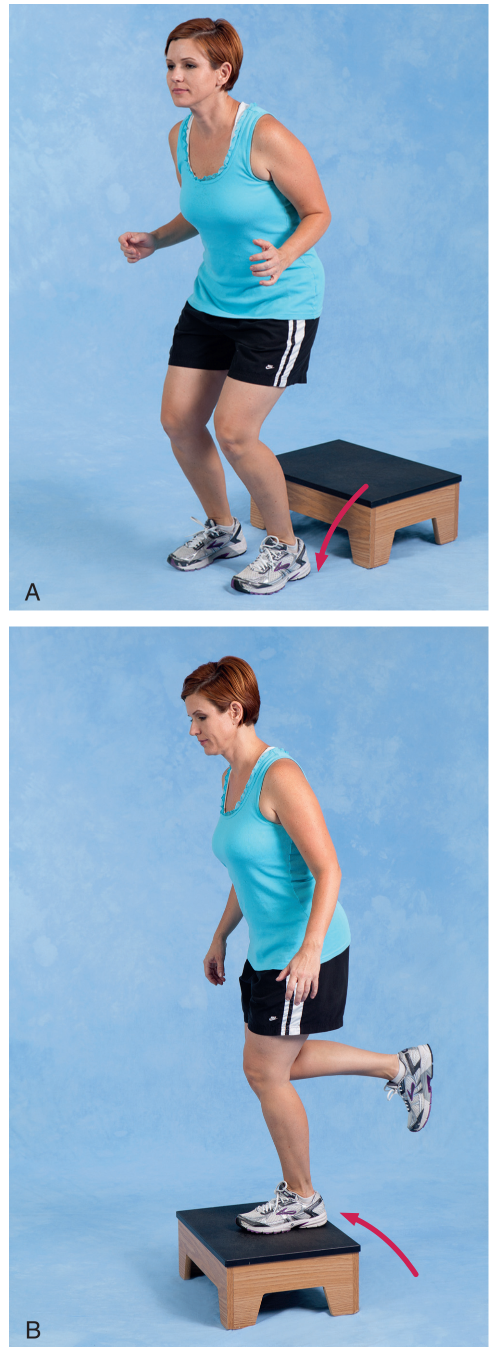

FIGURE 23.15 Jump and freeze sequence and progression: **(A)** jumping down from a step and holding the end position and **(B)** hopping up onto a step and holding the end position.

Exercises for Strength and Power

Muscle strength and power are two critical elements for successful performance of many high-demand functional tasks and activities, such as moving heavy objects in the

FIGURE 23.16 Side shuffle and freeze.

workplace and home or participating in selected sports. Muscle endurance also is necessary when performance involves tasks that must be repeated or sustained over time. Some functional activities involve slow, controlled, and sometimes repetitive movements, whereas others require bursts of movement or quick changes of direction. Therefore, an effective exercise program should address the areas of muscle performance associated with the unique qualities of each patient's physically demanding activities.

The remainder of this chapter focuses on exercises designed to improve muscle strength and/or power output—specifically, advanced strengthening exercises for the upper and lower extremities and plyometric exercises, which involve resisted movements performed at rapid speeds. All of the exercises described are built on a foundation of dynamic stability of proximal body regions (shoulder girdle, trunk, pelvic girdle), as well as balance. Conversely, a program of advanced strengthening exercises and plyometric training also imposes significant demands on a patient's balance and dynamic stability and, therefore, has been shown to improve these areas of physical function.[8]

CLINICAL TIP

When teaching a patient a program of advanced strengthening and plyometric exercises, always emphasize the patient's use of proper exercise technique before increasing the resistance imposed, the number repetitions and sets of an exercise, or the number of exercises in a treatment session.

Advanced Strengthening Exercises

As discussed in Chapter 6, progressive resistance is a necessary element of exercises designed to develop muscle strength, whereas increasing the duration of exercise (repetitions or time) is necessary to develop muscle endurance. The strengthening exercises in this section utilize functionally based and often total body movement patterns, such as pushing and pulling or lifting and lowering motions, against the resistance of body weight or external loads. They are implemented during the advanced phase of rehabilitation in preparation for returning to high-demand tasks and activities.

Many advanced strengthening exercises are carried out using weight machines designed to target specific muscle groups or by using a variety of set-ups with weight-pulley systems and isokinetic equipment. The exercises in this section, however, can be performed using simple but versatile resistance equipment, such as handheld weights or elastic bands or tubing. Other suggested exercises involve the use of equipment typically employed for cardiopulmonary training, such as a treadmill or stepping machine. Furthermore, some of the exercises described can be progressed by performing the exercises on unstable surfaces, using selected balance equipment to impose greater challenges.

Advanced Strengthening: Upper Extremities

The following exercises, performed in either weight-bearing or nonweight-bearing positions of the upper extremities, are designed to develop strength of selected upper extremity muscle groups. However, advanced upper extremity strengthening also requires activation of the trunk and lower extremity musculature. Therefore, before progressing to these exercises, be sure that the patient has developed sufficient scapular, shoulder girdle, and trunk stability and, for many of the exercises, sufficient balance in upright positions.

Exercises with a BodyBlade®

- *Patient position and procedure:* While sitting or standing, have the patient hold the vibrating blade with one or both hands in a variety of shoulder positions with the elbow(s) extended or flexed (Figs. 23.17 A and B).
- *Progression:* Move the vibrating blade through a variety of anatomical and diagonal upper extremity patterns. Incorporate trunk rotation and weight shifting on the lower extremities for a total body exercise.

Upper Extremity Weight-Bearing Exercises Using Selected Equipment

- *Hand-walking on a treadmill:* While kneeling at the end of the treadmill, have the patient "walk" with his or her hands while bearing weight through the shoulders. The surface can be moving forward or backward.
- *"Climbing" with hands on a stepping machine:* While in a kneeling position and with each hand on a step of the unit, have the patient alternately push on each pedal to target scapular stabilizers and elbow extensors.

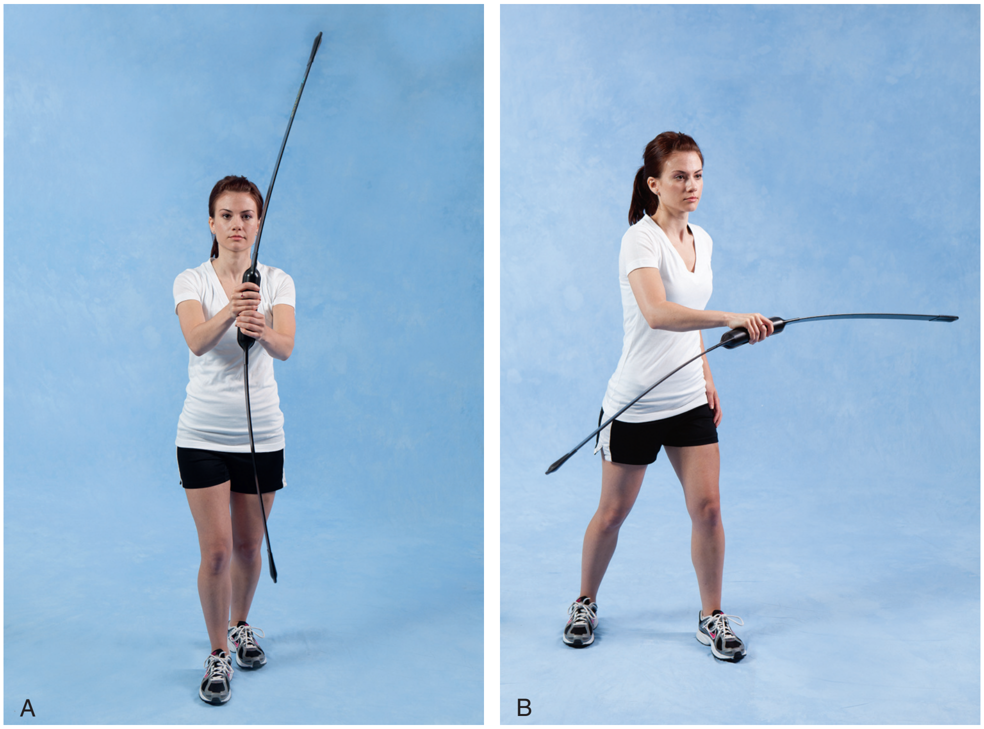

FIGURE 23.17 Exercises with a BodyBlade®: **(A)** bilateral isometric strengthening of shoulder rotators with additional activation of trunk stabilizers; and **(B)** unilateral isometric strengthening of elbow flexors/extensors.

Pushing/Pulling and Lifting/Lowering Exercises

The following exercises involve various pushing and pulling or lifting and lowering motions. They are useful for developing upper extremity strength for functional tasks that require concentric and eccentric control of shoulder, elbow, and forearm musculature in combined movement patterns for moving objects of varying sizes and weights from one place to another. Depending on the size of the object, an exercise may be performed bilaterally or unilaterally. It is important to remind the patient to use proper body mechanics by maintaining a neutral spine and contracting the trunk stabilizing muscles during the task and by maintaining a stable base of support during each of these exercises.

- *Pushing or pulling motions*
  - Perform pushing and pulling motions against the resistance of an elastic band by moving the upper extremities in forward, backward, upward, and downward directions.
  - Using an upper extremity ergometer, perform pushing or pulling motions, "pedaling" against resistance in a forward or backward direction. Adjust the direction, speed, and arc of motion to replicate various functional tasks.
  - Reposition a heavy crate on a level surface by pulling (Fig. 23.18) or pushing (see Fig. 18.21) it from one place to another.

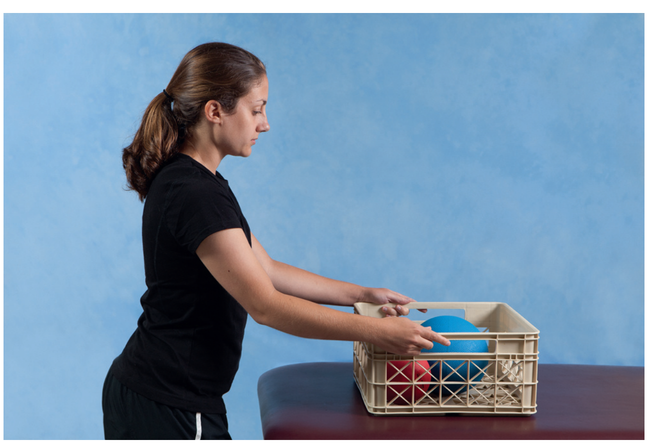

FIGURE 23.18 Strengthening shoulder and elbow musculature by pulling (sliding) a heavy object from one position to another.

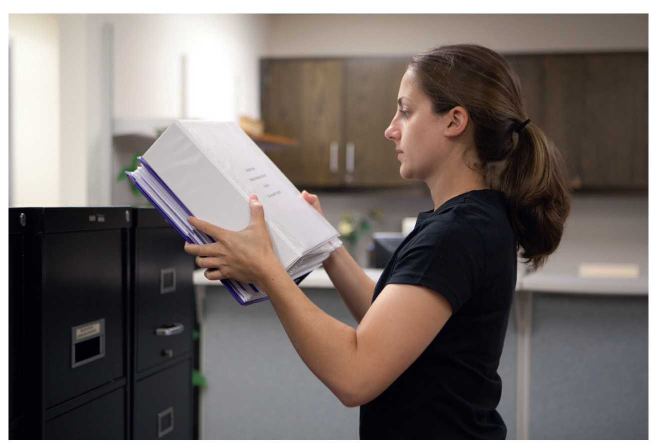

FIGURE 23.19 Strengthening shoulder and elbow musculature by lifting or lowering a heavy object to and from a high surface.

- *Lifting or lowering motions*
  - Lift a weighted crate from the surface of a table, hold it close to the body, and lower it to a different position on the table.
  - Lift and lower a heavy object to and/or from high and low surfaces (Fig. 23.19).

Seated Push-Ups on Unstable Surfaces VIDEO 23.5

- *Patient position and procedure:* While in a long-sitting position on the floor with heels placed on a firm foam roller or BOSU®, have the patient lift the hips from the floor by performing a seated push-up (Fig. 23.20 A).
- *Patient position and procedure:* Have the patient sit on a firm foam roller, the flat side of a BOSU®, or a balance board with legs on the floor and hands on the unstable surface at either side of the hips and lift the hips upward by performing a seated push-up (Fig. 23.20 B).

Prone Push-Ups in a Head-Down Position

Patient position and procedure: Once the patient can perform a prone push-up with hands and feet on the floor, progress to a prone push-up in a head-down position on an incline board, over a therapy ball, or on the floor with feet elevated on a platform to shift greater body weight to the upper extremities (Fig. 23.21).

A

B

FIGURE 23.20 Seated push-ups in a long-sitting position **(A)** with lower legs on an unstable (soft) surface; and **(B)** with hands on an unstable surface.

FIGURE 23.21 Prone push-ups in a head-down position.

Upper Extremity Step-Ups Combined with Prone Push-Ups VIDEO 23.5

Patient position and procedure: Have the patient perform a prone push-up with both hands on the floor. While maintaining the push-up position, move one hand up onto and then off of a low platform (Fig. 23.22). Repeat the sequence, gradually increasing the number of repetitions. This exercise increases the weight-bearing force on the extremity that remains on the floor.

FIGURE 23.22 Upper extremity step-up with the right upper extremity following a prone push-up.

Prone Push-ups on Unstable Surfaces

- *Patient position and procedure:* Have the patient perform a series of push-ups with hands on the floor and knees on a foam roller (Fig. 23.23 A).
- *Patient position and procedure:* Have the patient perform a series of push-ups with hands on a foam roller or small ball and knees or feet on the floor (Fig. 23.23 B).
- *Patient position and procedure:* Have the patient perform a series of push-ups with hands on a balance board, BOSU ®, or small ball and knees on a foam roller (Fig. 23.23 C).

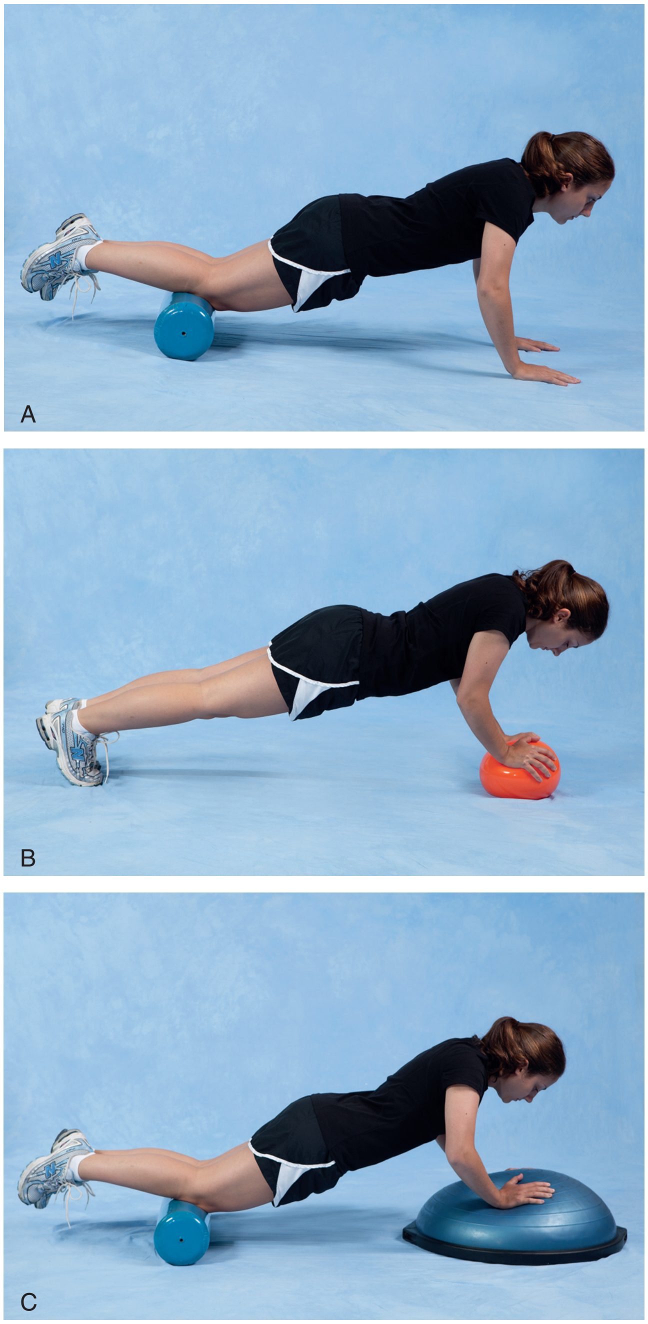

FIGURE 23.23 Prone push-ups on unstable surfaces: **(A)** with hands on the floor and knees on a foam roller; **(B)** with hands on a small ball and feet on the floor; and **(C)** with hands on a BOSU® and knees on a foam roller.

Ball "Walk-Out" VIDEO 23.5

- *Patient position and procedure:* In a prone position with hands on the floor and lower extremities on a large therapy ball, have the patient "walk" forward and then backward on the hands while keeping the lower extremities in contact with the ball (Fig. 23.24). To increase the challenge, perform a prone push-up before "walking" backward.

Plantar-Grade "Walking"

Plantar-grade walking with weight on hands and feet (also referred to as "bear-walking") places considerable weight through the upper extremities and can be used to develop

FIGURE 23.24 Ball "walk-out" on hands with lower extremities rolling on a large therapy ball.

strength of the musculature that stabilizes the scapulothoracic and glenohumeral joints.

- *Patient position and procedure:* Have the patient assume the plantar-grade position on hands and feet and "walk" forward.
- *Progression:* Perform plantar-grade "walking" against the resistance of an elastic cord harnessed around the pelvis and fixed to the wall or to a heavy piece of equipment.

Advanced Strengthening: Lower Extremities VIDEO 23.6

The following exercises, some of which are progressions of exercises described in Chapters 20 through 22, are performed in functional movement patterns against progressive resistance and are implemented to develop advanced levels of strength of the lower extremities. Many of these exercises also improve dynamic stability of the trunk and balance.

Unilateral Supine Pelvic Bridges

Patient position and procedure: With one foot planted on the floor and the other extremity off the floor in either hip/knee flexion or hip flexion and knee extension, have the patient lift and lower the pelvis first against body weight and then while holding a weighted ball in both hands. Increase the challenge by planting the weight-bearing foot on an unstable surface, such as a BOSU® or small balance disk (Fig. 23.25).

Supine Pelvic Bridges on an Elevated Surface

- *Patient position and procedure:* While on the floor in a long-sitting position with both feet on a chair, platform, or a large therapy ball and hands on the floor, have the patient extend the hips, lifting them from the floor (Fig. 23.26).
- *Progression:* Lift the hips from the floor with just one foot placed on the chair or platform and the other leg flexed toward the chest.

Supine Hamstring Curls on a Ball VIDEO 23.6

- *Patient position and procedure:* While lying in the supine position on the floor, have the patient place both feet on a large therapy ball and roll it toward the hips by flexing the knees (Fig. 23.27). In addition to strengthening the hamstrings, this exercise also challenges the trunk stabilizers.

FIGURE 23.25 Unilateral supine pelvic bridge on an unstable surface while holding a weighted ball in both hands for additional resistance.

FIGURE 23.26 Supine pelvic bridge with the lower extremities elevated on a platform or chair and hands on the floor.

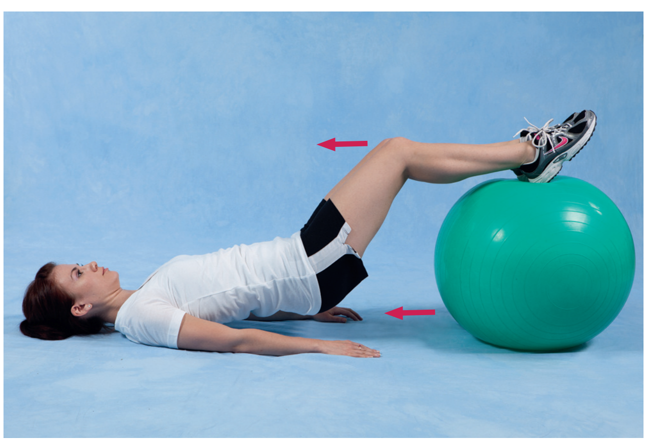

FIGURE 23.27 Supine hamstring curls on a ball.

- *Progression:* Have the patient perform the exercise unilaterally by lifting one foot off the ball and rolling the ball toward the hips with just one foot on the ball.

Hamstrings or Quadriceps Strengthening: Kneeling

- *Patient position and procedure:* Have the patient begin in a high-kneeling position on a padded surface for comfort.
- *To strengthen the hamstrings:* While manually stabilizing the patient's lower legs, have the patient lean *forward* from the vertical position as far as possible (Fig. 23.28 A), keeping the trunk erect and maintaining balance, and then return to the upright position by flexing the knees. In addition to strengthening the hamstrings eccentrically and concentrically in a closed-chain position, this exercise provides a significant challenge to the patient's balance.
- *To strengthen the quadriceps:* Have the patient lean *backward* as far as possible from the upright position without touching the buttocks to the heels and then return to the high-kneeling position. As the patient leans backward, the quadriceps contract eccentrically to control movement at the knees and then concentrically as the patient returns to the vertical position.
- *Progression:* Add a weight held close to the chest for additional resistance (Fig. 23.28 B).

Unilateral Wall Slides: Standing

- *Patient position and procedure:* While in unilateral stance with the back against a wall (but the weight-bearing foot

FIGURE 23.28 (A) Strengthening the hamstrings against the resistance of body weight by leaning forward from a high-kneeling position; **(B)** strengthening the quadriceps by leaning backward from the high-kneeling position while holding a weighted for additional resistance.

several feet away from the wall), have the patient slide down the wall until the knee is flexed to 90° (Fig. 23.29), making sure the knee does not move into valgus or anterior to the toes. Hold the position, and then return to a standing position. This exercise strengthens the hip and knee extensors eccentrically and concentrically.

- *Progression:* Hold weights in both hands for additional resistance. Gradually increase the number of repetitions and/or the duration that the 90° position is held. Increase the challenge by placing a large therapy ball behind the back for these exercises.

FIGURE 23.29 Unilateral wallslides in standing with a midrange hold.

Deep Squats

- *Patient position and procedure:* In bilateral stance with feet a comfortable distance apart, have the patient perform a deep squat by flexing the hips and knees (Fig. 23.30). Keep body weight distributed posteriorly through the heels, and be sure to keep the lower legs as vertical as possible to the floor so that the knees do not move anterior to the toes. Hold the deep squat position, and then return to the standing position. Have the patient hold both arms out in front of the body for balance or place one hand lightly on a countertop, if necessary.
- *Progression:* Perform repeated deep squats while holding weights or by combining squats with resisted upper extremity motions. This activity is beneficial for developing body mechanics in individuals who do heavy lifting in the work setting.

Variations of Lunges VIDEO 23.6

- *Deep forward lunge:* While maintaining the trunk in an erect position, have the patient place one foot forward and perform a deep lunge, flexing the forward knee to a 90° position but keeping the lower leg vertical and the knee posterior to the toes (Fig. 23.31 A); then return to the standing position. Place one hand lightly on a stable surface (wall, countertop) for balance, if necessary.
  - As balance improves, have the patient perform deep forward lunges while holding a weighted ball away from the chest and performing trunk rotation.
  - Place the forward foot on an unstable surface, such as a balance disk, while performing the forward lunge exercise.

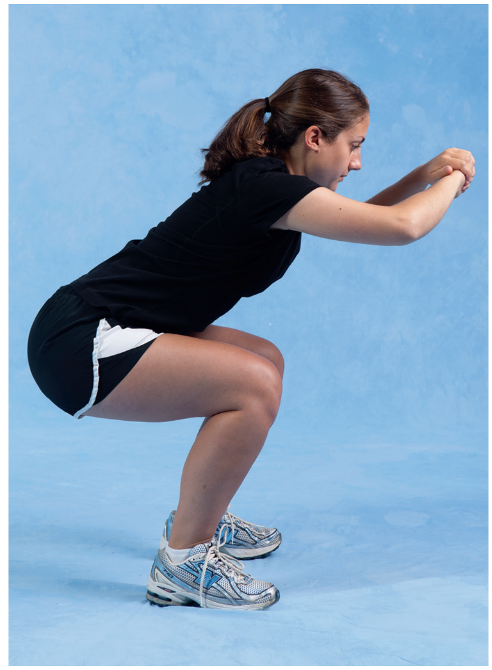

FIGURE 23.30 Deep squats with an end-range hold, while trying to keep the knees posterior to the toes.

FOCUS ON EVIDENCE

Although the forward lunge exercise typically is performed with the trunk erect, there is evidence demonstrating that changing the position of the trunk and upper extremities alters the recruitment of muscle groups in the lead lower extremity during the lunge. Farrokhi and colleagues[7] conducted a motion analysis and electromyographic (EMG) study of the lead lower extremity during variations of the forward lunge exercise with ten healthy adults (five men, five women) as subjects. The investigators found that there was a small but statistically significant increase in hip extensor muscle (gluteus maximus and biceps femoris) recruitment of the lead leg when forward lunges were performed with the trunk and upper extremities in a forward position compared with when the trunk was erect and upper extremities were positioned along the sides of the trunk. These findings confirmed a previously held clinical assumption. In contrast, despite clinical speculation that knee extensor muscle activation may increase in the lead leg if forward lunges are performed with the trunk

FIGURE 23.31 **(A)** Deep forward lunge while lightly touching a stable surface for balance; **(B)** multidirectional lunges on a star pattern on the floor; and **(C)** deep lateral lunge against elastic resistance.

in full extension, the results of this study revealed that there were no significant differences in the levels of activation of hip or knee extensor muscle groups compared with lunges performed in the erect trunk position.

- *Multidirectional lunges:* Have the patient perform lunges diagonally forward, out to the side, diagonally backward, and then directly backward. This sequence is facilitated by placing four intersecting lines on the floor (in a star pattern or like spokes of a wheel) and having the patient keep one foot planted where the lines intersect. The patient steps out onto each line (Fig. 23.31 B) and returns to the upright position. Motion in the same direction can be repeated multiple times before progressing to the next line, or the patient can step out onto each line in succession.
- *Lunges against added resistance:* Increase the difficulty of the exercise by performing lunges against elastic resistance looped around the lower legs (Fig. 23.31 C) or holding weights or a weighted ball, wearing a weight belt, or holding a barbell on the shoulders. Controlling weights while performing lunges is beneficial for developing strength for individuals returning to work settings that require heavy lifting.
- *Lunge-walking:* Perform a series of lunges in various directions to move across the floor or to pick up objects of decreasing height (e.g., 16 to 4 in.) from various places on the floor.
- *Lunge-jumps:* Refer to the description and figure (see Fig. 23.63) in the next section on plyometric training.

Sitting Down and Standing Up from a Chair Against Elastic Resistance

- *Patient position and procedure:* Have the patient sit down against the resistance of an elastic band looped around the posterior aspect of the pelvis (Fig. 23.32 A).
- *Patient position and procedure:* Have the patient stand up against elastic resistance looped around the anterior aspect of the pelvis (Fig. 23.32 B).

Bilateral or Unilateral Heel-Lowering Over a Step

- *Patient position and procedure:* While standing with heels over the edge of a step or low platform, have the patient perform heel lowering and then a heel raise in bilateral stance. Place one hand *lightly* on a railing or a stable surface for balance. Heel lowering imposes eccentric loading of the gastrocnemius-soleus musculature against the resistance of body weight.
- *Progression:* Perform the same exercise while wearing a weight belt or vest or holding weights (Fig. 23.33), then progress to unilateral stance.

Band Walking

- *Patient position and procedure:* Have the patient walk forward (Fig. 23.34 A), sideward (Fig. 23.34 B), and backward against elastic resistance looped around the pelvis.
- *Patient position and procedure:* Have the patient walk forward against elastic resistance looped around the thighs for closed-chain strengthening of the external rotators (Fig. 23.35).

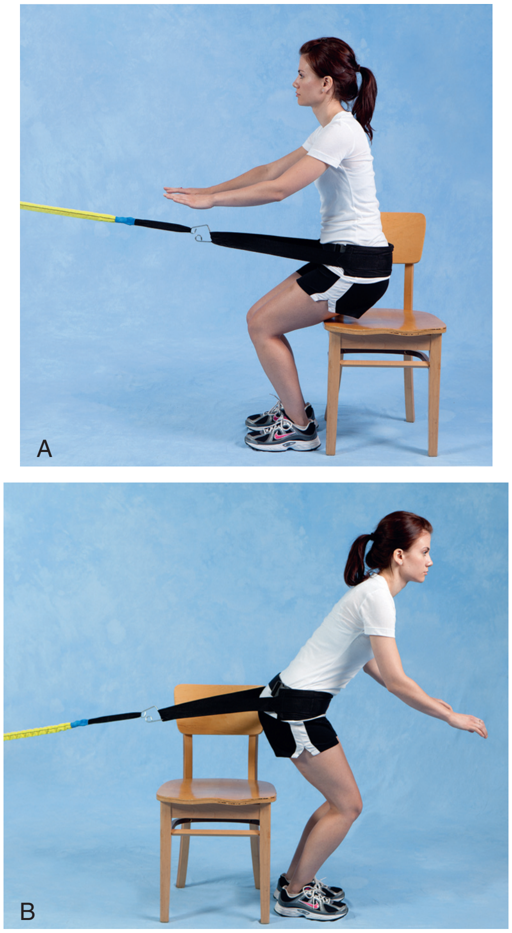

FIGURE 23.32 **(A)** Sitting down; and **(B)** standing up against elastic resistance.

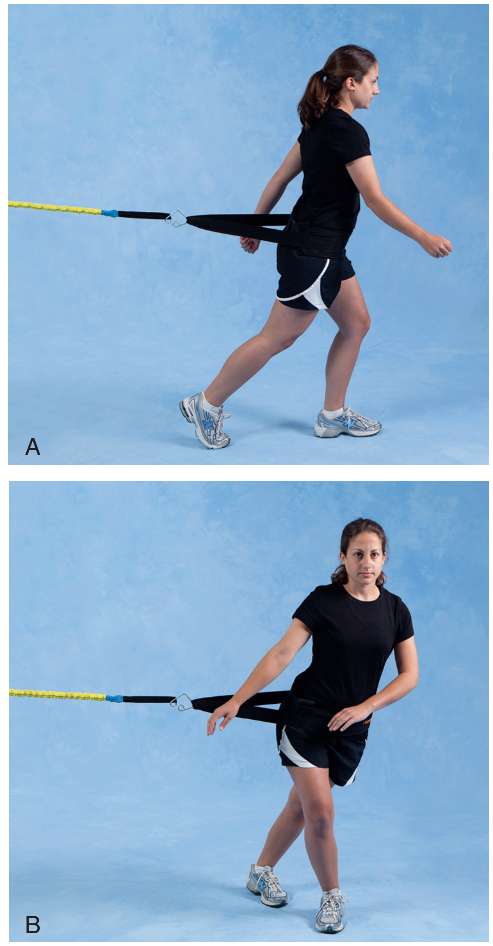

FIGURE 23.34 Band walking: **(A)** in a forward direction; and **(B)** in a sideward direction against elastic resistance looped around the pelvis.

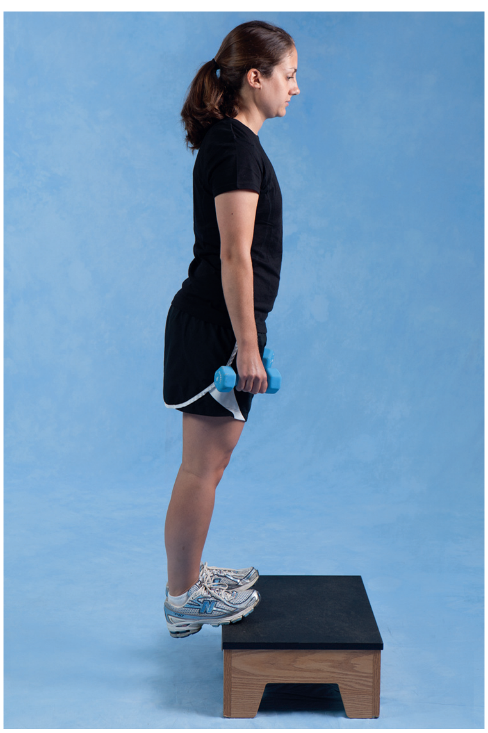

FIGURE 23.33 Heel-lowering over a step while holding weights for additional resistance.

FIGURE 23.35 Band walking in a forward direction against elastic resistance looped around the thighs for closed-chain strengthening of the hip external rotators.

Pulling or Pushing a Heavy Object

- *Patient position and procedure:* With the arms positioned in a stable and comfortable position, have the patient use primarily lower extremity strength to pull (Fig. 23.36) or push a heavy object, such as a weighted sled or cart, across the floor. Select positions for pulling or pushing similar to the anticipated work-related tasks or sport activity. Be certain the patient uses proper body mechanics.
- *Progression:* Gradually increase the amount of weight moved from one place to another.

FIGURE 23.36 Pulling increasingly heavy objects across the floor.

Resisted Running Start and Resisted Running

Patient position and procedure: While wearing a harness placed around the trunk and pelvis, have the patient move from the starting position typically assumed prior to a sprint and then run forward against the resistance of a heavy-grade elastic cord that is attached to the harness and affixed to the wall or a stationary surface (Fig. 23.37). As an alternative, the patient can perform backward running against resistance.

FIGURE 23.37 Resisted running start.

Plyometric Training: Stretch-Shortening Drills

Most pieces of equipment used for resistance training, such as free weights, weight machines or weight-pulley systems, are designed for developing advanced levels of strength but not power in that they provide substantial resistance but typically are used by performing slow, controlled movements. However, reactive bursts of force in functional movement patterns are often necessary if a patient is to return to high-demand occupational, recreational, or sport-related activities. A program of high-intensity, high-velocity exercises, known as *plyometric training*, not only improves muscle strength but also develops power output, quick neuromuscular reactions, and coordination.[4,11] This form of exercise also is recommended to improve athletic performance and reduce the risk of musculoskeletal injury.[4,6,9,17]

Plyometric training typically is integrated into the advanced phase of rehabilitation as a mechanism to train the neuromuscular system to react quickly in order to prepare for activities that require rapid starting and stopping movements or quick changes of direction. This form of training is appropriate only for carefully selected patients who wish to return to high-demand functional activities and sports.

Definitions and Characteristics

Plyometric training,[4,11,14] also called *stretch-shortening drills*[17] or stretch-strengthening drills,[15] employs high-velocity eccentric to concentric muscle loading, reflexive reactions, and functional movement patterns. Plyometric training is defined as a system of high-velocity resistance training characterized by a rapid, resisted, eccentric (lengthening) contraction during which the muscle elongates, immediately followed by a rapid reversal of movement with a resisted concentric (shortening) contraction of the same muscle.[11,16,17] The rapid eccentric loading phase is the stretch cycle, and the concentric phase is the shortening cycle. The period of time between the stretch and shortening cycles is known as the amortization phase. It is important that the amortization phase be kept very brief by a rapid reversal of movements to capitalize on the increased tension in the muscle.

Body weight or an external form of loading, such as elastic bands or tubing or a weighted ball, are possible sources of resistance. An example of a stretch-shortening drill for the lower extremities against the resistance of body weight is represented in Figure 23.38. Additional examples of plyometric training for the upper and lower extremities are noted in Box 23.1.

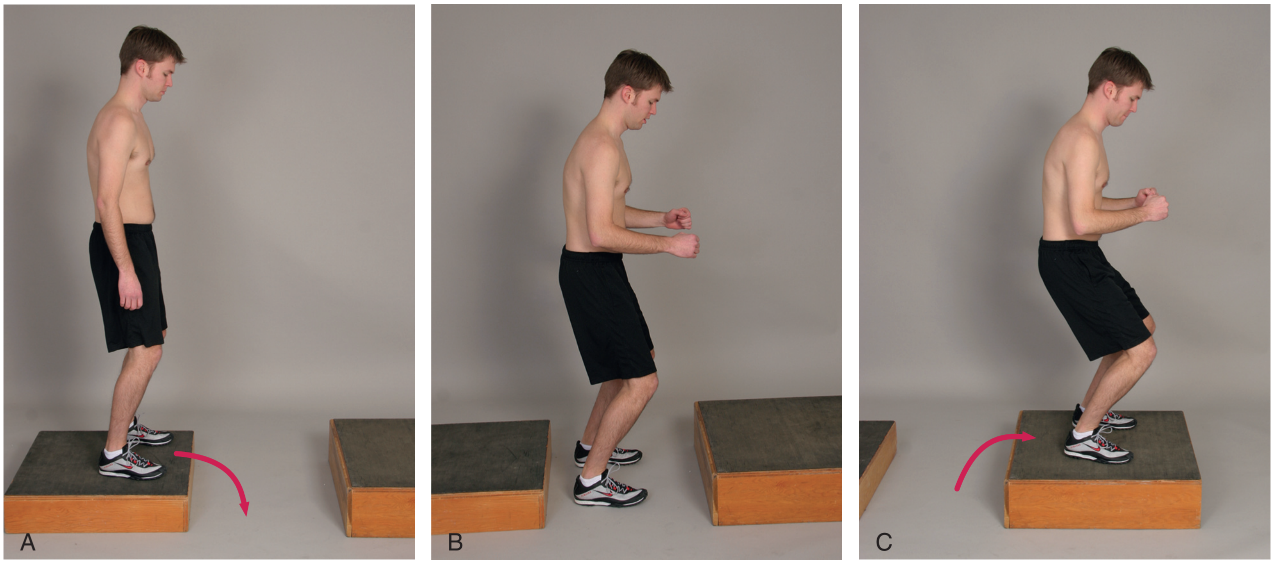

FIGURE 23.38 Plyometric lower extremity sequence against the resistance of body weight: **(A)** patient stands on a low platform; **(B)** jumps off the platform to the floor, controlling the impact with a loaded, lengthening contraction of the hip and knee extensors and plantar flexors—the stretch phase; and **(C)** then without delay jumps forward onto the next platform using a concentric contraction of the same muscle groups—the shortening phase.

BOX 23.1 Plyometric Activities for the Upper and Lower Extremities

Upper Extremities

- Catching and throwing a weighted ball with a partner or against a wall, bilaterally then unilaterally
- Stretch-shortening drills with elastic tubing using anatomical and diagonal motions
- Swinging a weighted object (weighted ball, golf club, bat)
- Dribbling a ball on the floor or against a wall
- Push-offs from a wall or countertop while standing
- Drop push-ups from a low platform to the floor and back onto the platform
- Clap push-ups

Lower Extremities

- Repetitive jumping on the floor: in place; forward/backward; side-to-side; diagonally to four corners; jump with rotation; zigzag jumping; later, jump on foam
- Vertical jumps and reaches and proper landing
- Multiple jumps across a floor (bounding)
- Box jumps: initially off and freeze, then off and back on box, increasing speed and height
- Side-to-side jumps (box to floor to box)
- Jumping over objects on the floor
- Hopping activities: in place, across a surface, over objects on the floor
- Depth jumps (advanced): jumping from a box, squatting to absorb the shock, and then jumping and reaching as high as possible

Neurological and Biomechanical Influences

Plyometric training is thought to utilize the series-elastic properties of connective tissues and the stretch reflex of the neuromuscular unit. The spring-like properties of the series-elastic components of muscle-tendon units create elastic energy during the initial phase (the stretch cycle) as the muscle contracts eccentrically and lengthens while loaded. This energy is stored briefly and then retrieved for use during the concentric contraction (shortening cycle) that follows immediately. The storage and release of this elastic energy augments the force production of the concentric muscle contraction.[1,4,11,14]

Furthermore, the stretch-shortening cycle is thought to stimulate the proprioceptors of muscles, tendons, ligaments, and joints; increase the excitability of the neuromuscular receptors; and improve the reactivity of the neuromuscular system. Therefore, the term *reactive neuromuscular training* also has been used to describe this approach to exercise. More specifically, the loaded, eccentric contraction (stretch cycle) is thought to prepare the contractile elements of the muscle for a concentric contraction (shortening cycle) by stimulation and activation of the monosynaptic stretch reflex.[4,5,14] Muscle spindles, the receptors that lie in parallel with muscle fibers, sense the length of a muscle and the velocity of stretch applied to a muscle and transmit this information to the CNS via afferent pathways. Impulses are then sent back to the muscle from the CNS, which reflexively facilitates activation of a shortening contraction of the stretched muscle (the shortening cycle).[3,10] Therefore, the more rapid the eccentric muscle

contraction (the stretch), the more likely it is that the stretch reflex will be activated.

It has been suggested that the ability to use this stored elastic energy and neural facilitation is contingent on the velocity and magnitude of the stretch and the transition time between the stretch and shortening phases (the amortization phase).[4,11] During the amortization phase, the muscle must reverse its action, switching from deceleration to acceleration of the load. A decrease in the duration of the amortization phase theoretically increases the force output during the shortening cycle.[1,4,14,16]

Effects of Plyometric Training

The evidence to support the effectiveness of plyometric training for developing muscle strength and power is substantial.[11] There is also evidence indicating that plyometric training is associated with an increase in a muscle's ability to resist stretch, which may enhance the muscle's dynamic restraint capabilities.[1] In addition, there is promising, but limited, evidence to suggest that plyometric training may enhance physical performance[2,9] and may decrease the incidence of lower extremity injury.[12,13]

FOCUS ON EVIDENCE

The results of a recent systematic review and meta-analysis of the literature support the conclusions of many previous studies that plyometric training is an effective method to improve muscle strength and power. Greatest gains in strength have been shown to occur when plyometric training was combined with progressive weight training. The review also indicated that plyometric training is beneficial for individuals with moderately low as well as high fitness levels prior to the start of training.[11]

Studies also have been carried out to investigate the impact of plyometric training on performance of selected upper and lower extremity activities. Carter and colleagues[2] carried out a prospective study of the effect of a plyometric program on throwing velocity in a group of intercollegiate baseball plays. Following pretesting of throwing velocity and isokinetic strength of the shoulder rotators, participants were randomly assigned to either the plyometric training group (n=13) or the control group (n=11). Both groups participated in an off-season strength and conditioning program that included exercises with elastic resistance for the shoulder rotators, but only the experimental group performed a program of six plyometric exercises with a weighted ball for the upper extremities twice weekly for 8 weeks. At the conclusion of the program, the throwing velocity of the plyometric group increased significantly compared with the control group, but there continued to be no significant differences in shoulder strength between groups. The investigators concluded that a combined program of strengthening exercises and plyometric training is superior for improving throwing velocity than strengthening exercises alone.

In a prospective study by Hewett[9]. two groups of high school-aged female athletes were monitored during a season of participation in one of three sports (soccer, volleyball, and basketball). One group (n=366) participated in a 6-week preseason training program, whereas the other group (n=463) did not. The preseason training focused on jumping and landing techniques. At the end of the sport season, there was a significantly higher incidence (3.6 times higher) of knee injury in the untrained group than in the trained group. The investigators concluded that preseason plyometric training may reduce the risk of knee injury in female athletes, possibly owing to increased dynamic knee stability.

Application and Progression of Plyometric Exercises

Plyometric training is appropriate only in the advanced phases of rehabilitation for carefully selected, active individuals who must achieve a high level of physical performance in specific, high-demand activities.

CONTRAINDICATIONS: Plyometric activities should not be implemented in the presence of inflammation, pain, or significant joint instability.

Preparation for plyometrics. Prior to initiation of plyometric training, a patient should have an adequate base of muscle strength and endurance, as well as flexibility of the muscles to be exercised. Criteria that should be met to begin plyometric training usually include an 80% to 85% level of strength of the involved muscle groups (compared to the contralateral extremity) and 90% to 95% *pain-free* ROM of the moving joints.[4] Sufficient strength and stability of proximal regions of the body (trunk and limb) for balance and postural control are necessary prerequisites as well. For example, scapulothoracic stability with the absence of scapular winging is necessary before engaging in a progression of advanced push-ups.

Specificity of training. A plyometric drill should be designed with specific functional activities in mind and should include movement patterns that replicate the desired activity.

Progression and parameters. When planning and implementing a plyometric training program, exercises should be sequenced from easy to difficult and progressed gradually. Box 23.2 summarizes a sequence of sample activities for upper extremity plyometric training.[2,4,14,16,17] Programs also should be individually designed to meet each patient's needs and goals. Note that prior to initiating each session of plyometric activities, a series of warm-up exercises should be performed in order to reduce the risk of injury to the contracting muscle groups.

BOX 23.2 Sample Plyometric Sequence for the Upper Extremities

Warm-Up Activities

- Trunk exercises holding lightweight ball: rotation, side-bending, chopping motions
- Upper extremity exercises in anatomical and diagonal planes of motion with light-grade elastic tubing
- Prone push-ups

For each of the following plyometric activities, perform a quick reversal between the eccentric and concentric phases.

- Bilateral throwing motions with a weighted ball to and from an exercise partner: bilateral chest press; bilateral overhead throw; bilateral side throw
- ER/IR against elastic tubing (first with the arm positioned slightly away from the side of the trunk in some shoulder abduction and then in the 90/90 position of shoulder and elbow)
- Diagonal patterns against elastic resistance
- Unilateral catching/throwing motions with a weighted ball: side throws → overhead throws → baseball throws

Additional Exercises

- Trunk exercises holding weighted ball: abdominal curl-ups, back extension, sit-up and bilateral throw, long sitting throws
- Push-offs from a wall or countertop while in a standing position
- Clap push-ups
- Drop push-ups: prone push-ups from platform to floor and back to platform

The following parameters should be considered when progressing a plyometric program.

- ***Speed of drills.*** Drills should be performed rapidly but safely. The rate of stretch of the contracting muscle is more important than the length of the stretch.[11,14] Emphasis should be placed on decreasing the reversal time when transitioning from an eccentric to a concentric contraction (decreasing the amortization phase). This trains the muscle to generate tension in the shortest time possible. If a jumping activity is performed, for example, progression of the plyometric activity should center on reducing the time on the ground between each jump.
- ***Intensity.*** Resistance should be increased gradually so as not to slow down the activity. Methods for increasing external resistance include using a weight belt or vest, heavier weighted balls, or heavier grade elastic resistance; progressing from double-leg to single-leg activities; and increasing the height of platforms for jumping and hopping activities. Intensity also may be increased by progressing from simple to complex movements.
- ***Repetitions, frequency, and duration.*** The number of repetitions of an activity should be increased as long as proper form (technique) is maintained. The number of plyometric exercises in a single session also is increased gradually, working up to perhaps six different activities.[2] The optimal frequency of plyometric sessions is two sessions per week, which allows a 48- to 72-hour recovery period between sessions.[4,11,14] Maximum training benefits typically occur within an 8- to 10-week duration.[11]

Precautions. Because of the emphasis on eccentric loading and rapid reversal to concentric muscle contractions, the potential for tissue damage is increased with plyometric activities. As with other forms of high-intensity resistance training, special precautions must be followed to ensure patient safety.[4,14] These precautions are listed in Box 23.3.

Plyometric Exercises: Upper Extremities

Plyometric exercises for the upper extremities can be performed in a variety of nonweight-bearing and weight-bearing positions, using anatomical motions that target a key muscle group or using combined movement patterns that involve multiple muscle groups throughout the entire upper extremity.[2,6,17] Many combined patterns used in plyometric activities incorporate trunk stability and balance into the movement sequence and often simulate desired functional motor skills that occur during work or recreational activities.

BOX 23.3 Precautions for Plyometric Training

- If high-stress, shock-absorbing activities are not permissible, do not incorporate plyometric training into a patient's rehabilitation program.
- If a decision is made to include plyometric activities in a rehabilitation program for children or elderly patients, select only beginning-level stretch-shortening drills against light resistance. Do not include high-impact, heavy-load activities—such as drop jumps or weighted jumps—that could place excessive stress on joints.
- Be sure the patient has adequate flexibility and strength before initiating plyometric exercises.
- Wear shoes that provide support for lower extremity plyometrics.
- Always warm-up prior to plyometric training with a series of active, dynamic trunk and extremity exercises.
- During jumping activities, emphasize learning techniques for a safe landing before progressing to rebounding.
- Progress repetitions of an exercise before increasing the level of resistance used or the height or length of jumps.
- For high-level athletes who progress to high-intensity plyometric drills, increase the rest intervals between sets and decrease the frequency of drills as the intensity of the drills increases.
- Allow adequate time for recovery with 48 to 72 hours between sessions of plyometric activities.
- Stop an exercise if a patient can no longer perform the plyometric activity with good form and landing technique because of fatigue.

A variety of plyometric exercises for the upper extremities that could be incorporated into the final phase of rehabilitation as a component of advanced functional training are presented in this section.

Bilateral Diagonal Upper Extremity Movements

Patient position and procedure: While holding a weighted ball with both hands, have the patient perform diagonal patterns (D_1 or D_2) with a quick transition from the flexion to extension patterns. Incorporate trunk rotation into the movement patterns. These exercises also develop dynamic stability of the trunk rotators and lower extremities.

Bilateral Chest Press and Throw: Supine

Patient position and procedure: Supine with both hands reaching toward the ceiling. Have the patient catch a weighted ball dropped from above by the therapist (Fig. 23.39), control and lower it to the chest (eccentric phase), and then quickly throw it vertically back to the therapist. As the ball moves toward the chest, shoulder flexors and elbow extensors are loaded eccentrically.

Bilateral Chest Press and Throw: Standing

Patient position and procedure: While standing and with feet placed in a stride position for balance, have the patient catch a weighted ball with both hands, bringing it to the chest (eccentric phase) (Fig. 23.40), and then throw it back to the therapist or onto a rebounder (concentric phase).

Bilateral Overhead Catch and Throw

Patient position and procedure: While standing and with feet placed in a stride position for balance, have the patient use both hands to catch a weighted ball thrown over the head, controlling the momentum of the ball with shoulder and elbow musculature (eccentric phase), and then throw the ball back quickly to the therapist or onto a rebounder (concentric phase) (Fig. 23.41). This exercise targets the shoulder and elbow extensors.

FIGURE 23.39 Bilateral chest press and throw—supine.

FIGURE 23.40 Bilateral chest press and throw—standing.

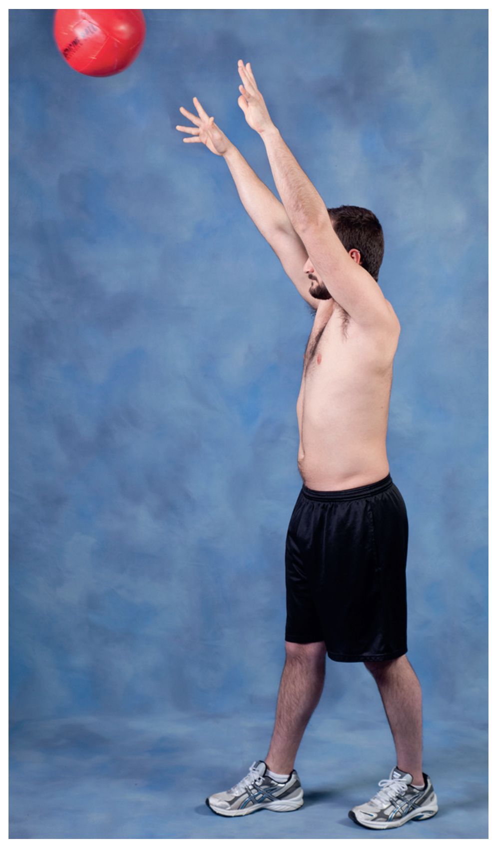

FIGURE 23.41 Bilateral overhead catch and throw.

Bilateral Horizontal Side Throw and Catch VIDEO 23.7

Patient position and procedure: While standing with one side of the body about 10 feet away from a rebounder, have the patient hold a weighted ball in both hands with arms positioned across the chest and then throw the ball toward the rebounder by rotating the trunk and moving the arms across the chest in the transverse plane. The patient then catches the ball as it bounces back from the rebounder, controlling the momentum of the ball by allowing the arms to move back across the chest and rotating the trunk (eccentric phase). The patient then throws the ball back to the rebounder by reversing the movements of the arms and trunk (concentric phase) (Fig. 23.42). This exercise targets the horizontal abductors and adductors of the shoulder and trunk rotators. If a rebounder is not available, the exercise can be performed with a therapist or exercise partner.

Hand-to-Hand Overhead Catch and Throw

Patient position and procedure: While standing or kneeling with both upper extremities elevated to about 120° (aligned just anterior to the frontal plane of the trunk), elbows extended, and forearms supinated (palms facing upward), have the patient throw a bean bag or weighted ball over the head with one upper extremity and catch it with the opposite hand, controlling the weight of the ball with that shoulder (eccentric phase). Then throw the ball back to the other hand by abducting the shoulder (concentric phase). Repeat the sequence as if juggling the ball overhead (Fig. 23.43). This exercises targets the shoulder abductors.

FIGURE 23.43 Hand-to-hand overhead catch and throw.

Unilateral Plyometric Shoulder Exercises Using Elastic Resistance

Plyometric activities using elastic resistance can be set up to target individual or multiple muscle groups depending on the patient's position, the line of pull of the elastic, and which joints are moving during the exercise. Refer to Chapter 6 to review the principles of use of elastic resistance products. Setups for the shoulder rotators are described here.

FIGURE 23.42 Bilateral side throw and catch using horizontal abduction and adduction of the shoulders and trunk rotation.

- *Patient position and procedure:* To target the external rotators of the shoulder, have the patient stand facing a wall or doorframe and grasp one end of a length of elastic tubing or band attached to the wall at eye level. Begin with the shoulder and elbow in the 90/90 position (shoulder abducted 90° and in full external rotation and the elbow flexed 90°) (Fig. 23.44). Have the patient release the externally rotated position, controlling movement into internal rotation (eccentric phase), and then quickly reverse the motion by

FIGURE 23.44 Unilateral plyometric exercise for the shoulder external rotators using elastic resistance.

moving the shoulder into external rotation (concentric phase). The elastic should remain taut throughout the exercise.

- *Patient position and procedure:* To target the internal rotators of the shoulder, have the patient stand facing away from the doorframe or wall to which the elastic resistance is attached. Begin with tension on the elastic while the shoulder is in 90° abduction and full internal rotation, and control movement of the shoulder into external rotation (eccentric phase), then quickly return to internal rotation (concentric phase).

Bounce a Weighted Ball: Prone-Lying

Patient position and procedure: While lying prone on a table with the scapula retracted and the upper arm (humerus) supported on the table, position the shoulder in 90° abduction and external rotation and the elbow in 90° flexion. Have the patient bounce a weighted ball on the floor by internally rotating the shoulder; catch it, moving the shoulder back into external rotation under control (eccentric phase); and quickly bounce it again by internally rotating the shoulder (concentric phase) (Fig. 23.45). This exercise targets the shoulder internal rotators.

Unilateral Side Catch and Throw

These exercises target the internal rotators of shoulder.

- *Patient position and procedure:* While standing in the stride position and with the shoulder positioned in some degree of abduction (upper arm slightly away from the trunk), have the patient face the therapist, catch a weighted ball thrown to one side by the therapist, allowing the shoulder to externally rotate to control the momentum of the ball (eccentric phase) (Fig. 23.46 A), and return the ball using primarily shoulder internal rotation (concentric phase). If a rebounder is available, the patient can perform the exercise independently.
- *Patient position and procedure:* While standing in the stride position and with the shoulder abducted and externally rotated and the elbow flexed, have the patient catch and throw a weighted ball using shoulder rotation (a simulated baseball throw) (Fig. 23.46 B). Incorporate trunk rotation in the backward and forward motion of the shoulder. **VIDEO 23.7**

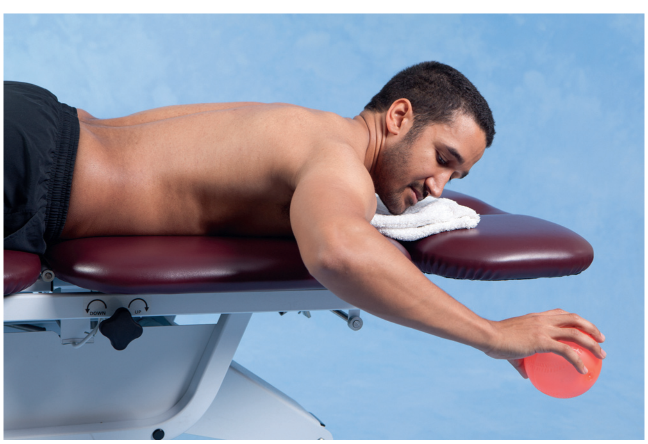

FIGURE 23.45 Unilateral plyometric exercise for the shoulder internal rotators—bounce a weighted ball in the prone-lying position.

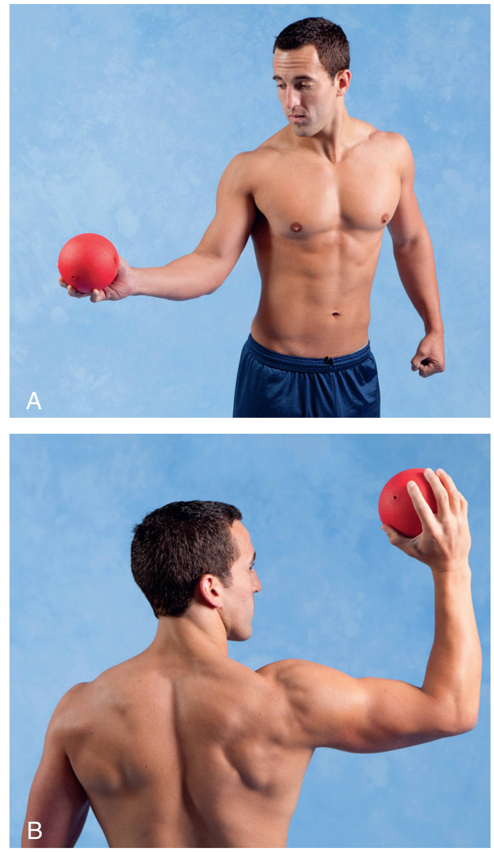

FIGURE 23.46 Unilateral plyometric exercise for the shoulder internal rotators: **(A)** side catch and throw; and **(B)** a simulated baseball throw with the shoulder abducted to 90° and elbow flexed.

Unilateral Reverse Catch and Throw

This exercise primarily targets the external rotators of shoulder in the end-range.

Patient position and procedure: Have the patient assume a half-kneeling position, facing away from the therapist, with the involved shoulder abducted 90° and externally rotated, the elbow flexed to 90°, and the forearm pronated (palm facing therapist). Instruct the patient to look at the hand and catch a soft, lightweight object (ball or bean bag) thrown toward the hand by the therapist; control the momentum of the object by allowing the shoulder to move into internal rotation; and then quickly throw the object back to the therapist by externally rotating the shoulder (Figs. 23.47 A, B, and C).

Throw and Catch with Elbow Action

- *Patient position and procedure:* While in a standing position and with the arm positioned along the side of the trunk, have the patient throw a weighted ball into the air with one hand, using primarily elbow flexion; catch it, allowing the elbow to extend with control (eccentric phase); and then quickly throw it into the air again (concentric phase) (Fig. 23.48). This exercise targets the elbow flexors.
- *Patient position and procedure:* While standing and with one or both arms positioned overhead, have the patient catch a weighted ball and return it to the therapist or to a rebounder using primarily elbow action. This exercise targets the elbow extensors and can be done bilaterally or unilaterally.

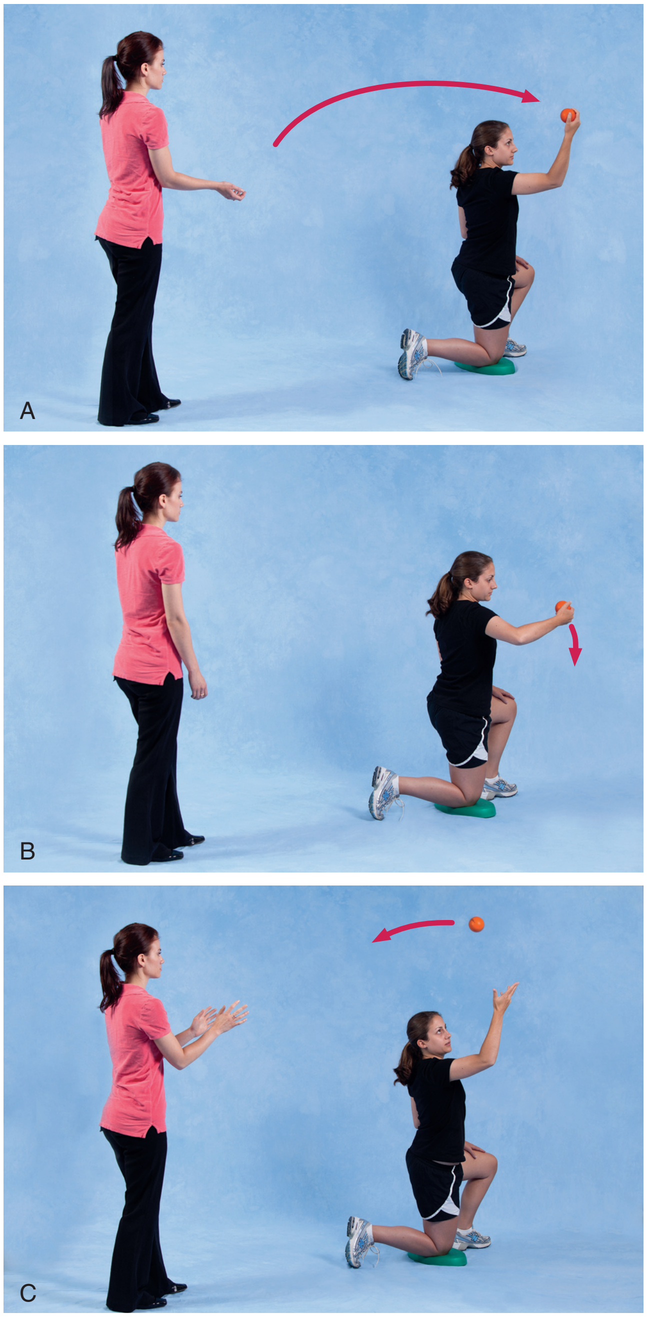

FIGURE 23.47 Unilateral plyometric exercise for the shoulder external rotators—reverse catch and throw: The patient: **(A)** catches a soft, lightweight object with the shoulder abducted and externally rotated and the elbow flexed; **(B)** allows the shoulder to internally rotate with control; and **(C)** externally rotates the shoulder to throw the object back to the therapist.

FIGURE 23.48 Unilateral plyometric exercise targeting the elbow flexors.

FIGURE 23.49 Unilateral plyometric exercise targeting the wrist flexors.

Unilateral Throw and Catch with Wrist Action

Patient position and procedure: While seated, have the patient stabilize the elbow on the thigh in about 90° flexion, and with the forearm supinated, toss a weighted ball or bean bag into the air using primarily wrist flexion; catch it, allowing the wrist to extend under control (eccentric phases); and then quickly toss it into the air again (concentric phase) (Fig. 23.49). This exercise targets the wrist flexors.

Simulated Sport Activities

- Dribble a weighted ball or basketball against a wall (Fig. 23.50) or on the floor using either elbow or wrist actions. This activity targets either the elbow extensors or wrist flexors.
- Bounce a tennis ball or racquetball into the air or onto the floor (forearm supinated or pronated, respectively) with

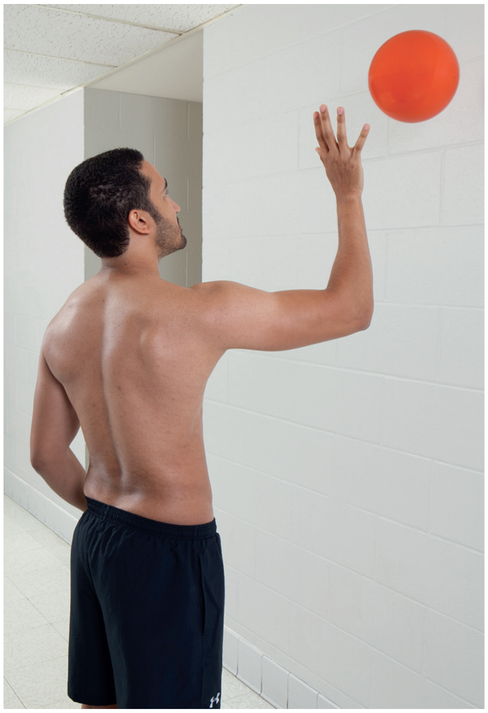

FIGURE 23.50 Dribble a ball against the wall to target the wrist flexors.

FIGURE 23.52 Practice a golf swing using a weighted club.

a short-handled racquet, progressing to a long-handled racquet. These activities emphasize the wrist flexors. In contrast, bouncing a ball into the air with the forearm pronated emphasizes the wrist extensors (Fig. 23.51).

- Swing a weighted golf club (Fig. 23.52) or baseball bat. The backward motion followed by a rapid reversal forward provides the plyometric stimulus.

Upper Extremity Weight-Bearing Movements on a Slide Board

Use of a slide board, such as a ProFitter™, provides an unstable, moving surface for performing movements of the shoulders that require quick changes of direction combined with weight bearing through the upper extremities.

- *Patient position and procedure:* Have the patient place both hands on a spring-loaded slide board while kneeling along one side of the equipment. Shift the arms side-to-side from the shoulders (Fig. 23.53), gradually increasing the speed of the shoulder movements and changes of direction.
- *Patient position and procedure:* Have the patient kneel at one end of the slide board and move the arms forward and backward from the shoulders.
- *Progression:* Perform the same movements while kneeling and bearing weight on one hand.

FIGURE 23.51 Using a short-handled racquet, bounce a ball into the air with the forearm pronated to target the wrist extensors.

FIGURE 23.53 Bilateral plyometric exercise while bearing weight through the upper extremities—side-to-side movements with quick changes of direction on a ProFitter®.

Push-Offs from a Wall

- *Patient position and procedure:* While the patient is standing several feet away from a wall (or countertop), gently push the patient directly forward toward the wall. Instruct the patient to catch himself/herself with equal weight on both hands, allowing the elbows to flex under control (eccentric phase) as the trunk moves toward the wall (Fig. 23.54 A). Then have the patient quickly push away from the wall with both hands (concentric phase) (Fig. 23.54 B), catch the patient as he/she falls backward, and then push the patient forward again to repeat the sequence.
- *Alternative activity:* Have the patient perform the sequence independently by falling forward to the wall and quickly pushing away.
- *Progression:* Have the patient use one hand to catch self and push away from the wall.

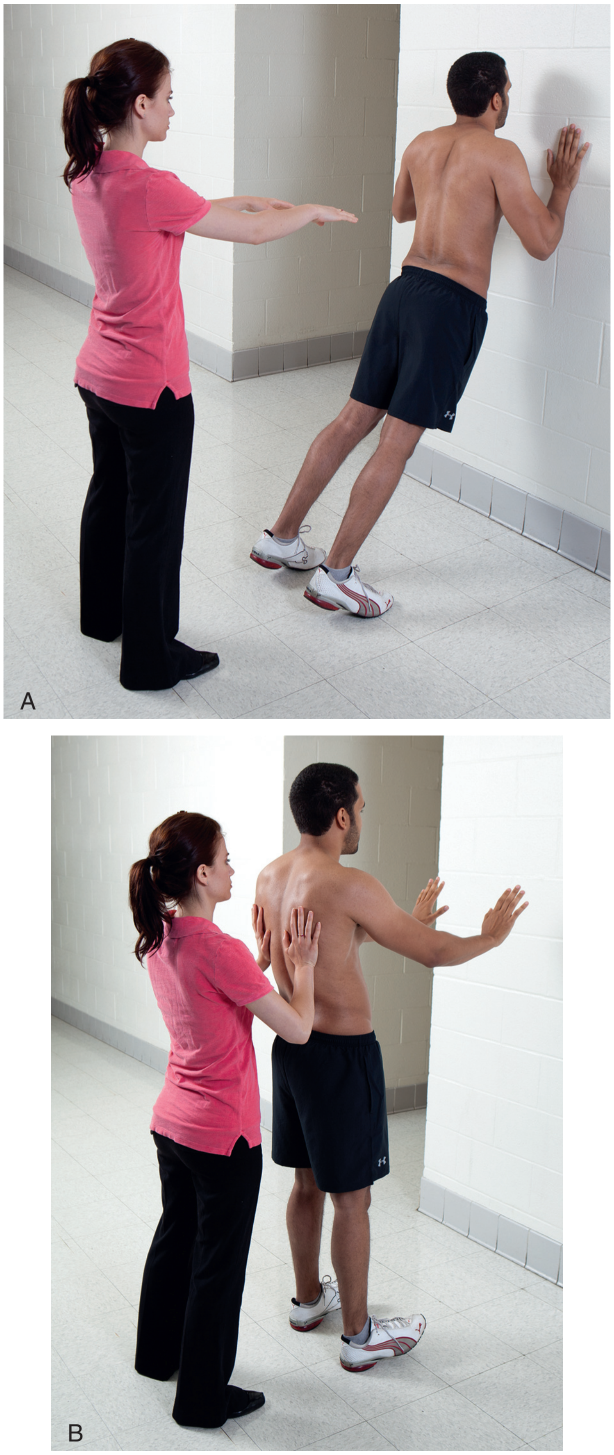

FIGURE 23.54 Repeated push-offs from a wall: **(A)** falling directly forward toward the wall and catching self with both hands; and **(B)** pushing away from the wall to the upright position.

Side-to-Side Push-Offs from a Waist-Level Surface VIDEO 23.8

Patient position and procedure: While standing and maintaining both feet approximately 3 feet away from a waist-height, stable surface (countertop, heavy table), have the patient fall forward and slightly to the right of midline and catch self with hands on the edge of the countertop or table; push off and shift arms and trunk to the left; catch self with both hands; and push off again, moving arms and trunk back to the right, past midline (Fig. 23.55). This exercise alternately places greater weight on the right and then the left upper extremity.

Variations of Prone Push-Ups VIDEO 23.8

- *Clap push-ups*: While on the floor, have the patient perform a forceful prone push-up from knees or feet; clap hands together; catch self with both hands, allowing elbows to flex

FIGURE 23.55 Alternating side-to-side push-offs to and from a stable, waist-high surface.

(eccentric phase); and quickly perform another push-up (concentric phase).

- *Drop push-ups*: Have the patient perform a prone push-up from knees or feet with hands on platforms positioned a shoulder width apart. Drop both hands and the chest to the floor, controlling the descent of the trunk (eccentric phase); quickly perform another push-up (concentric phase); and return both hands to the platforms (Figs. 23.56 A, B, and C).

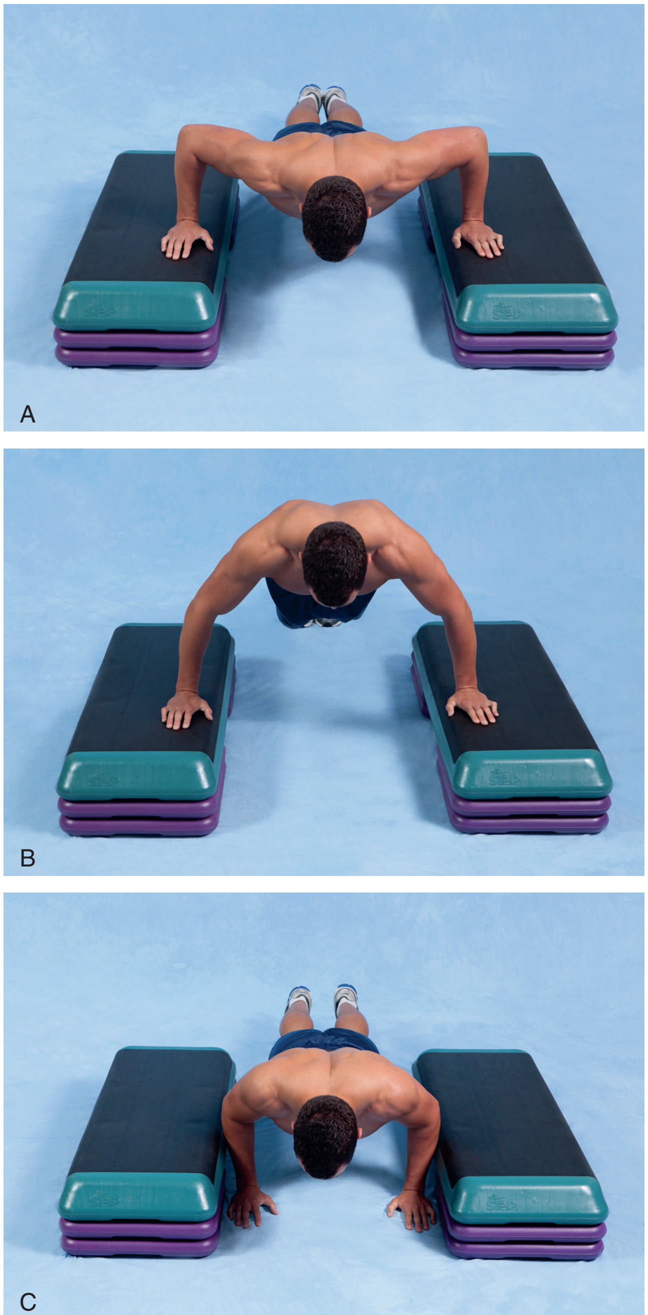

FIGURE 23.56 Drop push-ups in the prone position: **(A)** Starting position; **(B)** prone push-up; and **(C)** drop hands to floor, allowing elbows to flex. Push up from the floor and quickly return hands to platforms as in *(A)*.

Plyometric Exercises: Lower Extremities

Most plyometric exercises for the lower extremities are performed while standing and require eccentric and concentric control of the hip and knee extensors and ankle plantarflexors against body weight. These exercises require postural stability and balance because of the quick changes of direction involved. Plyometric activities can be progressed by adding an external load (a weighted belt, vest, or backpack) to augment body weight or by first performing the exercises in bilateral stance (jumping) and then in unilateral stance (hopping).

The following plyometric exercises are examples of lower extremity activities that can be incorporated into the final phase of rehabilitation in preparation for functional activities ranging from community ambulation to high-intensity sports.

CLINICAL TIP

Have the patient wear supportive footwear when performing jumping and hopping activities. When teaching these activities, reinforce proper landing techniques. Specifically, make sure the patient flexes the knee(s) for shock absorption but maintains the lower leg(s) in vertical alignment with respect to the foot, thus avoiding valgus collapse at the knee(s).

Kicking a Ball

These exercises involve rapid eccentric and concentric open-chain contractions of hip musculature. Be sure the patient is wearing shoes during kicking activities.

- *Patient position and procedure:* While standing and facing an exercise partner, have the patient swing one lower extremity backward into hip extension (eccentric phase), then quickly swing the same extremity forward into hip flexion (concentric phase) and kick a ball to the partner with the anterior aspect of the foot. This activity targets the hip flexors and knee extensors.
- *Patient position and procedure:* While standing with one shoulder positioned toward an exercise partner, have the patient stand on the leg closer to the partner, swing the opposite hip into abduction, and then quickly adduct the hip to kick the ball back to the partner using the medial aspect of the foot (as in a soccer kick). This exercise targets the hip adductors.

Sit-to-Stand from a Ball

- *Patient position and procedure:* While in sitting, have the patient bounce on a therapy ball (stabilized by the therapist), come to a partial standing position, and then sit back down on the ball and quickly come to a partial standing position again (Fig. 23.57). Progress the exercise by eventually coming to a full standing position. This activity requires contraction of the hip and knee extensors against the resistance of body weight. To be effective, rapid reversals must occur between the lowering (eccentric) and standing-up (concentric) phases.

FIGURE 23.57 Moving from sit-to-stand by bouncing on a ball.

FIGURE 23.58 Side-to-side movements on a Pro-Fitter®.

Bilateral Heel Raises on a Mini-Trampoline

Patient position and procedure: In bilateral stance, have the patient bounce on a mini-trampoline by performing repeated heel raises and lowering. This activity targets the gastrocnemius-soleus muscle groups.

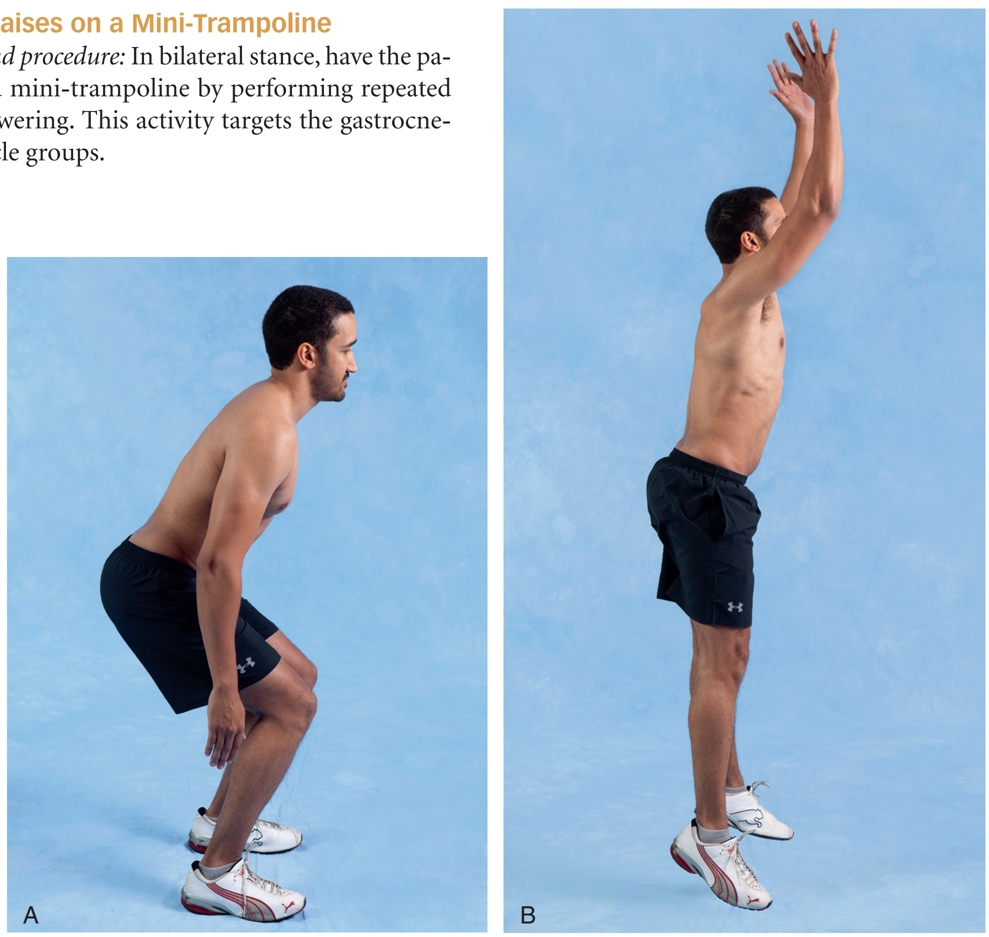

FIGURE 23.59 Squat jumps: **(A)** from a squat position, perform a **(B)** vertical jump.

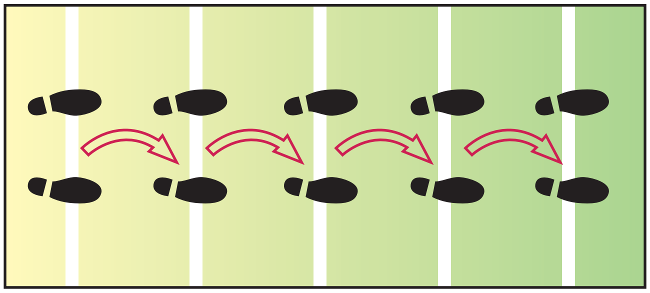

FIGURE 23.60 Bounding: a series of forward jumps across a floor.

Side-to-Side Shuffle

Patient position and procedure: Have the patient take several quick side steps to the right and then back to the left, and repeat. This exercise requires rapid contractions of the hip abductors and adductors against body weight during each change of direction.

Side-to-Side Movements on a Slide Board

Patient position and procedure: While standing on a slide board, such as a Pro-Fitter®, have the patient shift body weight side-to-side (Fig. 23.58), gradually increasing the speed of the directional changes as skill and coordination improve.

Squat Jumps VIDEO 23.9

Patient position and procedure: Have the patient move quickly from a standing position into a squat position (eccentric phase) (Fig. 23.59 A), quickly transition to a vertical jump (concentric phase) (Fig. 23.59 B), return to the squat position, and then perform another vertical jump. When landing and moving into the squat position, be sure the patient keeps the lower legs aligned as close to vertical as possible.

Bounding

- *Patient position and procedure:* Have the patient start with the feet positioned shoulder width apart, and take multiple jumps forward in a straight line across the floor (Fig. 23.60).
- *Progressions:* Increase the speed at which the activity is performed, and then increase the distance of each jump. When able, have the patient perform forward hopping across the floor.

Four-Quadrant Jumps or Hops VIDEO 23.9

- *Patient position and procedure:* Using two lines on the floor intersecting at right angles as a guide, have the patient jump forward, backward, side-to-side, and diagonally from one quadrant to another, using quick directional changes (Fig. 23.61).

Tuck Jumps

- *Patient position and procedure:* Have the patient begin in standing position, quickly lower the body into a squat position (eccentric phase), perform a tuck jump as high as possible, bringing the knees toward the chest (Fig. 23.62),

FIGURE 23.61 Four-quadrant jumping or hopping.

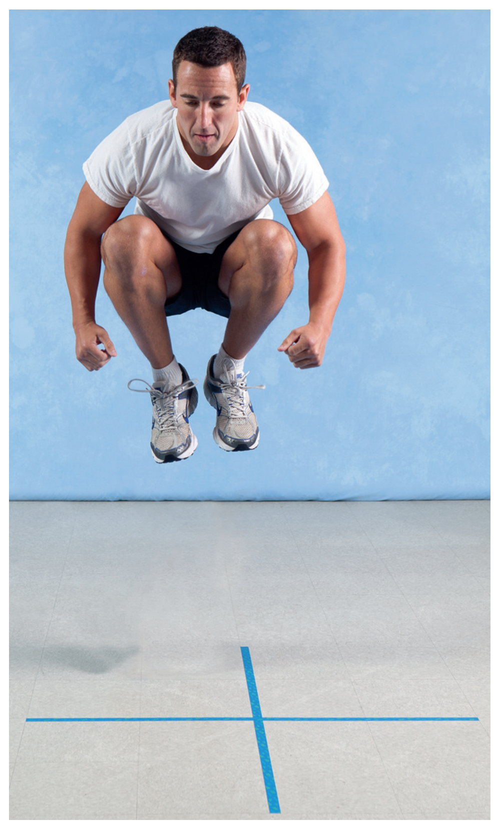

FIGURE 23.62 Tuck jump.

FIGURE 23.63 **(A)**, **(B)**, *and* **(C)** Lunge-jumps: alternately landing with right, then left lower extremity forward.

and then land in proper alignment and return to the squat position to initiate the next tuck jump.

- *Progression:* Perform a series of side-to-side tuck jumps over a barrier.

Lunge Jumps VIDEO 23.9

- *Patient position and procedure:* Have the patient begin in a symmetrical standing position, jump vertically, and land in a forward lunge position (eccentric phase); then quickly jump vertically (concentric phase) and again land in a forward lunge position. Perform multiple repetitions by landing with the same foot forward each time.
- *Alternative activity—Scissor-lunge jumps:* Perform a sequence of lunge-jumps, alternately bringing the right and then left foot forward, as in a scissoring motion (Fig. 23.63 A, B, and C).
- *Progression:* Increase the challenge by performing lunge-jumps while wearing a weighted vest or holding weights in both hands.

Zigzag Forward Jumping or Hopping

Patient position and procedure: Have the patient jump or hop across the floor in a zigzag pattern marked on the floor (Fig. 23.64). Progress by increasing the speed of jumping or hopping and the distance between jumps or hops.

Hopping Over Objects VIDEO 23.9

Patient position and procedure: Have the patient hop over objects of various sizes placed on the floor like an obstacle course (Fig. 23.65).

Single Platform Jumping or Hopping

Patient position and procedure: Have the patient jump and progress to hopping onto and off of a single, low platform in forward (Fig. 23.66), backward, and lateral directions, being certain to use proper landing technique. To progress, first increase the speed and repetitions of the jumping or hopping activity, then increase the height of the platform.

Multiple Platform Jumping or Hopping

Patient position and procedure: Have the patient jump (or hop) in a forward direction off of a platform to the floor and then jump forward again onto another platform (see Fig. 23.18 A, B, and C). Progress by performing the sequence more rapidly or by increasing the height of the platforms.

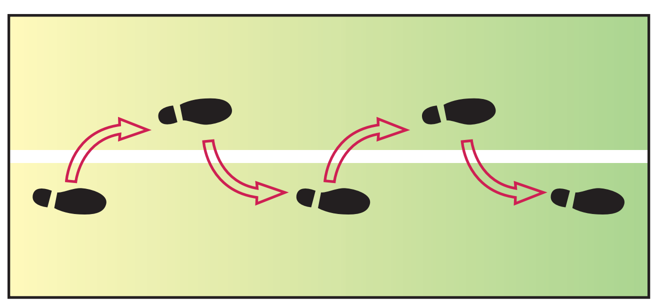

FIGURE 23.64 Zigzag forward hopping.

FIGURE 23.65 Lateral hopping over objects of varying sizes set up in an obstacle course on the floor.

FIGURE 23.66 Hopping onto and off of a single platform using proper landing technique.

Independent Learning Activities

Critical Thinking Questions

1. Review the principles of balance training described in Chapter 8. Describe how each of the advanced balance activities presented in this chapter (Chapter 23) can be used to enhance the static, dynamic, anticipatory, or reactive aspects of balance.
2. Develop a sequence of balance activities in the standing position from least to most difficult, using progressively more challenging movements and equipment.
3. Identify the benefits, as well as the risks, of performing a program of plyometric exercises (stretch-shortening drills).
4. Analyze the plyometric training activities listed in Box 23.1, and determine in which muscle groups training-induced gains in strength and power would occur and what functional tasks each of the activities could enhance.
5. Develop a plyometric sequence for the lower extremities and trunk progressing from simple to more difficult (similar to the sequence for the upper extremities described in Box 23.3).

Laboratory Activities

1. Practice the sequence of balance activities in the standing position that you developed to answer Critical Thinking Question #2. Take turns with a laboratory partner role-playing the therapist and the patient. If you are the therapist, use proper safety precautions, critically analyze how your patient performs each balance task, and give your patient feedback to facilitate learning correct alignment and technique.
2. Perform and analyze a variety of plyometric exercises for the upper or lower extremities, and identify which muscle groups are loaded eccentrically or concentrically during the two phases of each activity.
   - Catch and throw a weighted ball with both hands (or one hand) while assuming supine, prone, and upright positions.
   - While kneeling and with hands placed on a slide board and elbows extended, move the arms forward and backward or side-to-side.

- While standing a few feet from a wall, fall forward, catching yourself with both hands, and then push off the wall to return to a standing position.
- In the prone position, perform bilateral drop push-ups to and from two low platforms.
- While standing on a mini-trampoline, bounce your heels off and on the surface using only ankle motion.
- Jump off of and back onto a low platform—forward, backward, and side-to-side.

Case Studies

Case Study #1

You have been following a 21-year-old female college volleyball player, who underwent an arthroscopic ACL reconstruction of the left knee 4 months ago. She now has full, pain-free ROM of the knee and 80% to 85% strength of left knee and hip musculature compared with the sound right lower extremity. Arthrometer measurements indicate that A-P stability of the operated knee is comparable to the sound side. However, her performance on a single step-down test reveals continued evidence of abnormal alignment of the operated lower extremity (excessive hip adduction, and internal rotation, knee valgus, and foot pronation). She has been given approval by her surgeon to return to intercollegiate play by 6 months postoperatively, following completion of an advanced training program individualized to her needs and goals.

- Develop an 8-week training program of advanced strengthening, balance, and plyometric drills for this patient. Identify specific exercises that would be included in each training session and how the exercises will be progressed over the 8-week period.
- In addition to exercises to enhance stability, control, and strength of the lower extremity, identify exercises that should be included to improve her upper extremity function.

Case Study #2

You have been working with a 35-year-old "weekend warrior" who was diagnosed with chronic tennis elbow. His symptoms are now under control, and he wants to return to competitive play at the local tennis club. Develop a training program of advanced strengthening and plyometric drills for this individual. Identify each exercise and its progression in terms of repetitions, resistance, control, and precautions. Include both upper and lower extremity drills and progressions that include total body-coordinated effort.

Additional Case Studies

For additional study, review the following case studies from previous chapters and modify your exercise interventions to include advanced drills based on the information you studied in this chapter.

1. Case study #4 in Chapter 17
2. Case study #2 and #3 in Chapter 20
3. Case study #2, #3, and #4 Chapter 22

Women's Health: Obstetrics and Pelvic Floor

BARBARA SETTLES HUGE, PT ■ CAROLYN KISNER, PT, MS

Throughout a woman's life cycle, specific gender differences need to be recognized for their relevance to rehabilitation. Recent research has shown repeatedly that women have specific and distinct physiological processes that extend beyond the obvious considerations of anatomy and hormones, including differences in symptoms of heart attacks and in metabolism of medications.[58] Clearly, the pregnant or postpartum patient presents a unique gender-based clinical challenge for the physical therapist. Although pregnancy is a time of tremendous musculoskeletal, physiological, and emotional change, it is nonetheless a state of wellness. Pregnant women are typically well motivated, willing to learn, and highly responsive to treatment suggestions. For many women, the therapist is able to assess and monitor the physical changes with the primary focus on maintaining wellness. The ability to educate women about the role of exercise and health promotion during this key life transition provides a significant professional opportunity and responsibility.

In cases of musculoskeletal impairment related to pregnancy, the therapist is able to examine and treat the patient by incorporating knowledge of injury and tissue healing with knowledge of the changes during pregnancy. By considering a broader perspective, it is recognized that all female patients can benefit from education regarding the role of the pelvic floor muscles in musculoskeletal health, specifically in trunk stabilization. Specialized treatment of pelvic floor dysfunction is critical to quality of life for women experiencing incontinence, pelvic organ prolapse, and a variety of pelvic pain syndromes. Although all physical therapists can fairly easily incorporate activation of the pelvic floor muscles as a key component of trunk stabilization exercises, true expertise

can come only with further training and mentoring. Advanced study of pelvic floor anatomy, evaluation, and treatment is highly recommended for therapists who wish to specialize in this area.

This chapter provides readers with basic information about the systemic changes of pregnancy as a foundation for the development of safe and effective exercise programs. In addition, a review of pelvic floor anatomy, function, and dysfunction serves as an introduction to the treatment of pelvic floor disorders. The chapter emphasizes modification of general exercises to meet the needs of the obstetric patient and provides information to assist in the development of an exercise program for an uncomplicated pregnancy. Cesarean delivery, high-risk pregnancy, and the special needs of patients with these conditions are also discussed.

Overview of Pregnancy, Labor, and Related Conditions

Characteristics of Pregnancy and Labor

Pregnancy

Pregnancy, which spans 40 weeks from conception to delivery, is divided into three trimesters, with characteristic changes during each.[36,53,74,82]

First Trimester Changes

During the first trimester (weeks 0 through 12), the following occur:

- Implantation of the fertilized ovum in the uterus occurs 7 to 10 days after fertilization.
- The mother is very fatigued, urinates more frequently, and may experience nausea and/or vomiting ("morning" sickness).
- Breast size may increase.
- There is a relatively small weight gain of 0 to 1455 g (0 to 3 lb is normal).
- Emotional changes may occur.
- By the end of the 12th week, the fetus is 6 to 7 cm long and weighs approximately 20 g (2 oz). The fetus now can kick, turn its head, and swallow and has a beating heart, but these movements are not yet felt by the mother.

Second Trimester Changes

During the second trimester (weeks 13 through 26), the following occur:

- The pregnancy becomes visible to others.
- The mother begins to feel movement at around 20 weeks.
- Most women now feel very good. Nausea and fatigue have usually disappeared.
- By the end of the second trimester, the fetus is 19 to 23 cm (14 in.) in length and weighs approximately 600 g (1 to 2 lb).
- The fetus now has eyebrows, eyelashes, and fingernails.

Third Trimester Changes

During the third trimester (weeks 27 through 40), the following occur:

- The uterus is now very large and has regular contractions, although these may be felt only occasionally.
- Common complaints during the third trimester are frequent urination, back pain, leg edema and fatigue, round ligament pain, shortness of breath, and constipation.
- By the time of birth, the baby will be 33 to 39 cm long (16 to 19 in.) and will weigh approximately 3400 g (7 lb, although a range of 5 to 10 lb is normal).

NOTE: Although pregnancy typically lasts 40 weeks, the range of 38 to 42 weeks is considered full term.

Labor

Labor is divided into three stages, each containing specific events.[16,54,78,80] The exact mechanism that initiates labor is not known. Regular and strong involuntary contractions of the smooth muscles of the uterus are the primary symptom of labor. True labor produces palpable changes in the cervix, which are known as effacement and dilation (Fig. 24.1).[80]

- *Effacement* is the shortening or thinning of the cervix from a thickness of 5 cm (2 in.) before onset of labor to the thickness of a piece of paper.
- *Dilation* is the opening of the cervix from the diameter of a fingertip to approximately 10 cm (4 in.).

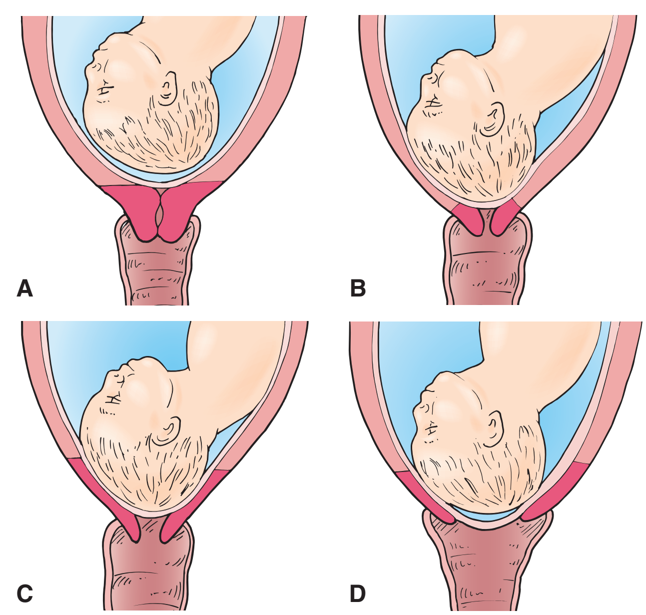

FIGURE 24.1 Effacement and dilation of the cervix. (Adapted from Ward, S, and Hisley, S: *Maternal-Child Nursing Care.* Philadelphia: F.A. Davis; 2009, with permission.)

Labor: Stage 1

Some women experience initial cervical dilation and effacement before they are in true labor. However, by the end of this stage, the cervix is fully dilated, and there is no doubt that a baby is about to be delivered. Stage 1 of labor is divided into three major phases.

Cervical dilation phase. The cervix dilates from 0 to 3 cm (0 to 1 in.) and will almost completely efface. Uterine contractions occur from the top down, causing the cervix to open and pushing the fetus downward.

Middle phase. The cervix dilates from 4 to 7 cm (1 to 3 in.). Contractions are stronger and more regular.

Transition phase. The cervix dilates from 8 to 10 cm (3 to 4 in.), and dilation is complete. Uterine contractions are very strong and close together.

Labor: Stage 2

Stage 2 involves "pushing" and expulsion of the fetus. Intra-abdominal pressure is the primary force expelling the fetus; it is produced by voluntary contraction of the abdominal muscles and diaphragm. Relaxation and stretching of the pelvic floor during stage 2 are also necessary for successful vaginal delivery. Uterine contractions may last as long as 90 seconds during this stage.

Fetal descent. Position changes (cardinal movements) by the fetus allow it to pass through the pelvis and be born (Fig. 24.2).[78] The position changes are described as:

- ***Engagement.*** The greatest transverse diameter of the fetal head passes through the pelvic inlet (the superior opening of the minor pelvis).
- ***Descent.*** Continued downward progression of the fetus occurs.
- ***Flexion.*** The fetal chin is brought closer to its thorax; this occurs when the descending head meets resistance from the walls and floor of the pelvis and the cervix.
- ***Internal rotation.*** The fetus turns its occiput toward the mother's symphysis pubis when the fetal head reaches the level of the ischial spines.

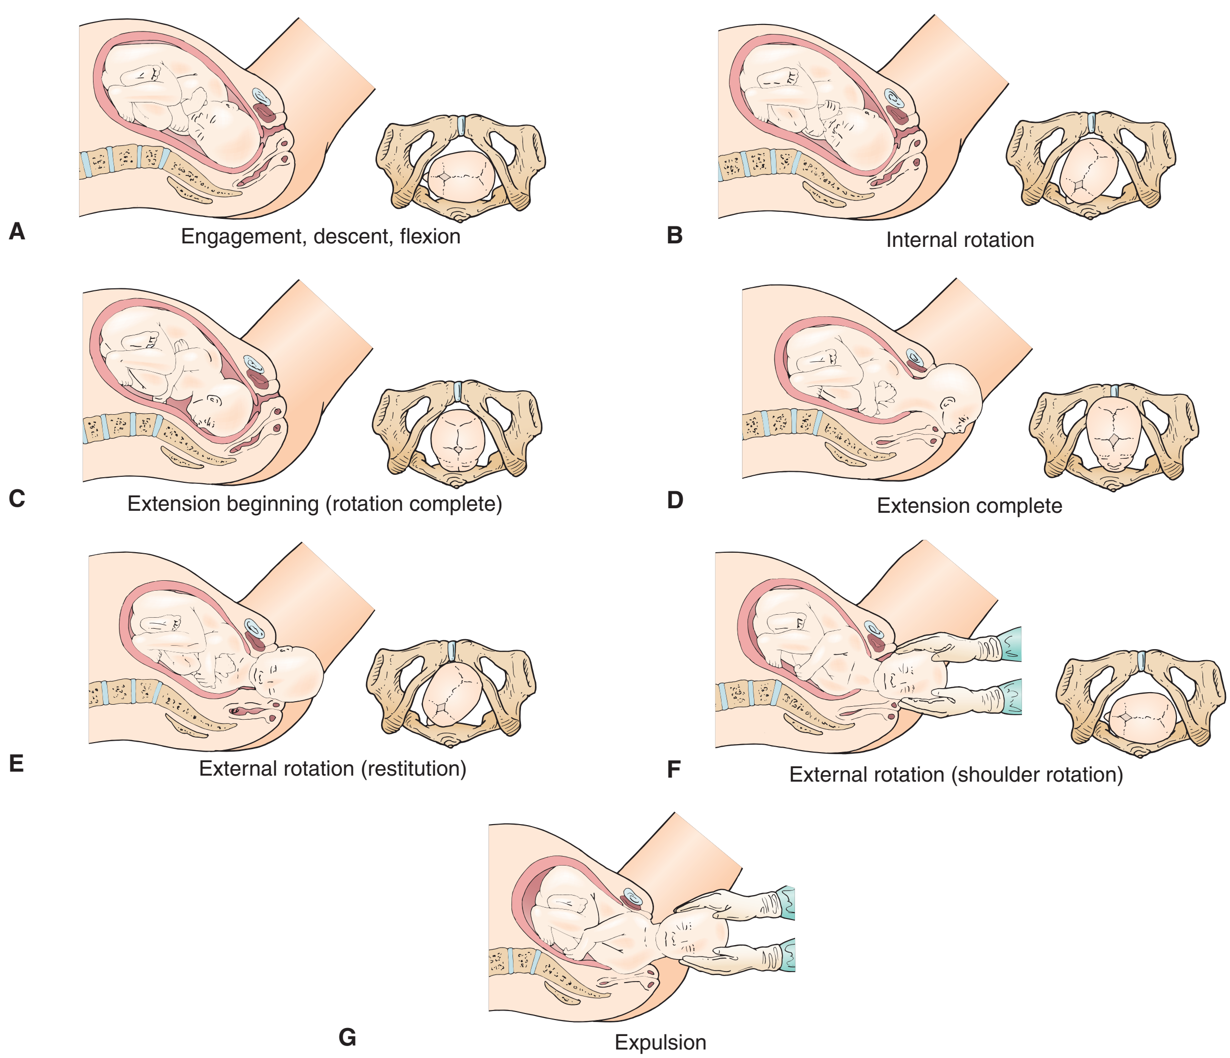

FIGURE 24.2 Principal movements in the mechanism of labor and delivery, left occiput anterior position. (From Ward, S, and Hisley, S. *Maternal-Child Nursing Care.* Philadelphia: F.A. Davis; 2009, with permission.)

- *Extension.* The flexed fetal head reaches the vulva; the fetus extends its head, bringing the base of the occiput in direct contact with the inferior margin of the maternal symphysis pubis; this phase ends when the fetal head is delivered.
- *External rotation.* The fetus rotates its occiput toward the mother's sacrum to allow the fetal shoulders to pass through the pelvis.

Expulsion. The fetal anterior shoulder passes under the symphysis pubis, and the rest of the body follows.

Labor: Stage 3

Placental stage (expulsion of the placenta). After delivery, the uterus continues to contract and shrink, causing the placenta to detach and be expelled.

- As the uterus decreases in size, the placenta detaches from the uterine wall, blood vessels are constricted, and bleeding slows. This can occur 5 to 30 minutes after the baby is delivered.
- A hematoma forms over the uterine placental site to prevent further significant blood loss; mild bleeding persists for 3 to 6 weeks after delivery.

Uterine involution. The uterus continues to contract and decrease in size for 3 to 6 weeks after delivery; the uterus always remains slightly enlarged over its prepregnant size.

Anatomical and Physiological Changes of Pregnancy

Considerable changes occur in the woman's body as the pregnancy progresses.[16,53,74,80,86,91]

Weight Gain During Pregnancy

Current recommendations for weight gain during pregnancy are an average of 25 to 35 lb[48,52] with a distribution as shown in Box 24.1.

BOX 24.1 Total Weight Gain (Ranges) for Single Fetus

Baby	3.36–3.88 kg	(7–8 lb)
Placenta	0.48–0.72 kg	(2–3 lb)
Amniotic fluid	0.72–0.97 kg	(2–3 lb)
Uterus and breasts	2.42–2.66 kg	(4–8 lb)
Blood and fluid	1.94–3.99 kg	(4 lb)
Fat stores	0.48–2.91 kg	(5–9 lb)
Total:	9.70–14.55 kg	(25–35 lb)

Changes in Organ Systems

Uterus and Related Connective Tissue

Uterus. The uterus increases from a prepregnant size of 5 by 10 cm (2 by 4 in.) to 25 by 36 cm (10 by 14 in.). It increases five to six times in size, 3,000 to 4,000 times in capacity, and 20 times in weight by the end of pregnancy. By the end of pregnancy, each muscle cell in the uterus has increased approximately 10 times over its prepregnancy length[91] Once the uterus expands upward and leaves the pelvis, it becomes an abdominal rather than a pelvic organ.

Connective tissues. Ligaments connected to the pelvic organs are more fibroelastic than ligaments supporting joint structures. The fascial tissues, which surround and enclose the organs in a continuous sheet, also include a significant amount of smooth muscle fibers.[27] The round, broad, and uterosacral ligaments in particular provide suspensory support for the uterus.

Urinary System

Kidneys. The kidneys increase in length by 1 cm (0.5 in.).

Ureters. The ureters enter the bladder at a perpendicular angle because of uterine enlargement. This may result in a reflux of urine out of the bladder and back into the ureter; therefore, during pregnancy, there is an increased chance of developing urinary tract infections because of urinary stasis.

Pulmonary System

Hormonal influences. Hormone changes affect pulmonary secretions and rib cage position.

- Edema and tissue congestion of the upper respiratory tract begin early in pregnancy because of hormonal changes. Hormonally stimulated upper respiratory hypersecretion also occurs.
- Changes in rib position are hormonally stimulated and occur prior to uterine enlargement. The subcostal angle progressively increases; the ribs flare up and out. The anteroposterior and transverse chest diameters each increase by 2 cm (1 in.). Total chest circumference increases by 5 to 7 cm (2 to 3 in.) and does not always return to the prepregnant state.
- The diaphragm is elevated by 4 cm (1.5 in.); this is a passive change caused by the change in rib position.

Respiration. Respiration rate is unchanged, but depth of respiration increases.[78]

- Tidal volume and minute ventilation increase, but total lung capacity is unchanged or slightly decreased.[78,91]
- There is a 15% to 20% increase in oxygen consumption; a natural state of hyperventilation exists throughout pregnancy to meet the oxygen demands of pregnancy.[78,91]

- The work of breathing increases because of hyperventilation; dyspnea is present with mild exercise as early as 20 weeks into the pregnancy.[78,91]

Cardiovascular System

Blood volume and pressure. Blood volume progressively increases 35% to 50% (1.5 to 2 L) throughout pregnancy and returns to normal by 6 to 8 weeks after delivery.

- Plasma increase is greater than red blood cell increase, leading to the "physiologic anemia" of pregnancy, which is not a true anemia but is representative of the greater increase of plasma volume. The increase in plasma volume occurs as a result of hormonal stimulation to meet the oxygen demands of pregnancy.
- Venous pressure in the lower extremities increases during standing as a result of increased uterine size and increased venous distensibility.
- Pressure in the inferior vena cava rises in late pregnancy, especially in the supine position, because of compression by the uterus just below the diaphragm. In some women, the decline in venous return and resulting decrease in cardiac output may lead to symptomatic supine hypotensive syndrome. The aorta is partially occluded in the supine position.
- Blood pressure decreases early in the first trimester. There is a slight decrease of systolic pressure and a greater decrease of diastolic pressure. Blood pressure reaches its lowest level approximately midway through pregnancy and then rises gradually from mid-pregnancy to reach the prepregnant level approximately 6 weeks after delivery. Although cardiac output increases, blood pressure decreases because of venous distensibility.

Heart. Heart size increases, and the heart is elevated because of the movement of the diaphragm.

- Heart rhythm disturbances are more common during pregnancy.
- Heart rate usually increases 10 to 20 beats per minute by full term and returns to normal levels within 6 weeks after delivery.
- Cardiac output increases 30% to 60% during pregnancy and is most significantly increased when a woman is in the left side-lying position, in which the uterus places the least pressure on the aorta.

Musculoskeletal System

Abdominal muscles. The abdominal muscles, particularly both sides of the rectus, as well as the linea alba, are all subjected to significant biomechanical changes and become stretched to the point of their elastic limit by the end of pregnancy. This greatly decreases the muscles' ability to generate a strong contraction and thus decreases their efficiency of contraction. The shift in the center of gravity also decreases the mechanical advantage of the abdominal muscles.[54,91]

Pelvic floor muscles. The pelvic floor muscles, in their antigravity position, must withstand the total change in weight; the pelvic floor drops as much as 2.5 cm (1 in.) as a result of pregnancy.[86]

Connective tissues and joints. The hormonal influence on the ligaments is profound, producing a systemic decrease in ligamentous tensile strength. Joint laxity has been measured in multiple joints during pregnancy and postpartum. The evidence is inconclusive in terms of indentifying which specific hormones are responsible. These changes in joint stability have been noted as many as 4 months postpartum.[53]

- The thoracolumbar fascia is lengthened via its connection to the abdominal wall, which diminishes its ability to support and stabilize the trunk effectively.[28]
- Joint hypermobility occurs as a result of ligamentous laxity and may predispose the patient to injury, especially in the weight-bearing joints of the back, pelvis, and lower extremities.

Thermoregulatory System

Metabolic rate. During pregnancy, basal metabolic rate and heat production increase.[3]

- An additional intake of 300 calories per day is needed to meet the basic metabolic needs of pregnancy.
- In pregnant women, normal fasting blood glucose levels are lower than in nonpregnant women.[3]

Changes in Posture and Balance

Center of Gravity

The center of gravity shifts upward and forward because of the enlargement of the uterus and breasts. This requires postural compensations to maintain balance and stability.[54,74,91]

- The *lumbar and cervical lordoses* increase to compensate for the shift in the center of gravity.
- The *shoulder girdle and upper back* become rounded with scapular protraction and upper extremity internal rotation because of breast enlargement; this postural tendency persists in the postpartum period due to infant care demands. Tightness of the pectoralis muscles and weakness of the scapular stabilizers may be preexisting to or induced by the pregnancy postural changes.
- The *suboccipital muscles* respond in an effort to maintain appropriate eye level (optical righting reflex), and to moderate forward head posture along with the change in shoulder alignment.
- A tendency toward genu recurvatum will shift weight toward the heels in an attempt to counteract the anterior pull of the growing fetus.
- Changes in posture do not automatically correct after childbirth, and the pregnant posture may become habitual. In addition, many child care activities contribute to persistent postural faults and asymmetry.

Balance

With the increased weight and redistribution of body mass, there are compensations to maintain balance.[74,91]

- The pregnant woman usually walks with a wider base of support and increased external rotation at the hips.
- This change in stance, along with growth of the baby, makes some activities such as walking, stooping, stair climbing, lifting, reaching, and other activities of daily living (ADLs) progressively more challenging.
- Activities requiring fine balance and rapid changes in direction, such as aerobic dancing and bicycle riding, may become inadvisable, especially during the third trimester.

Overview of Pelvic Floor Anatomy, Function, and Dysfunction

Treatment of pelvic floor impairment has become more visible and accepted in the physical therapy community over the past 10 to 15 years. In 2010, the specialty area of Women's Health was recognized on a national level at Combined Sections Meeting of the American Physical Therapy Association (APTA), at which 60 newly certified Women's Health Clinical Specialists (WCS) were acknowledged for their achievements. Advanced and in-depth study of anatomy, including internal muscle assessment, physiology, evaluation, and treatment continues to be highly recommended for therapists who specialize in this area.*

Pelvic Floor Musculature

The pelvic floor musculature is composed of three layers in a funnel-shaped orientation, with boney attachments to the pubic bone and the coccyx. Laterally, the tissues blend into a fascial layer overlying the obturator internus. The prime mover of the pelvic floor is the levator ani. The levator ani, in combination with the coccygeus, forms the pelvic diaphragm. The most superficial muscles of the pelvic floor include the superficial transverse perineal muscles, the ischiocavernosus, the bulbocavernosus, and the external anal sphincter. Both the right and left sides of the pelvic floor complex contribute fibers to the perineal body located superficially between the vagina and rectum (Fig. 24.3). The structure and action of the muscles of each layer are summarized in Table 24.1. The combined action of these muscles creates a superior force toward the heart and a puckering or drawstring motion around the sphincters.

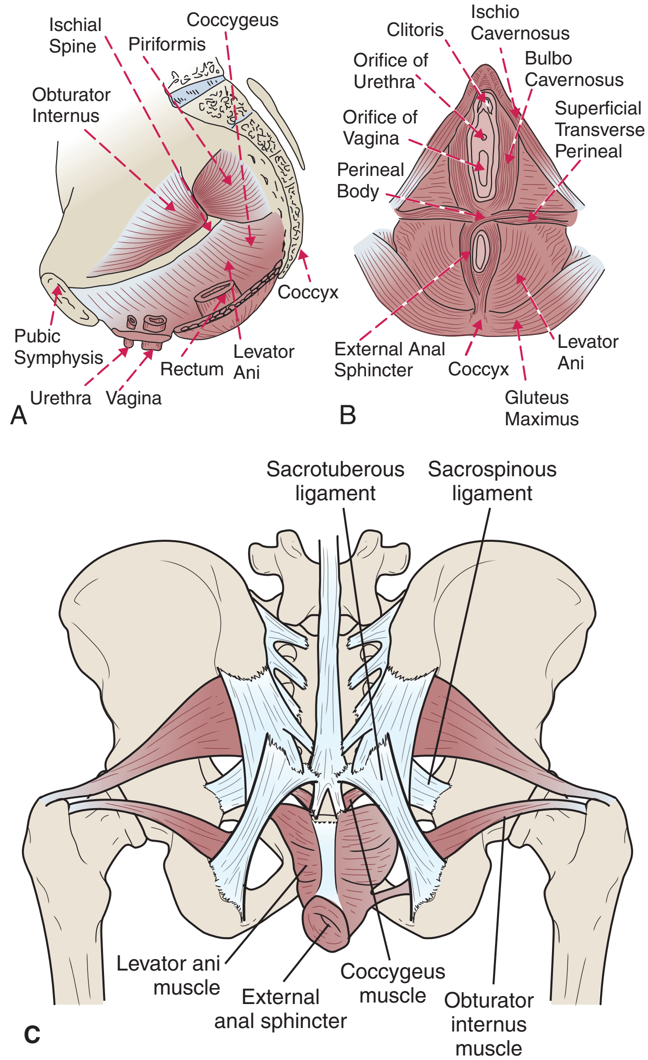

FIGURE 24.3 Pelvic floor muscles. **(A)** Sagittal section—note sling/hammock orientation; **(B)** viewed from below—note figure-eight orientation of the muscles around the orifice of the urethra/vagina and the anal sphincter; and **(C)** posterior view—note the funnel shape of the pelvic muscles.

Female Pelvic Floor

The female pelvic floor allows for passage of the urethra, vagina, and rectum. This automatically results in less intrinsic stability and pelvic organ support when compared to the male anatomy.

Innervation

Recent cadaveric studies have uncovered many variations in configuration of the nerves to the pelvic floor complex.[8,42,90] The nerve supply to the perineal tissues includes the pudendal nerve (with its three terminal branches, the dorsal, perineal and rectal), the levator ani nerve, and direct branches from the sacral nerve roots, with conflicting findings as to sacral levels. This dual and apparently inconsistent innervation provides a safeguard against damage

TABLE 24.1 Pelvic Floor Anatomy: From Superficial to Deep

Muscle Layer	Structure	Action
Superficial (outlet)		
	Ischiocavernosus	Clitoral erection
	Bulbocavernosus	"Drawing in" of the introitus, clitoral erection
	Superficial transverse perineal	Fixes perineal body
	External anal sphincter	Closure of anus
Urogenital diaphragm (perineal membrane)		
	Deep transverse perineal Compressor urethrae Urethrovaginal sphincter	Compression of urethra and ventral wall of vagina Support of the perineal body and introitus
Pelvic diaphragm (primary muscular support)		
	Levator ani ■ Pubococcygeus ■ Puborectalis ■ Iliococcygeus	Prime mover of the pelvic floor, Puborectalis aids in closure of the rectum
	Coccygeus	Flexes coccyx

during labor and vaginal delivery, which would be more likely with a single-nerve arrangement.

Function

The pelvic floor musculature has the following essential roles:

- Provide support for the pelvic organs and their contents
- Withstand increases in intra-abdominal pressure
- Contribute to stabilization of the spine/pelvis
- Maintain continence at the urethral and anal sphincters
- Sexual response and reproductive function

Effect of Childbirth on the Pelvic Floor

Neurological Compromise

Stretch and compression of the pudendal and levator ani nerves occur during labor as the baby's head travels through the birth canal; this stretch can be as much as 20% of the total length of the nerve.[9,83] This compromise to the nerve tissue is most intense during pushing (the second stage of labor), through the completion of vaginal delivery.

Muscular Impairment

Extreme stretching of the pelvic floor tissues is inherent in the process of labor and vaginal delivery. Recent research simulations specific to the biomechanics of childbirth are adding to the understanding of these impairments. Muscle injury during vaginal birth diminishes the maximal closure pressure of the pelvic floor complex, which makes the muscle complex more vulnerable to increased intra-abdominal pressure and changes force transmission to the distal vagina, possibly leading to prolapse.[6]

The pelvic floor musculature may also be torn or incised during the birth process. Additional soft tissue trauma can occur as a result of forceps use, necessitating suturing throughout the musculature and into the vaginal vault.

Episiotomy

An episiotomy is an incision made in the perineal body (see Fig. 24.3). It is automatically considered a second-degree laceration according to the following classification of perineal lacerations.[78]

- First degree—only skin
- Second degree—includes underlying superficial muscle layer (see Fig. 24.3 B)
- Third degree—extends to anal sphincter
- Fourth degree—tears through the sphincter and into the rectum, possibly into the deeper muscular layer of the pelvic floor (see Fig. 24.3 A)

Although episiotomy is common, occurring in 33% to 54% of vaginal deliveries, there is no strong medical evidence supporting its use. In fact, outcomes with episiotomy are worse in some cases, including pain with intercourse and extension of the episiotomy into the sphincter or rectum. Anal sphincter defects were linked with fecal incontinence in the postpartum period as many as 6 months after delivery in a study done by the Pelvic Floor Disorders Network.[14] There is

consistent agreement in the literature that episiotomy is closely associated with forceps-assisted delivery; additionally, if epidural anesthesia, forceps, and episiotomy are all utilized during labor and delivery, the risk of anal sphincter tear is even greater.[1,14,35,45,58] Pregnant women have many questions about labor in general and episiotomy in particular; the clinician is able to provide education and support for the patient as she explores her options with her physician.

FOCUS ON EVIDENCE

A randomized, controlled trial of 459 Canadian women during their first pregnancy found a significant protective effect against third- and fourth-degree tears (extensions following episiotomy) in women who participated in "strenuous" exercise three or more times per week. The researchers defined "strenuous" exercise as bicycling, jogging, tennis, skiing, and weight training, as opposed to "non-strenuous" exercise such as walking, swimming, prenatal classes, and yoga. Data were collected regarding type, frequency, and duration of exercise for a 12-month period including prepregnancy and postpartum time frames. In the "strenuous" exercise group, 200 of the women did *not* have third- or fourth-degree tears compared with only 25 women who did experience this tearing. In addition, this study helped dispel the theory that serious exercisers may have overdeveloped perineal musculature; these women were not at increased risk for episiotomy when compared to casual exercisers.

Classification of Pelvic Floor Dysfunction

This is a very broad category that encompasses bladder, bowel and sexual symptoms in a variety of combinations. Some patients with pelvic floor disuse atrophy, weakness, or nerve damage; others will have hypertonic pelvic floor musculature. Pelvic pain is another far-reaching diagnosis; many of these patients will be seen by multiple doctors prior to physical therapy being considered.

Prolapse

A prolapse is a supportive impairment. It refers to the descent of any of the pelvic viscera out of their normal alignment because of muscular, fascial, and/or ligamentous deficits and because of increased abdominal pressure (Fig. 24.4). A prolapse often worsens over time and with subsequent pregnancies and can be aggravated by constipation and/or straining with elimination.

- A cross-sectional study found stage I prolapse in 33% of the subjects and stage II descent in 62.9%. The sample included 270 women with a mean age of 68.3 years and median parity of three vaginal births.[70] This is critically important information for all clinicians prescribing trunk stabilization programs for female patients, regardless of diagnosis.

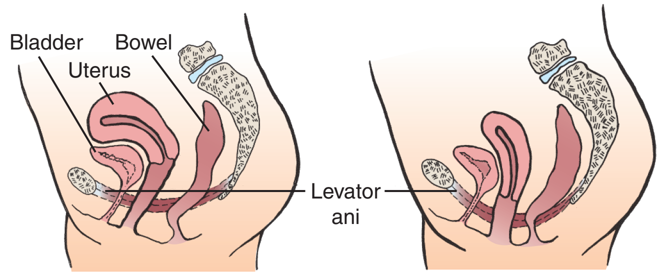

FIGURE 24.4 (A) Good pelvic floor support with a firm base, organs in normal position. **(B)** Inadequate support, pelvic organs descend.

- From a biomechanical aspect, activation of the pelvic floor is necessary in coordination with deep segmental muscle activation and trunk strengthening activities to prevent excessive downward forces. Otherwise, trunk strengthening will likely increase a previously undetected prolapse or aggravate an existing condition.
- As prolapse progresses, functional changes occur as a result of perineal pressure and heaviness, low back pain, abdominal pressure or pain, and difficulties with defecation.[17] These symptoms can interfere with exercise, recreation, household responsibilities, including yard work, and occasionally the ability to work outside the home.[68] Currently, there is very limited evidence regarding prevention or physical therapy treatment of pelvic organ prolapse.

Urinary or Fecal Incontinence

Involuntary loss of bladder or bowel contents, frequently a result of both neuromuscular and musculoskeletal impairments, often occurs in combination with prolapse. A conservative estimate of people affected with urinary incontinence is 15 million in the United States alone (approximately 1 in 20 people); women are twice as likely to have these symptoms as men.[30] These patients often have significant social discomfort and anxiety regarding leakage and hygiene concerns.

FOCUS ON EVIDENCE

Statistically significant improvements in urinary leakage were demonstrated as a result of a program of pelvic floor strengthening in three different studies[62,63,79] Both pregnant and postpartum women were studied in these trials, with follow-up until 1 year after delivery in two of the studies.[62,79]

In 2004, Bo[10] summarized current findings in support of pelvic floor rehabilitation in the treatment of stress urinary incontinence. There is case-controlled evidence for the following mechanisms:

- Strength training of the pelvic floor (using principles of exercise physiology) improves structural support of the organs and connective tissue in addition to facilitating more effective recruitment of motor units and more consistent, proficient contractions.

- Counterbracing of the pelvic floor musculature done intentionally and habitually prior to increases in intra-abdominal pressure becomes a form of behavioral modification with "trigger" activities.

Pain and Hypertonus

Pain and hypertonus may be related to delayed healing of perineal lacerations, trauma to the soft tissues or the sacrococcygeal joint during delivery, pelvic obliquity, multiple gynecologic/visceral diagnoses, cauda equina involvement, scar tissue restrictions, as well as high incidence clinically of protective muscle spasm, guarding, and anxiety regarding movement in general.

- One study described "nonmenstrual" pelvic pain as being most commonly caused by endometriosis, adhesions, interstitial cystitis, or irritable bowel syndrome, occurring in as much as 20% of women aged 15 to 50.[12] In another study with a total sample of 581 women (aged 18 to 45), the following prevalence was found: pelvic pain, 39%; dyspareunia (pain with intercourse), 46%; and dysmenorrhea, 90%.[55]
- Functional impairments may include pain with ADLs, decreased sitting tolerance, dyspareunia, and difficulty with elimination of bladder and bowel contents. In patients with pelvic pain impairments, often referred to as chronic pelvic pain (CPP), persistent tightness of the lumbar paraspinals and hip flexors is typically present.[7]
- Because of the breadth of this topic, treatment recommendations are conflicting. More attention is being given to the correlation of pelvic pain with a history of sexual abuse, which highlights the need for multidisciplinary assessment in order to address all potential causative factors. Sexual abuse continues to be underreported, yet recent studies cite rates of 20% to 25% of women who report childhood sexual trauma.[56,72,76]

Risk Factors for Dysfunction

Childbirth

Childbirth is clearly the most significant risk factor for pelvic floor impairments. The process of labor, particularly with vaginal delivery and current medical management, can produce significant trauma to the structures of the pelvic floor.

- A longitudinal cohort study with follow-up 15 years after delivery (n=55) showed that stress incontinence during the first pregnancy doubled the risk of reoccurrence 15 years later.[29] With respect to risk of future pelvic organ prolapse (POP), in a cohort study of over 17,000 women, those with one delivery were four times more likely and those with two children were over eight times more likely to have a subsequent hospital admission for POP. However, this study did not distinguish mode of delivery.[61]
- Other potential obstetric risk factors include mothers older than 30 years of age, multiple deliveries, prolonged second stage of labor, forced pushing, use of forceps, vacuum extraction or oxytocin, third-degree perineal tears, and birth weight greater than 8 lb.[54,69,83,89]

Other Causes

Women who have never been pregnant may also present with pelvic floor dysfunction. Excessive straining because of chronic constipation, smoking, chronic cough, obesity, and hysterectomy can contribute to these impairments in any woman.[9,30,47,89] The role of estrogen in the development of incontinence is still unclear, with some studies citing estrogen depletion as a risk factor[30] and others finding a connection between incontinence and estrogen replacement therapy.[47,89] High caffeine intake (more than 400 mg/day) is a specific risk factor for urge incontinence.[47]

Interventions for Pelvic Floor Impairments

Patient Education

Teach the patient about pelvic floor anatomy and function. Emphasis should be placed on appreciating all three dimensions of the muscle complex: the sling/hammock fibers, the figure-eight orientation of the musculature, and the "funnel" configuration extending inferiorly to the outlet (see Fig. 24.3). Use visual aids to help the patient visualize the fibers that run anterior-posterior as well as superior-inferior (to create a "lifting" motion toward the heart), as well as the circumferential fibers (which produce a drawstring or "pucker" effect).

Provide individual instruction in exercise performance. Detailed, individual instruction is linked to significant proprioceptive improvements and certainly meets the criteria for skilled care. Successful strengthening is unlikely without this individualized educational component along with later confirmation of correct exercise performance; instructing women in pelvic floor exercises by verbal instruction alone was *not* beneficial in 50% of women and, in fact, caused increased downward pressures to the bladder in 25% of women, rather than producing an appropriate superiorly directed force.[19]

Neuromuscular Reeducation

Facilitate pelvic floor muscular activation. Neuromuscular reeducation is essential, because many women have significant disuse atrophy and proprioceptive deficits of the pelvic floor muscles. Internal techniques of assessment and treatment are often indicated for optimal patient outcomes. For example, manual stretch facilitation (a proprioceptive neuromuscular facilitation technique) to the levator ani can be an effective treatment option. Initially, emphasis on isolated contractions of the pelvic floor is needed[11] because many patients exhibit excessive accessory muscle recruitment such as the gluteals, hip adductors, and abdominals. Once coordination has improved, the patient progresses to integration of pelvic floor activity with ADLs, lumbar stabilization, and other functional exercises.

Biofeedback

Use biofeedback with instrumentation. The definition of biofeedback is "the technique of using monitoring devices to furnish information regarding . . . bodily function . . . in an attempt to gain some voluntary control over that function" (www.thefreedictionary.com). This can be accomplished by a creative physical therapist in a number of ways. There are multiple types of instruments that can be used to provide sensory feedback as the pelvic floor muscles contract around the device. Some are pressurized objects, which allow for isotonic strengthening; traditional surface electromyography (SEMG) sensors are solid and provide isometric resistance to the muscular contraction. SEMG can also be applied through peri-anal electrodes for patients who are not candidates for internal assessment or treatment. Motor learning, which occurs due to the "real-time" capabilities of the equipment, is greatly enhanced when compared to exercise without this intervention.

Combine biofeedback with exercises. Specific exercises to address pelvic floor impairments are listed in the exercise section of the chapter. The use of exercise and biofeedback, including SEMG for treatment of pelvic floor dysfunction in a female population, has been studied with mixed results,[20,30,73,92] and the need for further research is great. SEMG provides immediate visual and/or auditory feedback regarding pelvic floor activity, which improves patient comprehension, appropriate recruitment patterns, and proprioceptive awareness. It is particularly invaluable for pelvic floor reeducation owing to generalized lack of knowledge of the muscles' existence, let alone their function and importance.

Manual Treatment and Modalities

Manual treatment and modalities, including intravaginal and intrarectal techniques, also play a role in the treatment of all pelvic floor disorders. Advanced training is necessary for true expertise with internal techniques.

Pregnancy-Induced Pathology

The combined influence of hormones, weight gain, and postural changes of pregnancy contributes to a variety of impairments (in addition to pelvic floor dysfunction that was described in the previous section) that can be addressed with physical therapy.

Diastasis Recti

Diastasis recti is separation of the rectus abdominis muscles in the midline at the linea alba. The etiology of this separation is unknown; however, the continuity and integrity of the abdominal musculature are disrupted (Fig. 24.5). Any separation larger than two finger widths is considered significant.[13,21,65]

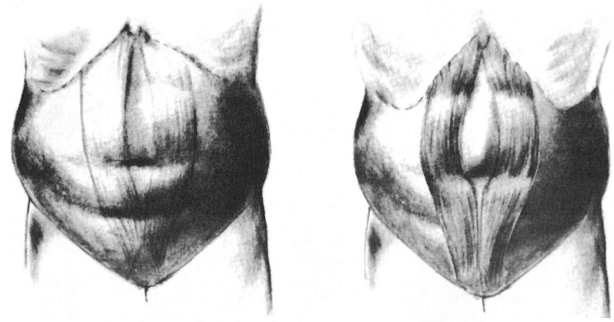

FIGURE 24.5 Diagrammatic representations of diastasis recti. (From Boissonnault, JS, and Kotarinos, RK: Diastasis recti. In Wilder, E [ed.]: *Obstetric and Gynecologic Physical Therapy*,[91] with permission.)

Incidence

The condition is not exclusive to childbearing women but is seen frequently in this population. In one study, Boissonnault and Blaschak tested 89 women for separation of the rectus abdominis muscles.[13] The sample included one group of women who were not pregnant, one group for each trimester of pregnancy, and two postpartum groups. The incidence in this study ranged from none in the nonpregnant and first trimester women to 27% in the second trimester to a high of 66% in the third trimester. Also of interest is that 36% of the women between 5 weeks and 3 months postpartum continued to display a separation. A second study, done by Bursch, found a significant diastasis in 62.5% of postpartum women tested within 92 hours of delivery.[19] More recently, in a population of 547 women seen in a urogynecology practice, 52% of these women had persistent diastasis recti; 66% of those women also had various combinations of stress or fecal incontinence and pelvic organ prolapse.[85]

- Diastasis recti may occur in pregnancy as a result of hormonal effects on the connective tissue and the biomechanical changes of pregnancy; it may also develop during labor, especially with excessive breath-holding during the second stage.[86] It causes no discomfort.
- It can occur above, below, or at the level of the umbilicus but appears to be less common below the umbilicus.
- It appears to be less common in women with good abdominal tone before pregnancy.[13]
- Clinically, a diastasis may be found in women well past their childbearing years and also in men. Routine assessment for this condition is highly recommended and can easily be done in conjunction with abdominal strength testing.

Significance

The condition of diastasis recti may produce musculoskeletal complaints, such as low back pain, possibly as a result of decreased ability of the abdominal musculature and thoracolumbar fascia to stabilize the pelvis and lumbar spine.

Activity limitations. Activity limitations can also occur, such as inability to perform independent supine-to-sitting transitions because of extreme loss of the mechanical alignment and

function of the rectus muscle. Again, this finding is not exclusive to childbearing patients.

Decreased fetal protection. In severe separations, the remaining midline layers of abdominal wall tissue are skin, fascia, subcutaneous fat, and peritoneum.[13,21,86] The lack of muscular support provides less protection for the fetus.

Potential for herniation. Severe cases of diastasis recti may progress to herniation of the abdominal viscera through the separation at the linea alba. This degree of separation requires surgical repair. Rehabilitation following this type of repair may include components of C-section rehabilitation, with specific precautions and input from the referring surgeon. There may be a need for very slow progression depending on the severity of the diastasis and how it was repaired.

Examination for Diastasis Recti

Test all pregnant patients for the presence of diastasis recti before performing any abdominal exercises. This test should be repeated throughout the pregnancy, and appropriate modifications should be made to existing exercises.

Instruct patients to perform a self-test on or after the third postpartum day for optimal accuracy. Until 3 days after delivery, the abdominal musculature has inadequate tone for valid test results.[65,86]

Patient position and procedure: Hook-lying. Have the patient slowly raise her head and shoulders off the floor, reaching her hands toward the knees, until the spines of the scapulae leave the floor. Place the fingers of one hand horizontally across the midline of the abdomen at the umbilicus (Fig. 24.6). If a separation exists, the fingers will sink into the gap between the rectus muscles, or a visible bulge between the rectus bellies may be appreciated. The number of fingers that can be placed between the muscle bellies is then documented. Because this condition can occur above, below, or at the level of the umbilicus, test for it at all three areas.

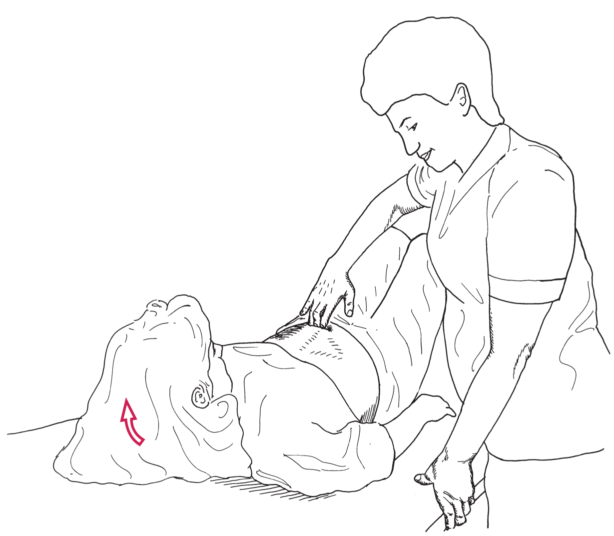

FIGURE 24.6 Diastasis recti test.

Intervention for Diastasis Recti

Teach the patient to perform the corrective exercise for diastasis recti (see Fig. 24.8 and accompanying text later in this chapter) until the separation is decreased to 2 cm or less prior to resuming more strenuous abdominal strengthening that increases intra-abdominal pressure.[65,86] Transverse abdominis exercises may be incorporated with the caution against breath-holding. Once the correction has been obtained, strengthening of the obliques and more advanced abdominal work can be resumed.[53]

Posture-Related Back Pain

Back pain commonly occurs because of the postural changes of pregnancy, increased ligamentous laxity, hormonal influences, and decreased abdominal muscle function.[5,28,54,65,71,74,77,91]

Incidence

Back pain is reported by 50% to 80% of pregnant women at some point during pregnancy[39,64]; this condition contributes to lost work days, decreased functional ability, and quality of life scores. In addition, symptoms may continue in the postpartum period, with prevalence in as many as 68% of women, for as long as 12 months after delivery.[64,70]

Characteristics

The symptoms of low back pain usually worsen with muscle fatigue from static postures or as the day progresses; symptoms are usually relieved with rest or change of position. Women who are physically fit generally have less back pain during pregnancy.[73]

Interventions

Low back pain symptoms can be treated effectively with many traditional low back exercises, proper body mechanics, posture instructions, improvement in work techniques, along with superficial modality application.[65,86] The use of deep heating agents, electrical stimulation, and traction is generally contraindicated during pregnancy.

FOCUS ON EVIDENCE

Garshasbi and Faghih Zadeh[39] studied more than 200 primigravid women (pregnant for the first time) in a prospective randomized study of the effect of exercise on the intensity of low back pain during pregnancy. Subjects were excluded if they had a history of exercise before pregnancy or history of orthopedic conditions. The exercise group was in a supervised exercise program for 3 hr/week for 12 weeks in the second and early third trimesters; the control group was women who were homemakers and had no significant change in activity level. The groups were statistically equal in maternal and neonatal weight gain, as well as length of pregnancy. The exercise group experienced significant decrease in intensity of low back pain by the end of the study,

whereas intensity was increased in the control group. The study did not describe the nature of the symptoms or differentiate between postural pain and sacroiliac pain. Interestingly, there was no significant difference in the change in lordosis between the two groups.

A recent Cochrane Review found pregnancy specific exercises—including "water gymnastics"—to provide relief of back or pelvic pain more than typical prenatal care alone, although the effect was small due to potential bias in the studies.[76]

Sacroiliac/Pelvic Girdle Pain

Characteristics

Sacroiliac pain is localized to the posterior pelvis and is described as stabbing deep into the buttocks distal and lateral to L5/S1. Pain may radiate into the posterior thigh or knee but not into the foot. Symptoms include pain with prolonged sitting, standing or walking, climbing stairs, turning in bed, unilateral standing, or torsion activities. Symptoms may not be relieved by rest and frequently worsen with activity. Pubic symphysis dysfunction may occur alone or in combination with sacroiliac symptoms and includes significant tenderness to palpation at the symphysis, radiating pain into the groin and medial thigh, and pain with weight bearing. In addition, excessive separation and translation at the joint may occur.[28,86] One study reported a four times greater incidence of posterior pelvic pain than low back pain in pregnant women.[71]

Interventions

Pelvic girdle and sacroiliac symptoms are treated via modification or elimination of activities that may further aggravate sensitive tissue, stabilization exercises, and the use of belts and corsets to provide external support to the pelvis.

Activity modification. Daily activities should be adapted to minimize asymmetrical forces acting on the trunk and pelvis. For example, getting into a car is done by sitting down first, then pivoting both legs and the trunk into the car, keeping the knees together; side-lying is made more symmetrical by placing a pillow between the knees and under the abdomen; and sexual positions are altered to avoid full range of hip abduction. Single-leg weight bearing, excessive abduction, and sitting on very soft surfaces should be avoided. In addition, caution patients to avoid climbing more than one step at a time, swinging one leg out of bed at a time when getting up, or crossing the legs when sitting.[28,86]

Exercise modification. Exercise must be modified so as not to aggravate the condition. Avoid exercises that require single-leg weight bearing and excessive hip abduction or hyperextension. Teach the patient to activate the pelvic floor and transverse abdominals when transitioning from one position to another and with any lifting in order to stabilize the pelvis.

FOCUS ON EVIDENCE

A randomized, clinical trial with 2-year follow-up looked at long-term effects of physical therapy for pelvic girdle pain in the postpartum period.[87] Each group had 20 weeks of treatment, with the control group focusing on modalities, manual therapy, and general exercises. In addition, the second group had specific focus on trunk/hip stabilizing exercises, with particular attention to the transverse abdominals. All participants received individual instruction from an experienced physical therapist. Outcome measures included the Oswestry Disability Questionnaire, pain scales, and a health-related quality of life (QOL) tool that measured eight subscales. At 1 year postpartum, the group with specific stabilizing exercises showed significantly better scores on all measures of those three tools, except for the social functioning subscale of the QOL tool. The same measurements were collected at 2 years postdelivery, and the benefit for the stabilization group persisted, with significant differences in functional status and morning and evening pain. The specific exercise group had scores on QOL comparable to those of a representative group of the general population.

External stabilization. Use of external stabilization such as belts or corsets designed for use during pregnancy helps reduce posterior pelvic pain, especially when walking.

FOCUS ON EVIDENCE

Ostgaard and colleagues[71] found that the use of nonelastic external stabilization designed for use during pregnancy helped reduce posterior pelvic pain in 82% of women. This was a large, randomized, controlled study (n=407). More recent studies have validated the use of external stabilization for pelvic girdle pain (n=118)[64] but found no effect with a support belt in cases of pubic symphysis pain (n=87).[28]

Varicose Veins

Varicosities are aggravated in pregnancy by the increased uterine weight, venous stasis in the legs, and increased venous distensibility.

Characteristics

Varicosities can present in the first trimester and are more prevalent with repeated pregnancies. They can occur in the lower extremities, the rectum (hemorrhoids), or vulva. Symptoms usually include heaviness or aching discomfort, especially with dependent leg positions; intensity may become severe as the pregnancy progresses. In addition, pregnant women are more susceptible to deep vein thrombosis.[86]

Interventions

Exercise modification. If there is discomfort, exercises may need to be modified so that minimal dependent positioning of the legs occurs.

External support. Elastic support stockings should be worn to provide an external pressure gradient against the distended veins, and the woman should be encouraged to perform lower extremity exercises and to elevate the lower extremities as often as possible. Vulvar varicosities may benefit from use of a perineal pad or belt that provides counter-pressure and support to the tissues.[65]

Joint Laxity

Significance

All joint structures are at increased risk of injury during pregnancy and during the immediate postpartum period. The tensile quality of the ligamentous support is decreased, and therefore injury can occur if women are not educated regarding joint protection. There is much controversy regarding the impact of postpartum hormone levels; however, elevated levels have been found 3 to 5 months after delivery.[86] This elevation may persist even longer if the woman is nursing. Many patients are aware of persistent symptoms in conjunction with the menstrual cycle.

Interventions

Exercise modification. Teach the woman safe exercises to perform during the childbearing year, including modification of exercises to decrease excessive joint stress (see exercises described in the management section of this chapter).

Aerobic exercise. Suggest nonweight-bearing or less stressful aerobic activities such as swimming, walking, or biking, particularly for women who were relatively sedentary before pregnancy.

Nerve Compression Syndromes

Causes

Impairments from conditions such as thoracic outlet syndrome (TOS) or carpal tunnel syndrome (CTS) may be caused by one or more of the following in pregnancy: postural changes in the neck and upper quarter, fluid retention, hormonal changes, or circulatory compromise. Overall, women are three times as likely as men to experience carpal tunnel syndrome. Occurrence in pregnancy can be as high as 41%.[73] (See Chapter 13 for discussion of CTS and TOS and Chapter 14 for discussion of posture.)

Nerve compression syndromes (for example, of the lateral femoral cutaneous nerve) may also occur in the lower extremities because of the weight of the fetus, fluid retention, hormonal changes, or circulatory compromise.

Interventions

Typical protocols include postural correction exercises, manual techniques, ergonomic assessment, and modalities (see Chapter 13 for management of nerve compression syndromes). Splints may be used in the treatment of carpal tunnel syndrome. Carpal tunnel surgery in the pregnant population is rare, because symptoms generally resolve soon after delivery; a longer course of the problem has been noted in women who breastfeed.[86]

Exercise Interventions for Pregnancy, Labor, and Related Conditions

Physiological Effects of Aerobic Exercise During Pregnancy

Many women who have been doing aerobic exercises choose to continue exercising during pregnancy to maintain their cardiopulmonary fitness. Maternal[5,23,25,57,91] and fetal[3,23,24,26,38,57,84,91] responses have been well studied; therefore, this information is used to guide both the therapist and the patient in determining necessary modifications to an existing exercise program.

Maternal Response to Aerobic Exercise

Blood Flow

Aerobic exercise does not reduce blood flow to the brain and heart. It does, however, cause a redistribution of blood flow away from the internal organs (and possibly the uterus) and toward the working muscles. This raises two concerns: that the reduction in blood flow may decrease the oxygen and nutrient availability to the fetus and that uterine contractions and preterm labor may be stimulated.[23] Stroke volume and cardiac output both increase with steady-state exercise. This, coupled with increased blood volume and reduction in systemic vascular resistance during pregnancy, may help offset the effects of the vascular shunting.

Respiratory Rate

The maternal respiration rate appears to adapt to mild exercise but does not increase proportionately with moderate and severe exercise when compared with a nonpregnant state. The pregnant woman reaches a maximum exercise capacity at a lower work level than a nonpregnant woman because of the increased oxygen requirements of exercise.

Hematocrit Level

The maternal hematocrit level during pregnancy is lowered; however, it rises as many as 10 percentage points within 15 minutes of beginning vigorous exercise. This condition continues for as many as 4 weeks postpartum. As a result, cardiac reserve is decreased during exercise.

Inferior Vena Cava Compression

Compression of the inferior vena cava by the uterus can occur after the fourth month of pregnancy, with relative obstruction

of venous return. This leads to decreased cardiac output and orthostatic hypotension. It occurs most often in supine or static standing positions, and therefore prolonged time in these positions should be avoided.[3]

Energy Needs

Hypoglycemia occurs more readily during pregnancy; therefore, adequate carbohydrate intake is important for the pregnant woman who exercises.[24] A caloric intake of an additional 500 calories per day is suggested to support the energy needs of pregnancy and exercise, dependent on the intensity and duration of the exercise. In comparison, a sedentary pregnant woman requires a 300 calorie per day increase.[5]

Core Temperature

Vigorous physical activity and dehydration through perspiration leads to increased core temperature in anyone who exercises. Concern has been expressed over this occurring in the pregnant woman because of the relationship of elevated core temperature to neural tube defects of the fetus. Studies report that during pregnancy the core temperature of physically fit women actually decreases during exercise. These women appeared to be more efficient in regulating their core temperature, and thus the thermal stress on the embryo and fetus is reduced.[24,25]

Uterine Contractions

Norepinephrine and epinephrine levels increase with exercise. Norepinephrine increases the strength and frequency of uterine contractions. This may pose a problem for the woman at risk of premature labor.

Responses of Healthy Women

Studies have shown that healthy women who continue to run throughout pregnancy deliver an average of 5 to 7 days sooner compared with controls.[23,24] Clapp[23–25] found that exercise, including weight bearing (even with ballistic motions such as during aerobic dancing), can be performed in mid- and late pregnancy without risk of preterm labor or premature rupture of the membranes. Women who wish to continue strenuous or competitive exercise or participate in specific athletic training require close supervision by a specialist during pregnancy.[3,84]

Fetal Response to Maternal Aerobic Exercise

No human research has conclusively proven a detrimental fetal response to mild- or moderate-intensity maternal exercise. Recent studies suggest that even vigorous exercise does not have the detrimental effects on the fetus that once were feared, and therefore restrictions on exercise because of concerns for the effects on the embryo and fetus have been lessened. In fact, fit women who maintained their volume of exercise after 20 weeks' gestation delivered babies with lower fat mass than those who decreased exercise intensity midway through the pregnancy.[23–25] Given the epidemic of obesity in the United States, the need for future research to define further the connections between fetal nutrition and adult disease is imperative.[26]

Blood Flow

A 50% or greater reduction of uterine blood flow is necessary before fetal well-being is affected (based on animal research). No studies have documented such decreases in pregnant women who exercise, even vigorously. It is suggested that the cardiovascular adaptations in exercising women offset any redistribution of blood to muscles during exercise.[23]

Fetal Heart Rate

Brief submaximal maternal exercise (as much as 70% maternal aerobic power) does not adversely affect fetal heart rate (FHR).[3] The FHR usually increases 10 to 30 beats/minute at the onset of maternal exercise. After mild to moderate maternal exercise, the FHR usually returns to normal levels within 15 minutes, but in some cases of strenuous maternal exercise, the FHR may remain elevated as long as 30 min. Fetal bradycardia (indicating fetal asphyxia) during maternal exercise has been reported in the literature with the return to preexercise FHR levels within 3 min after maternal exercise, followed by a brief period of fetal tachycardia.[38] The healthy fetus appears to be able to tolerate brief episodes of asphyxia with no detrimental results.

Heat Dissipation

The fetus has no mechanism such as perspiration or respiration by which to dissipate heat. However, physically fit women are able to dissipate heat and regulate their core temperature more efficiently, thus reducing risk.[23]

Newborn Status

Newborn children of women who continue endurance exercises into the third trimester of pregnancy are reported to have an average decrease in birth weight of 310 g There is no change in head circumference or heel-crown length. Further study of these children (as old as 5 years of age) has shown slightly better neurodevelopmental status in addition to higher percentage of lean body mass.[25]

Exercise for the Uncomplicated Pregnancy and Postpartum

Exercise classes during pregnancy and after childbirth are designed to minimize impairments and help the woman maintain or regain function while she is preparing for the arrival of the baby and then caring for the infant.* The potential structural and functional impairments and the management guidelines related to uncomplicated pregnancies are summarized in Box 24.2, and a suggested sequence for teaching an exercise class is listed in Box 24.3.[5,74,86,91]

*3,5,31,32,38,39,54,57,62–65,71,73–75,79,82,84,86,87,91

BOX 24.2 MANAGEMENT GUIDELINES—Pregnancy and Postpartum

Potential Structural and Functional Impairments

Musculoskeletal pain and muscle imbalances from faulty postures
Poor body mechanics related to lack of knowledge, changing body size, and physical demands of child care
Lower extremity edema and discomfort from altered circulation and varicose veins
Pelvic floor dysfunction, including:
- urinary or fecal incontinence
- organ prolapse
- hypertonus
- poor episiotomy healing
- poor proprioceptive awareness and disuse atrophy

Abdominal muscle stretch, trauma, and diastasis recti
Potential decrease in cardiovascular fitness
Lack of knowledge of body changes and safe exercises to use during and after pregnancy
Changing body image
Lack of physical preparation (strength, endurance, relaxation) necessary for labor and delivery
Lack of knowledge of appropriate positioning for optimal comfort in labor and delivery
Lack of adequate postpartum rehabilitation

Plan of Care	Interventions
1. Develop awareness and control of posture during and after pregnancy	1. Stretch, train, and strengthen postural muscles Posture awareness training
2. Learn safe body mechanics.	2. Body mechanics in sitting, standing, lifting, and lying as well as transitions from one position to another Body mechanics with baby equipment and child care activities. Positioning options for labor and delivery
3. Develop upper extremity strength for the demands of infant care.	3. Resistive exercises to appropriate muscles
4. Promote increased body awareness and a positive body image.	4. Body awareness and proprioception activities Posture reinforcement
5. Prepare the lower extremities for the demands of increased weight bearing and circulatory compromise.	5. Use of elastic support stockings Stretching exercises Toning and resistive exercises to appropriate muscles
6. Develop awareness and control of the pelvic floor musculature.	6. Awareness of isolated pelvic floor muscle contraction and relaxation Train and strengthen for muscle control, integration with ADLs
7. Maintain abdominal function and prevent or correct diastasis recti.	7. Monitor diastasis recti. Diastasis recti exercises Safe abdominal-strengthening exercises with diastasis recti protection
8. Promote or maintain safe cardiovascular fitness.	8. Safe progression of aerobic exercises
9. Learn about the changes of pregnancy and birth.	9. Patient/family instruction Refer to other disciplines as indicated
10. Learn relaxation skills.	10. Relaxation and breathing techniques
11. Prevent impairments associated with pregnancy	11. Education about potential problems of pregnancy Teach prevention techniques and appropriate exercises

Continued

BOX 24.2 MANAGEMENT GUIDELINES—Pregnancy and Postpartum—cont'd

Plan of Care	Interventions
12. Prepare physically for labor, delivery, and postpartum activities.	12. Strengthen muscles needed in labor and delivery, and train responses Teach comfort measures for labor and delivery
13. Provide education on safe postpartum exercise progression.	13. Postpartum exercise instruction
14. Develop awareness of treatment options for pelvic floor dysfunction.	14. Comprehensive approach for prolapse, incontinence, or hypertonus

BOX 24.3 Suggested Sequence for Exercises Classes

1. General rhythmic activities to "warm-up"
2. Gentle selective stretching for postural alignment and for perineum and adductor flexibility
3. Aerobic activity for cardiovascular conditioning (duration/intensity may need to be individualized)
4. Postural exercises; upper/lower extremity strengthening and individualized abdominal exercises
5. Cool-down activities
6. Pelvic floor exercises
7. Relaxation techniques
8. Labor and delivery techniques
9. Educational information
10. Postpartum exercise instruction (e.g., when to begin exercises, how to safely progress, precautions) because the patient may not be attending a postpartum class. Include education regarding body mechanics relative to child care.

Guidelines and techniques for exercise class instruction are included in this section.[3,5,31,54,65,74,84,86,91] In addition, interventions for women receiving individualized care for specific impairments are noted throughout this section. Interventions for special situations such as cesarean childbirth and high-risk pregnancy are described in the following sections.

Guidelines for Managing the Pregnant Woman

Suggest that your patients discuss with their physicians any guidelines or restrictions to exercise before engaging in an exercise program, either in a class or on a one-to-one basis. As always, follow your state practice act for physical therapy regarding referral, evaluation, and treatment.

Examination. Individually examine each woman before participation to screen for preexisting musculoskeletal problems, posture, and fitness level.

Education. Educate your patients that increased uterine cramping *may* occur with moderate activity; this is acceptable as long as the cramping stops when the activity is completed. Teach your patient all exercise guidelines and precautions so that exercises may be carried out safely at home. Include the following:

- Do not exceed 5 minutes of supine positioning at any one time after the first trimester of pregnancy to avoid vena cava compression by the uterus. Educate your patients that compression of the vena cava also occurs with motionless standing. For supine exercise, place a small wedge or rolled towel under the right hip to lessen the effects of uterine compression on abdominal vessels and to improve cardiac output. The wedge turns the patient slightly toward the left (Fig. 24.7).[5] This modification is also helpful during physical therapy evaluation and treatment when the patient is positioned supine.
- To avoid the effects of orthostatic hypotension, instruct the woman to always rise slowly when moving from lying down or sitting to standing positions.
- Discourage breath-holding, and avoid activities that tend to elicit Valsalva's maneuver because this may lead to undesirable downward forces on the uterus and pelvic floor. In addition, breath-holding causes stress to the cardiovascular system in terms of blood pressure and heart rate.

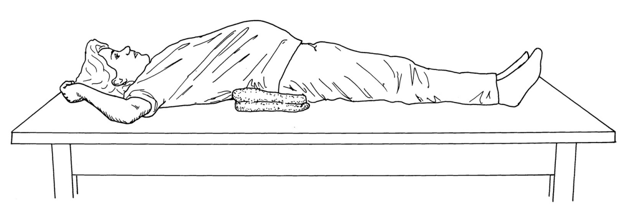

FIGURE 24.7 To prevent inferior vena cava compression when the patient is lying supine, a folded towel can be placed under the right side of the pelvis so the patient is tipped slightly to the left.

- Break frequently for fluid replenishment. The risk of dehydration during exercise is increased in pregnancy. Avoid exercising in high temperature or humidity. Increase water intake in proportion to time spent exercising and as environmental temperature increases.
- Encourage complete bladder emptying before exercise. A full bladder places increased stress on an already weakened pelvic floor.
- Include appropriate warm-up and cool-down activities.
- Modify or discontinue any exercise that causes pain.
- Limit activities in which single-leg weight bearing is required, such as standing leg kicks. In addition to possible loss of balance, these activities can promote sacroiliac or pubic symphysis discomfort.

Stretching/flexibility. Choose stretching exercises that are specific to a single muscle or muscle group; do not involve several groups at once. Asymmetrical stretching or stretching multiple muscle groups can promote joint instability.

- Avoid ballistic movements.
- Do not allow any joint to be taken beyond its normal physiological range.
- Use caution with hamstring and adductor stretches. Overstretching of these muscle groups can increase pelvic instability or hypermobility.

CLINICAL TIP

Consider use of muscle energy techniques using light resistance for a client with pelvic instability and one whose pelvic boney landmarks are out of alignment. (See Chapter 15 for description of techniques.)

Muscle performance and aerobic fitness. Recommendations and adaptations for pelvic floor training, general strengthening, and cardiopulmonary conditioning during pregnancy and postpartum are described in the exercise section of this chapter. Exercises to prepare for labor and delivery are also described in the exercise section.

PRECAUTIONS: Observe participants closely for signs of overexertion or complications. The following signs are reasons to *discontinue exercise* and *contact a physician*[3,84]:

- Persistent pain, especially in the chest, pelvic girdle, or low back
- Leakage of amniotic fluid
- Uterine contractions that persist beyond the exercise session
- Vaginal bleeding
- Decreased fetal movements
- Persistent shortness of breath
- Irregular heartbeat
- Tachycardia
- Dizziness/faintness
- Swelling/pain in the calf (rule out phlebitis)
- Difficulty in walking

CLINICAL TIP

Keep in mind when developing intervention programs, whether providing advice to a class or providing individual therapy, that most physical agents are *contraindicated* in pregnancy. Superficial heat or ice may be beneficial to relieve pain/spasm and improve circulation.

- Electric stimulation may be added postpartum to modulate pain and to stimulate muscle contractions, respectively.
- Ultrasound may be helpful in cases of poor episiotomy healing and painful scar tissue.

Recommendations for Fitness Exercise

NOTE: These recommendations are for pregnant women with no maternal or fetal risk factors.*

- It is strongly recommended for all women to participate in mild to moderate exercise, for both strength and cardiopulmonary benefits, 15 to 30 minutes/session, most days of the week. Individualized programs, based on prepregnancy fitness level, are preferable.[3,84]
- Currently, there are no data in humans suggesting that pregnant women need to decrease their intensity of exercise or lower their target heart rates, but because of decreased oxygen supply, they should modify exercise intensity according to their tolerance.
  - Conventional (age-based) target heart rate zones may be too aggressive for the average pregnant patient.
  - Use of the Borg scale of perceived exertion (Box 24.4) is more appropriate in this population, with exertion between 12 and 14 suggested during uncomplicated pregnancy.[15,84]
  - When fatigued, a woman should stop exercising, and she should never exercise to exhaustion.
- Activities to avoid include contact sports, anything with a high risk of abdominal trauma or falling, high-altitude activities (greater than 6,000 ft), and scuba diving. The fetus is at increased risk of decompression sickness during scuba diving.[84]
- Nonweight-bearing aerobic exercises, such as stationary cycling, swimming, or water aerobics, will minimize the risk of injury throughout pregnancy and the postpartum period.
- If the woman cannot safely maintain balance because of the shifting and increasing weight, have her modify exercises that could result in falling and injuring herself or the fetus.
- Adequate caloric intake for nutrition, adequate fluid intake, and appropriate clothing for heat dissipation are critical.
- Resumption of prepregnancy exercise routines during the postpartum period should be gradual. Initiation of pelvic floor exercises immediately postpartum may reduce symptoms and duration of incontinence.[62–64]

19—Very, very hard
20—Exhaustion

- Physiological and morphological changes of pregnancy continue for a minimum of 4 to 6 weeks postpartum—longer if the woman is breastfeeding. Encourage continued joint protection.
- Breastfeeding women can be reassured that moderate exercise does not impair quantity or quality of breast milk or infant growth.
  - Lactating women will have slower weight loss in the postpartum period; an additional 500 calories/day are needed to support production of breast milk.
  - Water intake continues to be important; 12 or more glasses per day are recommended.
  - There may be a short-term increase in lactic acid secreted in breast milk after high-intensity exercise; if the baby appears to eat less after an exercise session, this can easily be remedied by nursing before exercise.[3,54,84]

Precautions and Contraindications to Exercise

There are some circumstances in which exercise is contraindicated or requires very specific restrictions and precautions.[3-5,18,39,40,48,52,65-67,73,74,82,84,86,91] Discussion of interventions for patients with high-risk pregnancy are described later in this chapter.

Absolute Contraindications

- Incompetent cervix: early dilation of the cervix before the pregnancy is full term
- Vaginal bleeding, especially second or third trimester
- Placenta previa: placenta is located on the uterus in a position in which it may detach before the baby is delivered
- Multiple gestation with risk of premature labor[3,54,66]
- Preeclampsia: pregnancy-induced hypertension
- Rupture of membranes: loss of amniotic fluid before the onset of labor
- Premature labor: labor beginning before the 37th week of pregnancy
- Maternal heart disease, thyroid disease, or serious respiratory disorder
- Maternal type 1 diabetes
- Intrauterine growth retardation

Precautions to Exercise

The woman with one or more of the following conditions may participate in an exercise program under close observation by a physician[4,5,18,49,54,65] and a therapist as long as no further complications arise. Exercises may require modification.[3,84]

- Gestational diabetes
- Severe anemia
- Systemic infection
- Extreme fatigue
- Musculoskeletal complaints and/or pain
- Overheating
- Extreme obesity or extreme underweight/eating disorder
- Diastasis recti

Critical Areas of Emphasis and Selected Exercise Techniques

Posture Exercises

The growing fetus places added stress on postural muscles as the center of gravity shifts forward and upward and the spine shifts to compensate and maintain stability. In addition, after delivery, activities involving holding and caring for the baby stress postural muscles. Muscles that require emphasis are listed in Box 24.5. General exercise descriptions are listed in respective chapters. Subsequent sections describe adaptations of exercises specific for the pregnant woman.

Flexibility and stretching exercises are implemented with caution. Remember that connective tissues and supporting joint structures are at increased risk of injury from forceful stresses during pregnancy and the immediate postpartum period because of hormonal changes. Resistance exercises are performed at a low intensity.

Corrective Exercises for Diastasis Recti

A check for diastasis recti must always be performed before initiating abdominal exercise. Only the corrective exercises (head lift or head lift with pelvic tilt) should be used until the separation is corrected to 2 cm (two finger widths) or less.[65]

Head Lift

Patient position and procedure: Hook-lying with her hands crossed over midline at the level of the diastasis for support. Have the woman exhale and lift only her head off the floor. At the same time, her hands should gently approximate the rectus muscles toward midline (Fig. 24.8). Then have the

BOX 24.5 Selected Stretching and Resistance Exercises During Pregnancy

Stretching (with Caution)
- Upper neck extensors and scalenes (Chapter 16)
- Scapular protractors, shoulder internal rotators, and levator scapulae (Chapter 17)
- Low back extensors (Chapter 16)
- Hip flexors, adductors, and hamstrings (Chapter 20). CAUTION: women with pelvic instabilities should not overstretch these muscles.
- Ankle plantarflexors (Chapter 22)

Strengthening (Low Intensity with Modifications Described in This Chapter)
- Upper neck flexors and lower neck and upper thoracic extensors (Chapter 16)
- Scapular retractors and depressors (Chapter 17)
- Shoulder external rotators (Chapter 17)
- Trunk flexors (Chapter 16), particularly lower abdominals; use corrective exercises for diastasis recti if present
- Hip extensors (Chapter 20)
- Knee extensors (Chapter 21)
- Ankle dorsiflexors (Chapter 22)

woman lower her head slowly and relax. This exercise emphasizes the rectus abdominis muscle and minimizes the obliques. Some women may not be able to successfully reach over their abdomens. In this case, the use of a sheet wrapped around the trunk at the level of the separation can be used to provide support and approximation.[65]

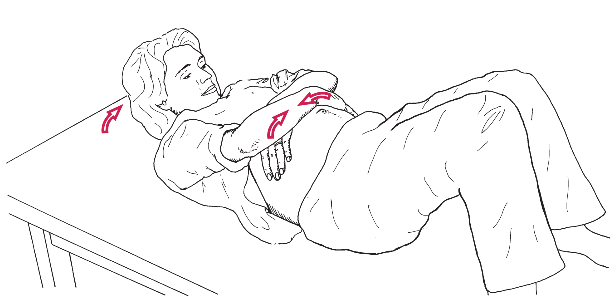

FIGURE 24.8 Corrective exercise for diastasis recti. The patient gently approximates the rectus muscle toward the midline by pulling with the crossed arms.

Head Lift with Pelvic Tilt

Patient position and procedure: Hook-lying. The arms are crossed over the diastasis for support as before. Have the patient slowly lift only her head off the floor while approximating the rectus muscles and performing a posterior pelvic tilt, then slowly lower her head and relax. All abdominal contractions should be performed with an exhalation so that intra-abdominal pressure is minimized.

Stabilization Exercises

Exercises for activating the abdominal and low back muscles and developing control of their stabilizing function in the lumbar spine and pelvis are described in Chapter 16 (see Table 16.5, Fig. 16.47, and 16.48 [Level 3 A–C]; see also Table 16.6 and Fig. 16.49 A–D). The exercises should be initiated and progressed at the intensity that the woman is able to safely control. Slow, controlled breathing is emphasized while developing the stabilizing function of the muscles. As pregnancy progresses, the abdominals will undergo extreme overstretching. Therefore, exercise must be adapted to meet the needs of each individual, and periodic reassessment must be done (approximately every 4 weeks during pregnancy).

PRECAUTIONS:
- Because the trunk muscles are contracting isometrically in many of the stabilization exercises, there is a tendency to hold the breath; this is detrimental to the blood pressure and heart rate. Caution the woman to maintain a relaxed breathing pattern and exhale during the exertion phase of each exercise.
- If diastasis recti is present, adapt the stabilization exercises to protect the linea alba as described in the Corrective Exercises for Diastasis Recti section. Any progression of postpartum abdominal strengthening exercises should be postponed until the diastasis has been corrected to two finger widths or less.
- Keep in mind the 5-minute time limit for supine positioning when prescribing abdominal exercises after 13 weeks' gestation.

Dynamic Trunk Exercises

Pelvic Motion Training

These exercises are helpful in cases of posture-related back pain; they are beneficial for improving proprioceptive awareness, as well as lumbar, pelvic, and hip mobility.[32]

Pelvic tilt exercises. Begin in quadruped (on hands and knees). Instruct the patient to perform a posterior pelvic tilt. While the patient keeps her back straight, have her isometrically tighten (imagine drawing in) the lower abdominals and hold, then release and perform an anterior tilt through very small range.

- For additional exercise, while holding the abdominals in and the back straight, have the woman laterally flex the trunk to the right (side-bend to the right), looking at the right hip, then reverse to the left.
- Have the woman practice pelvic tilt exercises in a variety of positions, including side-lying and standing.

Pelvic clock. With the woman hook-lying, ask her to visualize the face of a clock on her lower abdomen. The umbilicus is 12 o'clock and the pubic symphysis is 6 o'clock. The patient's legs may move slightly while performing this exercise.

- Have her begin with gentle movements back and forth between 12 and 6 o'clock (the basic pelvic tilt exercise).

- Then ask her to move back and forth between 3 o'clock (weight shifted to left hip) and 9 o'clock (weight shifted to the right hip).
- Then move in a clockwise manner from 12 to 3 to 6 to 9 and then back to 12 o'clock, then reverse.

With practice, these will become very smooth and rhythmical movements and will not require such concentration on each number of the clock. Continue relaxed breathing throughout the exercise, and do not force any part of the movement. If the patient has difficulty with the motion, make the clock "smaller" until coordination improves.[32]

Pelvic clock progressions. Use the visual imagery of cutting the face of the clock in half so that there is a right side and a left side or a top half and a bottom half. Have the woman move her pelvis through the arc on the one side and back through the middle of the clock, and then move the pelvis through the opposite side and back through the middle. Initially, the woman may notice asymmetry when comparing the halves; this will improve with time.

- Once the patient understands and is able to perform the clockwise pattern, have her do counterclockwise motions with all of the activities mentioned previously, and then progress the exercises to the sitting position.[32]

Trunk Curls

- Curl-ups and curl-downs are classic abdominal exercises and can be used in the early stages of pregnancy *if tolerated and if no diastasis recti is present*. Have a pregnant patient protect the linea alba with crossed hands (see Fig. 24.8) while performing trunk curls.
- Diagonal curls are carried out to emphasize the oblique muscles. Have the woman lift one shoulder toward the outside of the opposite knee as she curls up and down and protects the linea alba with crossed hands.

Modified Upper and Lower Extremity Strengthening

As the abdomen enlarges, it becomes impossible to comfortably assume the prone position. Exercises that are usually performed in the prone position must be modified.

Standing Push-Ups

Patient position and procedure: Standing, facing a wall, feet pointing straight forward, shoulder-width apart, and approximately an arm-length away from the wall. The palms are placed on the wall at shoulder height. Have the woman slowly bend the elbows, bringing her upper body close to the wall, maintaining a stable trunk and pelvic position, and keeping the heels on the floor. Her elbows should be shoulder height. She then slowly pushes with her arms, bringing the body back to the original position.

Supine Bridging

Patient position and procedure: Supine in the hook-lying position. Have the woman perform a posterior pelvic tilt and then lift her pelvis off the floor. She can do repetitive bridges or hold the bridge position and alternately flex and extend her upper extremities to emphasize the stabilization function of the hip extensors and trunk musculature (see Fig. 20.21).

Quadruped Leg Raising

Patient position and procedure: On hands and knees (hands may be in fists or palms may be open and flat). Instruct the woman to first perform a posterior pelvic tilt and then slowly lift one leg, extending the hip to a level no higher than the pelvis while maintaining the posterior pelvic tilt (Fig. 24.9). She then slowly lowers the leg and repeats with the opposite side. The knee may remain flexed or can be straightened throughout the exercise. Monitor this exercise, and discontinue if there is stress on the sacroiliac joints or ligaments. If the woman cannot stabilize the pelvis while lifting the leg, have her just slide one leg posteriorly along the floor and return (see Fig. 16.50 A).

Modified Squatting

Wall slides and supported squatting exercises are used to strengthen the hip and knee extensors for good body mechanics and also to help stretch the perineal area for flexibility during the delivery process. In addition, if the woman wishes to use squatting for labor and delivery, the muscles must be strengthened and endurance trained in advance.

- *Patient position and procedure:* Standing with back against a wall and her feet shoulder-width apart. Have the woman slide her back down the wall as her hips and knees flex only as far as is comfortable, then slide back up (see Fig. 20.24).
- *Patient position and procedure:* Standing with feet shoulder-width apart or wider, facing a counter, chair, or wall on which the woman can rest her hands and/or forearms for support. Have the woman slowly squat as far as is

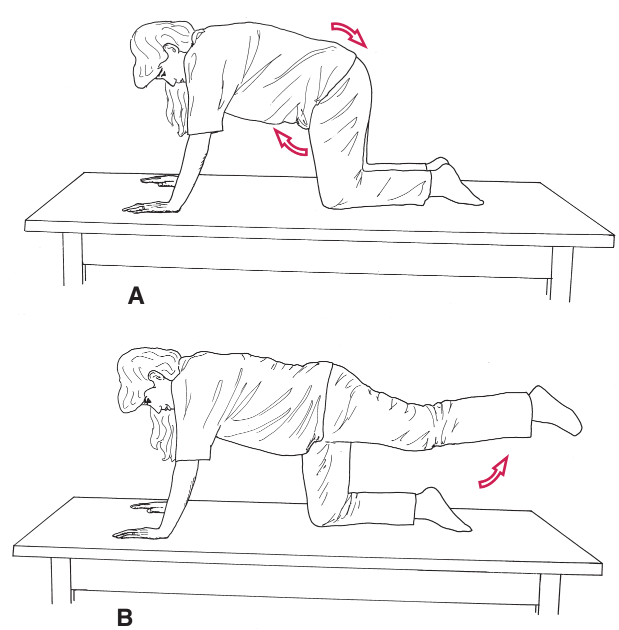

FIGURE 24.9 All-fours leg-raising. **(A)** Patient assumes quadruped position with posterior pelvic tilt. **(B)** Leg is raised only until it is in line with the trunk.

comfortable, keeping knees apart and over the feet and keeping the back straight. To protect her feet, she should wear shoes with good arch support. A woman with knee problems should perform only partial range of the squat. For optimal success with squatting during stage 2 of labor (pushing), increase the duration of the squat gradually to 60 to 90 seconds as tolerated.

Scapular Retraction

When scapular retraction exercises become difficult in the prone position, the woman should continue strengthening in the sitting or standing position (see Figs. 17.46 and 17.47.)

Perineum and Adductor Flexibility

In addition to the modified squatting exercises described in the preceding text, these flexibility exercises prepare the legs and pelvis for childbirth.[65,74,86]

Self-Stretching

- *Patient position and procedure:* Supine or side-lying. Instruct the woman to abduct the hips and pull the knees toward the sides of her chest and hold the position for as long as is comfortable (at least to the count of 10).
- *Patient position and procedure:* Sitting on a short stool with the hips abducted as far as possible and feet flat on the floor. Have her flex forward slightly at the hips (keeping the back straight), or have her gently press her knees outward with her hands for an additional stretch.

Pelvic Floor Awareness, Training, and Strengthening

Pelvic floor muscle training is a valuable modality regardless of a patient's presentation or cause of symptoms.* The majority of women are unfamiliar with the presence of the pelvic floor muscles and are even less aware of their function and role in daily activities. Intervention is slowly becoming more common during the childbearing years owing to the stress of pregnancy, labor, and delivery on the pelvic floor. Pelvic floor anatomy, function, and dysfunction are described in the first section of this chapter.

FOCUS ON EVIDENCE

A Cochrane review of 43 randomized trials concluded that pelvic floor muscle training is an effective treatment for stress or mixed urinary incontinence and is better than no treatment or placebo.[46] Functional improvements (decreased urinary incontinence and improved pelvic floor strength) have been noted in late pregnancy and from 3 to 12 months postpartum in a number of studies.[62,63,79] For optimal outcomes, pelvic floor contractions should be incorporated into routine ADLs, particularly activities that are "triggers" for leakage due to increased intra-abdominal pressure; used for stabilization prior to coughing or sneezing; and continued for life-long health benefits.[10,46]

Begin pelvic floor exercise training with an empty bladder. Gravity-assisted positioning (hips higher than the heart, such as supported bridge or elbows/knees position) may be indicated initially for some women with extreme weakness and proprioceptive deficits. Varied positions may need to be explored initially to maximize patient awareness and motor learning with progression into more challenging activities/positions as functional application becomes feasible.

Contract-Relax

Instruct the woman to tighten the pelvic floor as if attempting to stop urine flow or hold back gas. Hold for 3 to 5 seconds, and relax for at least the same length of time. Repeat as many as 10 times (if performed with proper technique). With significant coordination dysfunction or fatigue, substitution with the gluteals, abdominals, or hip adductors may occur. To maximize proprioception and motor learning, it is important initially to emphasize isolation of the pelvic floor and avoid the substitute muscle actions. In addition, watch for Valsalva's maneuver; if necessary, have the woman count out loud to encourage normal breathing patterns.

Quick Contractions

Have the woman perform quick, repeated contractions of the pelvic floor muscles while maintaining a normal breathing rate and keeping accessory muscles relaxed. Try for 15 to 20 repetitions per set. This type II-fiber response is important to develop in order to withstand pressure from above, especially with coughing or sneezing.

"Elevator" Exercise

Instruct the woman to imagine riding in an elevator. As the elevator goes up from one floor to the next, she contracts the pelvic floor muscles a little more. As strength and awareness improve, add more "floors" to the sequence of the contraction. Another way to increase difficulty is to ask the woman to relax the muscles gradually, as if the elevator were descending one floor at a time. This component requires an eccentric contraction and is very challenging.

Pelvic Floor Relaxation

- Instruct the woman to contract the pelvic floor as in the strengthening exercise, then allow total voluntary release and relaxation of the pelvic floor. Use of the "elevator" imagery should also be emphasized, with particular attention to taking the elevator to the "basement."
- Pelvic floor relaxation is closely linked with effective breathing and relaxation of the facial muscles. Instruct the woman to concentrate on a slow, deep breath and allow the pelvic floor to completely relax. Relaxation of the pelvic floor is extremely important during stage 2 of labor and vaginal delivery.[37,65,86]

*9,10,19,34,37,46,54,62,63,65,73,79,86,88,91

- Chronic inability to relax the pelvic floor muscles may lead to impairments such as hypertonus, pain with intercourse, or voiding dysfunction. Please refer to the earlier information on pelvic pain syndromes. If the patient presents with these symptoms, increase the rest time between pelvic floor contractions and sets; also use submaximal contractions to improve awareness of tension versus relaxation. Use of surface EMG for down-training and muscle reeducation is invaluable with these impairments for increasing awareness of holding patterns, pain inhibition, and resting tone.

Relaxation and Breathing Exercises for Use During Labor

Developing the ability to relax requires awareness of stress and muscle tension. Techniques of conscious relaxation allow the individual to control and cope with a variety of imposed stresses by being mentally alert to the task at hand while relaxing tense muscles that are superfluous to the activity (see Chapter 4). This is particularly important during labor and delivery when there are times that the woman should relax and allow the physiologic processes to occur without excessive tension in unrelated muscles.[65] Additional relaxation techniques for managing stress are described in Chapter 14. The following guidelines are most effective for the pregnant woman if consistently practiced in preparation for labor and delivery.

Visual Imagery

Use instrumental music and verbal guidance. Instruct the woman to concentrate on a relaxing image such as the beach, mountains, or a favorite vacation spot. Suggest that she focus on the same image throughout the pregnancy so that the image can be called up to the conscious level when recognizing the need to relax during labor.

Muscle Setting

- Have the woman lie in a comfortable position.
- Have her begin with the lower body. Instruct her to gently contract and then relax first the muscles in the feet, then legs, thighs, pelvic floor, and buttocks.
- Next, progress to the upper extremities and trunk, then to the neck and facial muscles.
- Reinforce the importance of remaining awake and aware of the contrasting sensations of the muscles. Emphasize "softening" of the muscles as the session continues.
- Add deep, slow, relaxed breathing to the routine.

Selective Tension

Progress the training by emphasizing awareness of muscles contracting in one part of the body while remaining relaxed in other parts. For example, while she is tensing the fist and upper extremity, the feet and legs should be limp. Reinforce the comparison between the two sensations and the ability to control both tension and relaxation.

CLINICAL TIP

While practicing *selective tension*, have your client work with a partner who gently shakes the extremity that is "relaxed" to make sure there is no tension in it.

Breathing

- Slow, deep breathing (with relaxation of the upper thorax) is the most efficient method for exchange of air to use with relaxation techniques and for controlled breathing during labor.
- Teach the woman to relax the abdomen during inspiration so that it feels as though the abdominal cavity is "filling up" and the ribs are expanding laterally. During exhalation, the abdominal cavity becomes smaller; active contraction of the abdominal muscles is not necessary with relaxed breathing.
- To prevent hyperventilation, emphasize a slow rate of breathing. Caution the woman to decrease the intensity of the breathing if she experiences dizziness or feels tingling in the lips and fingers.

Relaxation and Breathing During Labor

First Stage

As labor progresses, the contractions of the uterus become stronger, longer, and closer together. Relaxation during the contractions becomes more difficult. Provide the woman with suggested techniques to assist in relaxation.[65]

- Ensure the woman has emotional support from the father, family member, or special friend to provide encouragement and assist with overall comfort.
- Seek comfortable positions including walking, hands and knees (Fig. 24.10), lying on pillows, or sitting on a Swiss ball; include gentle repeated motions such as pelvic rocking.
- Breathe slowly with each contraction; use the visual imagery, and relax with each contraction. Some women find it helpful to focus their attention on a specific visual object. Other suggestions include singing, talking, or moaning during each contraction to prevent breath-holding and encourage slow breathing.
- During transition (near the end of the first stage), there is often an urge to push. Teach the woman to use quick blowing techniques, using the cheeks, not the abdominal muscles, to overcome the desire to push until the appropriate time.
- Massage or apply pressure to any areas that hurt, such as the low back. Using the hands may help distract the focus from the contractions.
- Apply heat or cold for local symptoms; wipe the face with a wet washcloth.

Second Stage

Once dilation of the cervix has occurred, the woman may become active in the birth process by assisting the uterus during

FIGURE 24.10 The use of a stability ball in labor can provide relief of back pain and the comfort of rhythmical, relaxing movements. The labor coach can massage the back and/or hip muscles and apply heat or ice if desired.

a contraction in pushing the baby down the birth canal.[65] Teach her the following techniques:

- While bearing down, take in a breath, contract the abdominal wall, and slowly breathe out. This will cause increased pressure within the abdomen along with relaxation of the pelvic floor.

PRECAUTION: Tell the woman that if she holds her breath, there will be increased tension and resistance in the pelvic floor. In addition, exertion with a closed glottis, known as Valsalva's maneuver, has adverse effects on the cardiovascular system.

- For maximum efficiency, maintain relaxation in the extremities, especially the legs and perineum. Keeping the face and jaw relaxed assists with this.
- Between contractions, perform total body relaxation.
- As the baby is delivered, just "let go," and breathe with light pants or groans to relax the pelvic floor as it stretches.

Unsafe Postures and Exercises During Pregnancy

Bilateral straight-leg raising. This exercise typically places more stress on the abdominal muscles and low back than they can tolerate. It can cause back injury or diastasis recti and therefore should not be attempted.

"Fire hydrant" exercise. This exercise is performed on hands and knees, and one hip is abducted and externally rotated at a time (the "image" of a dog at a fire hydrant). If the leg is elevated too high, the sacroiliac joint and lumbar vertebrae can be stressed. It should be avoided by any woman who has preexisting sacroiliac joint symptoms or women in whom symptoms develop.

All-fours (quadruped) hip extension. This exercise can be performed safely only as explained earlier in this chapter (see Fig. 24.9). It becomes unsafe and can cause low back pain when the leg is elevated beyond the physiologic range of hip extension, causing the pelvis to tilt anteriorly and the lumbar spine to hyperextend.

Unilateral weight-bearing activities. Weight bearing on one leg (which includes slouched standing with the majority of weight shifted to one leg and the pelvis tilted down on the opposite side) during pregnancy can cause sacroiliac joint irritation and should be avoided by women with preexisting sacroiliac joint symptoms. Unilateral weight bearing also can cause balance problems because of the increasing body weight and shifting of the center of gravity. This posture becomes a significant problem postpartum when the woman carries her growing child on one hip. Any asymmetries become accentuated, and painful symptoms may develop.

Exercise Critical to the Postpartum Period

After an uncomplicated vaginal delivery, exercise can be started as soon as the woman feels able to exercise and has been cleared by her physician or midwife.[3,5,54,62,63,65,79,84]

Pelvic floor strengthening. Exercises should be resumed as soon after the birth as possible. These exercises may increase circulation and aid healing of lacerations or episiotomy. Combining pelvic floor contractions with feeding or changing the baby may help them become integrated into the daily routine. When treating a postpartum client in the clinic, emphasize life-long need for pelvic floor exercise, especially when lifting or with significant exertion, to allow the pelvic floor muscles to provide additional trunk support.

Diastasis recti correction. The testing procedure for diastasis recti was described earlier in this chapter. The mother should be taught this test and encouraged to perform it on the third postpartum day. Corrective exercises (see Fig. 24.8) should continue until the separation is two finger widths or less. At that time, more vigorous abdominal exercise can be resumed.

Aerobic and strengthening exercises. As soon as the woman feels able, cardiopulmonary exercise and light resistance training can be resumed with gradually increasing intensity. A physical examination is suggested before the onset of vigorous exercise or sport-specific training.

PRECAUTIONS: Because the woman may not be seen for exercise instruction after the delivery, inform her of the following precautions:

- If bleeding increases or turns bright red, exercise should be postponed. Tell her to rest more and allow a longer recovery time.
- Joint laxity may be present for some time after delivery, especially if breastfeeding. Precautions should be taken to protect the joints as described previously.[74,86,91] Adequate warm-up and cool-down time is important.

Cesarean Childbirth

A *cesarean section* is the delivery of a baby through an incision in the abdominal wall and uterus rather than through the pelvis and vagina.[2,40,43,54,67] General, spinal, or epidural anesthesia may be used.

Significance to Physical Therapists

Surgical Risks

Cesarean section (C-section) delivery is now at an all-time high and is the most commonly performed surgical procedure in the United States. In 2007, the total number of C-sections was almost 1.5 million, for a record high rate of 31.8%[50] This statistic has fluctuated in the past three to four decades, in part depending on the type of hospital and the population it served. Since the early 1990s, the American College of Obstetricians and Gynecologists (ACOG) has discouraged repeat C-sections as routine practice, and the *Healthy People 2010* goal was to reduce the primary rate to 15%, with a target rate for repeat cesareans at 63%.[51] The Vaginal Birth After Cesarean (VBAC) movement was a factor in reducing C-sections from 1990 to 1996; however, since then, the rates have continued to climb. The medical community is continuing to discuss the short- and long-term benefits and harms to both mother and baby of a trial of labor following a previous C-section. Pregnant clients will have many questions regarding this evidence. Al-Zirqi and colleagues[2] identified specific risk factors for uterine rupture with a VBAC and determined that absolute risk was low (5.0/1,000 births; n=18,794). However, the use of prostaglandin induction significantly increased the odds for rupture when compared to spontaneous labor.

Recently, the perceived "convenience" of a C-section is becoming a factor, leading to increases in not only repeat but also elective C-sections. In addition to the appeal of scheduling a delivery date, there is some evidence that cesarean delivery may aid in prevention of future pelvic floor dysfunction.[6,43,83] These risks and benefits will continue to be discussed as maternal and fetal outcomes are detailed in the literature.

Pregnant women need to be informed of the risks and benefits of each choice in order to make informed decisions. Because these statistics continue to fluctuate and more changes will be inevitable as our healthcare system evolves, physical therapists must stay informed in order to address these issues with all pregnant patients.[2,6,35,40,43,58,61,67,69,83,86,89]

Interventions

Pelvic floor rehabilitation. Women who have had a cesarean delivery may still require pelvic floor rehabilitation. Many women experience a lengthy labor, including prolonged second stage (pushing), before a C-section is deemed necessary. Therefore, the pelvic floor musculature and the pudendal and levator ani nerves may still be compromised. Also, pregnancy itself creates significant strain on the pelvic floor musculature and other soft tissues.

Postsurgical rehabilitation. Postpartum intervention for the woman who has had a cesarean delivery is similar to that of the woman who has had a vaginal delivery. However, a C-section is a major abdominal surgery with all the risks and complications of such surgeries, and therefore the woman may also require general postsurgical rehabilitation.[40,43,67,86,] Impairments and management guidelines are summarized in Box 24.6.

BOX 24.6 MANAGEMENT GUIDELINES—**Postcesarean Section**

Potential Structural and Functional Impairments

Risk of pulmonary, gastrointestinal, or vascular complications
Postsurgical pain and discomfort
Development of adhesions at incision site
Faulty posture
Pelvic floor dysfunction

- Urinary or fecal incontinence
- Organ prolapse
- Hypertonus
- Poor proprioceptive awareness and disuse atrophy

Abdominal weakness, diastasis recti
General functional restrictions of post delivery

Plan of Care	Interventions
1. Improve pulmonary function and decrease the risk of pneumonia.	1. Breathing instruction, coughing and/or huffing

Continued

BOX 24.6 MANAGEMENT GUIDELINES—Postcesarean Section—cont'd

Plan of Care	Interventions
2. Decrease incisional pain with coughing, movement, or breast feeding.	2. Postoperative TENS; support incision with pillow when coughing or breastfeeding Incisional support with pillow or hands with movement education regarding incisional care and risk of injury
3. Prevent postsurgical vascular or gastrointestinal complications	3. Active leg exercises Early ambulation Teach abdominal massage to stimulate peristalsis[44]
4. Enhance incisional circulation and healing; prevent adhesion formation.	4. Gentle abdominal exercise with incisional support Scar mobilization and friction massage
5. Decrease postsurgical discomfort from flatulence, itching, or catheter.	5. Positioning instruction, massage, and supportive exercises
6. Correct posture.	6. Posture instruction, particularly regarding child care
7. Prevent injury and reduce low back pain.	7. Instruction in incisional splinting and positioning for ADLs Body mechanics instruction
8. Prevent pelvic floor dysfunction.	8. Pelvic floor exercises Education regarding risk factors and types of pelvic floor dysfunction
9. Develop abdominal strength.	9. Abdominal exercise progression, including corrective exercises for diastasis recti

Emotional support. All childbirth preparation classes do not adequately educate and prepare couples for the experience of a cesarean delivery. As a result, the woman with an unplanned C-section frequently feels as if her body has failed her, causing her to have more conflicting emotions than a woman who has experienced a vaginal delivery.

Suggested Activities for the Patient Following a Cesarean Section

Exercises

- Instruct the woman during her pregnancy in all appropriate exercises, with indicated precautions.
- Instruct the woman to begin preventive exercises as soon as possible during the recovery period.[40,65,66]
  - Ankle pumping, active lower extremity ROM, and walking are used to promote circulation and prevent venous stasis.
  - Pelvic floor exercises are used to regain tone and control of the muscles of the perineum.
  - Deep breathing and coughing or huffing are used to prevent pulmonary complications (see instructions that follow).
- Progress abdominal exercises slowly. Check for diastasis recti, and protect the area of the incision to improve comfort. Initiate nonstressful muscle-setting techniques and progress as tolerated, based on the degree of separation.[40,65,66,86]
- Teach posture correction as necessary. Retrain postural awareness and help realign posture with indicated therapeutic exercise. Develop control of the shoulder girdle muscles as they respond to the increased stress of caring for the new baby.
- Reinforce the value of deep diaphragmatic breathing techniques for pulmonary ventilation, especially when exercising, and relaxed breathing techniques to relieve stress and promote relaxation.
- Inform the woman that she should wait at least 6 to 8 weeks before resuming vigorous exercise. Emphasize the importance of progressing at a safe and controlled pace and not expecting to begin at her prepregnancy level.

Coughing or Huffing

Coughing is difficult following a C-section because of incisional pain. An alternative is huffing.[65] A huff is an outward breath caused by the upper abdominals contracting up and in against the diaphragm to push air out of the lungs. The

abdominals are pulled up and in, rather than pushed out, causing decreased pressure in the abdominal cavity and less strain on the incision. Huffing must be done quickly to generate sufficient force to expel mucus. Instruct the patient to support the incision with a pillow or the hands and say "ha" forcefully and repetitively while contracting the abdominal muscles.

Interventions to Relieve Intestinal Gas Pains

Abdominal massage or kneading. Have the patient lie supine or on the left side. This is very effective and typically done with either long or circular strokes. Begin on the right side at the ascending colon, stroking upward, then stroke across the transverse colon from right to left and down the descending colon, then finish with an "S" stroke along the sigmoid colon. This can also be particularly effective for stimulating peristalsis and improving constipation.[44]

Pelvic tilting and/or bridging. These can be done in conjunction with massage.

Bridge and twist. Have the patient maintain a position of bridging while twisting her hips to the right and left.

Scar Mobilization

Cross-friction massage should be initiated around the incision site as soon as sufficient healing has occurred. This will minimize adhesions that may contribute to postural problems and back pain.

High-Risk Pregnancy

A *high-risk pregnancy* is one that is complicated by disease or problems that put the mother or fetus at risk for illness or death before, during, or after delivery. Conditions may be preexisting, induced by pregnancy, or caused by an abnormal physiologic reaction during pregnancy.[41,54] The goal of medical intervention is to prevent preterm delivery, usually through use of bed rest, restriction of activity, and medications, when appropriate. Prolonged bed rest can impact not just the musculoskeletal system but also pulmonary, cardiovascular, and metabolic functions. Although these women may initially be seen in the home, the deconditioning present continues to create functional restrictions for the postpartum client in terms of strength and endurance, making this scenario ideal for physical therapy intervention. Here again, as with pelvic floor dysfunction, advanced education for the therapist and specialized care is required for successful outcomes.[41,53,54,73,74,77,86]

High-Risk Conditions

Premature onset of labor. If cervical dilation, effacement, and/or uterine contractions begin before 37 weeks' gestation, this is considered preterm labor. Clearly, the health of the baby is of primary concern if these signs are present. The mechanism for this condition is still unclear.[54]

Preterm rupture of membranes. The amniotic sac breaks, and amniotic fluid is lost before onset of labor. This can be dangerous to the fetus if it occurs before fetal development is complete. Labor may begin spontaneously after the membranes rupture. The chance for fetal infection also increases when the protection of the amniotic sac is lost. Leakage of amniotic fluid is an indication for immediate medical attention.

Incompetent cervix. An incompetent cervix is the painless dilation of the cervix that occurs in the second trimester (after 16 weeks' gestation) or early in the third trimester of pregnancy. This may lead to premature membrane rupture and delivery of a fetus too small to survive.

Placenta previa. The placenta attaches too low on the uterus, near the cervix. As the cervix dilates, the placenta begins to separate from the uterus and may present before the fetus, thus endangering fetal life. The primary symptom is intermittent, recurrent, or painless bleeding that increases in intensity.

Pregnancy-related hypertension or preeclampsia. Characterized by hypertension, protein in the urine, and severe fluid retention, preeclampsia can progress to maternal convulsions, coma, and death if it becomes severe (eclampsia). It usually occurs in the third trimester and disappears after birth. The cause is not understood.

Multiple gestation. More than one fetus develops. Complications of multiple gestations include premature onset of labor and birth, increased incidence of perinatal mortality, lower birth weight infants, and increased incidence of maternal complications (e.g., hypertension).

Diabetes. Diabetes can be present before pregnancy or may occur as a result of the physiological stress of pregnancy. *Gestational diabetes*, which presents or is first recognized in pregnancy, affects 7% of pregnant women and usually disappears after pregnancy; however, as many as 50% of these women may develop type 2 diabetes within 10 years.[49]

Unlike many of the previously discussed high-risk conditions, women with gestational diabetes may be appropriate candidates for more traditional physical therapy interventions. Supervised, individualized exercise programs are excellent options. Parameters for exercise in pregnancy for women with gestational diabetes were published by the American Diabetes Association in 2006.[4] They support aerobic exercise with limited duration and at 50% maximum aerobic capacity; alternatively, the Borg scale may be used with a range of 11 to 13 rate of perceived exertion (RPE) as maximal activity level (see Box 24.4). With appropriate monitoring of fetal/uterine activity, maternal heart rate, and blood glucose levels, exercise duration of 15 to 30 minutes appears to be safe.[54] Instruct patients to monitor for any postexercise uterine activity; contractions need to be fewer than one every 15 minutes.[4,54]

Exercise may actually prevent gestational diabetes in obese pregnant women.[3] In particular, recumbent bicycling or arm ergometer exercises have been shown to stabilize and lower glucose levels.[73]

FOCUS ON EVIDENCE

In a randomized study of overweight women with gestational diabetes (n=32), the control group was treated with diet alone, while the remaining women also participated in circuit resistance training. The diet-plus-exercise group was able to postpone the use of insulin therapy until later in the pregnancy ($p < 0.05$) and was also prescribed less insulin overall ($p < 0.05$) than the diet-alone group.[18]

Management Guidelines and Precautions for High-Risk Pregnancies

All exercise programs for high-risk populations should be individually established based on diagnosis, limitations, physical therapy examination and evaluation, and consultation with the physician. Activities must address patient needs but should not further complicate the condition.[74,86] Management guidelines for the woman who is confined to bed because of her high-risk status are summarized in Box 24.7.

Develop good rapport with the patient and instill trust. Closely monitor the patient during all activities; reevaluate her after each treatment, and note any changes. It is also important to teach the patient self-monitoring techniques so that she will be alert to adverse reactions and respond appropriately.

- Prolonged static positioning is a primary concern. The position of choice for the high-risk patient is left side-lying, which is optimal for reducing pressure on the inferior vena cava and for maximizing cardiac output, thereby enhancing maternal and fetal circulation.
- Some exercises, especially abdominal exercises, may stimulate uterine contractions. If this occurs, modify or discontinue them.
- Monitor and report any uterine contractions, bleeding, or amniotic fluid loss.
- Do not allow use of Valsalva's maneuver. Avoid any activities that increase intra-abdominal pressure. Body mechanics and postural instruction may stimulate abdominal contractions, so be sure the patient does not strain and closely monitor for adverse symptoms.
- Keep the exercises simple. Have the patient do them slowly, smoothly, and with minimal exertion.

BOX 24.7 MANAGEMENT GUIDELINES—High-Risk Pregnancy

Potential Structural and Functional Impairments, Activity Limitations, (Functional Limitation)

Primary activity limitations are inability to be out of bed and move about, prolonged static positioning, contributing to the following impairments:

- Joint stiffness and muscle aches
- Muscle weakness and disuse atrophy
- Vascular complications including risk of thrombosis and decreased uterine blood flow
- Decreased proprioception in distal body parts
- Constipation caused by lack of exercise
- Postural changes
- Boredom

Emotional stress; patient may be at risk of losing the baby

Guilt from the belief that some activity caused the problem or that the patient did not take good enough care of herself

Anxiety about her home situation, older children, finances, or the impending birth

Plan of Care	Interventions
1. Decrease stiffness.	1. Positioning instructions; assess for supports Facilitation of joint motion in available range
2. Maintain muscle length and bulk.	2. Stretching and strengthening exercises within limits imposed by the physician
3. Maximize circulation; prevent deep-vein thrombosis.	3. Ankle pumping; ROM
4. Improve proprioception.	4. Movement activities for as many body parts as possible
5. Improve posture within available limits.	5. Posture instruction, modified as necessary based on allowed activity level Bed mobility and transfer techniques if able (avoid Valsalva's maneuver)

Continued

BOX 24.7 MANAGEMENT GUIDELINES— High-Risk Pregnancy—cont'd

Plan of Care	Interventions
6. Relieve boredom.	6. Vary activities and positioning for exercises; encourage interaction with others on bed rest (http://www.sidelines.org)
7. Enhance relaxation.	7. Relaxation techniques/stress management
8. Prepare for delivery.	8. Childbirth education, breathing training, and exercises to assist and prepare for labor
9. Enhance postpartum recovery.	9. Exercise instruction and home program for postpartum period Body mechanics instruction, particularly related to child care

- Many high-risk pregnancies result in cesarean deliveries, so educate the woman about cesarean delivery rehabilitation.
- Incorporate maximum muscle efficiency into each movement.
- Teach the patient self-monitoring techniques.

Exercise Suggestions with High-Risk Pregnancies

Exercise suggestions are adaptations of interventions that have already been described that should be considered for the bedbound patient with a high-risk pregnancy.[73,74,86] Exercises to include are summarized in Box 24.8.

BOX 24.8 Bed Exercises for High-Risk Pregnancy

- Patient supine (with wedge under the right hip), semireclined or side-lying
- Cervical active ROM and chin tucks
- Backward shoulder circles (scapular retraction); reach to ceiling (protraction)
- Unilateral upper extremity diagonal patterns
- Shoulder, elbow flexion/extension; arm circles in side-lying
- Forearm pronation/supination; wrist flexion/extension, hand open/close
- Pelvic tilts
- Abdominal exercises (per physician consultation)
- Pelvic floor exercises (per physician consultation)
- Quad and gluteal isometric sets
- Unilateral hip abduction and adduction, internal/external rotation
- Unilateral hip and knee flexion/extension in side-lying
- Ankle pumping, ankle circles, ankle "alphabet"
- Toe flexion/extension

Positioning

- Left side-lying to prevent vena cava compression, enhance cardiac output, and decrease lower extremity edema
- Pillows between the knees and under the abdomen when side-lying
- Supine positioning for short periods, with a wedge placed under the right hip to decrease inferior vena cava compression (see Fig. 24.7)
- Modified prone positioning (side-lying, partially rolled toward prone, with pillow under abdomen) to decrease low back discomfort and pressure

Range of Motion (ROM)

- Active ROM of all joints.
- Motions should be slow, nonstressful, and through the full range if possible.
- Teach in a gravity-neutral position if antigravity ROM is too much exertion.
- Individualize the number of repetitions and frequency to the woman's condition.

Ambulation/Standing

Getting out of bed is almost always contraindicated; when allowed, it usually will be only to use the bathroom or to shower

- Encourage good posture in ambulation
- Tip-toe or heel walking to emphasize calf muscles
- Gentle, partial-range squatting to emphasize hip and thigh muscles

Relaxation Techniques, Bed Mobility, and Transfer Activities

- Relaxation as in the uncomplicated pregnancy
- Moving up, down, and side-to-side in bed
- Log rolling: incorporate neck and upper and lower extremities to aid movement
- Supine-to-sitting: use log-roll technique, assisted by arms

Preparation for Labor

- Relaxation techniques
- Substitutions for squatting: supine, sitting, or side-lying, bringing flexed knees toward chest (hips will have to be abducted)
- Pelvic floor relaxation
- Breathing exercises: minimize forced abdominal exhalations

Postpartum Exercise Instruction

Instructions are the same as previously described in the uncomplicated pregnancy section.

Independent Learning Activities

Critical Thinking and Discussion

1. Describe three normal changes of pregnancy that will affect exercise tolerance.
2. Explain the clinical significance of diastasis recti, the testing procedure, and the corrective exercise.
3. Differentiate between postural and sacroiliac back pain in the pregnant patient.
4. Name five risk factors for pelvic floor dysfunction.
5. What exercise guidelines are most helpful for a woman who has not exercised prior to becoming pregnant?
6. Discuss optimal positioning for an uncomplicated labor and delivery in terms of biomechanics, gravity, and energy conservation.
7. Vaginal delivery places great stretch and compression on which nerves?

Laboratory Practice

1. Practice giving instructions to a lab partner on how to perform the following exercises. Observe that they are being done correctly. Reverse the experience and provide feedback.
   - Diastasis recti exercises
   - Pelvic clock exercises
   - Breathing and relaxation for the different stages of labor and delivery
2. Practice giving instructions, and get verbal feedback as to the success of instructions for the pelvic floor awareness training and strengthening exercises.
3. Observe an exercise class for pregnant women. Critique the effectiveness and inclusiveness of the instruction.

Case Studies

1. Ms. V is a 32-year-old pregnant woman referred with a diagnosis of "low back pain," that became severe at 24 weeks' gestation. She reports (L) lumbar/thoracic, (R) anterior rib/pectoral, and cervical symptoms, which are worsening as the pregnancy progresses. Before her pregnancy, she wore a custom-made bra (32-MM), which is now much too small and provides inadequate support. Wearing this bra greatly increases her cervical and upper trapezius symptoms. Wearing a sports bra or standing more than 10 to 15 minutes causes increased low back symptoms. Pain is severely limiting her daily activities both at home and in the community. She has difficulty climbing stairs, grocery shopping, doing laundry, and other household chores. She is wakened at night by pain and also reports numbness in her lower extremities at night. She is a single mother of a 6-year-old son. Pertinent medical history includes: weight gain of 100 lb with her previous pregnancy, C-section delivery, removal of fibrocystic breast tissue three times. No systemic medical conditions or medications other than prenatal vitamins. Current weight: 238 lb, height: 5′4″.

Clinical Findings

Postural assessment reveals marked forward head/shoulders with internal rotation at both shoulder joints, significant lordosis (cervical and lumbar), recurvatum bilaterally, decreased longitudinal arches, increased base of support with excessive external rotation (ER) at both hips. All dynamic movements are pain inhibited: frequent weight shift and asymmetrical transitions, antalgic gait pattern with increased ER of hips. Lumbar extension and (L) cervical rotation most limited by pain and spasm.

Diastasis recti of 9 cm noted above umbilicus; abdominal strength 3–/5. Pelvic landmarks difficult to assess due to adipose tissue; leg lengths appear equal. Slight tenderness over pubic symphysis with palpation.

- Identify the impairments and functional limitations.
- Identify goals that deal with impairments and functional limitations.
- Develop a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

2. Mrs. W is a 71-year-old woman with an 11-year history of urinary incontinence and urgency. She experiences frequent, large-volume accidents, using 8 to 10 large incontinence pads and 8 panty liners per day for garment protection. Voiding frequency is 13 to 16 times every 24 hours. She also reports constipation and straining for evacuation, which improves with increased fiber intake. Caffeine intake is two servings per day. Mrs. W is a nonsmoker. She is much less active with social and community activities as a result of this problem. Urodynamic testing revealed diminished bladder capacity at 150 cc and confirmed the diagnosis of detrusor instability.

   Pertinent medical history includes nine pregnancies and seven live births (G9, P7) with one breech presentation. LBP and "sciatic nerve problems" of long standing were

reported with lumbar fusion done when she was 44 and 48 years of age. Other surgical history includes rectocele/cystocele repair when she was 36 and partial hysterectomy when she was 37. Hypertension and asthma are both well controlled with medication.

Clinical Findings

Pelvic floor muscle assessment reveals poor sensory awareness, decreased resting tone, and an MMT of 2/5. Patient able to hold a contraction 4 seconds and repeat 10 "quick flicks" in 10 seconds. Accessory recruitment of the abdominals noted. Pressure perineometry confirms muscle weakness with 6.35 cm of water pressure generated. Levator ani contraction is enhanced with stretch facilitation to the pelvic floor (R > L).

Abdominal strength is 3/5. Diastasis recti noted above the umbilicus of 4.5 cm. Diaphragmatic breathing pattern present; no Valsalva's with exertion. All dynamic movements of the trunk are mildly restricted because of lumbar fusion.

The patient underwent physical therapy treatments approximately 18 months ago and is independent with her low back (LB) program. (Because of insurance limitations of 10 visits, the patient requested primary attention to pelvic floor dysfunction and incontinence.)

- Identify the impairments and functional limitations.
- Identify goals that deal with the impairments and functional limitations.
- Design a treatment plan to meet the goals; identify specific interventions and parameters, number of times she will be seen, and any follow-up or referrals that you believe will be necessary.

Management of Lymphatic Disorders

KAREN L. HOCK, PT, MS, CLT-LANA ■ LYNN ALLEN COLBY, PT, MS

Impairments of the lymphatic system can lead to lymphatic insufficiencies that can result in significant physical impairments and subsequent loss of function of either the upper or lower extremities. Disturbances in structure or function can lead to accumulation of lymphatic fluids in the tissue of the body that affect the physiological health of the tissue, impair joint mobility, and impact daily functioning. Lymphatic dysfunction can be a result of a congenital or hereditary abnormality or can be caused by trauma, infection, or treatment for a cancer.

To contribute to the effective management of patients with lymphatic disorders, a therapist must possess a sound understanding of the underlying pathologies and the clinical manifestations of many types of lymphatic disorders, as well as the interplay between the lymphatic and venous systems. A therapist must also be aware of the use, effectiveness, and limitations of therapeutic exercise in the comprehensive management and rehabilitation of patients with lymphatic insufficiencies.

Disorders of the Lymphatic System

Structure and Function of the Lymphatic System

The primary function of the lymphatic system is to collect and transport fluid from the interstitial spaces back to the venous circulation (Fig. 25.1).[30,35,47,52,105,107] This is accomplished with a series of lymph vessels and lymph nodes.[30,35,107] The lymphatic system also has a role in the body's immune function.[30,105,107] When the lymphatic system is compromised either by impairment of lymphatic structures or by an overload of lymphatic fluid, the result is swelling in the tissue spaces. Edema is a natural consequence of trauma to and subsequent healing of soft tissues. If the lymphatic system is compromised and does not function efficiently, lymphedema develops and impedes wound healing.

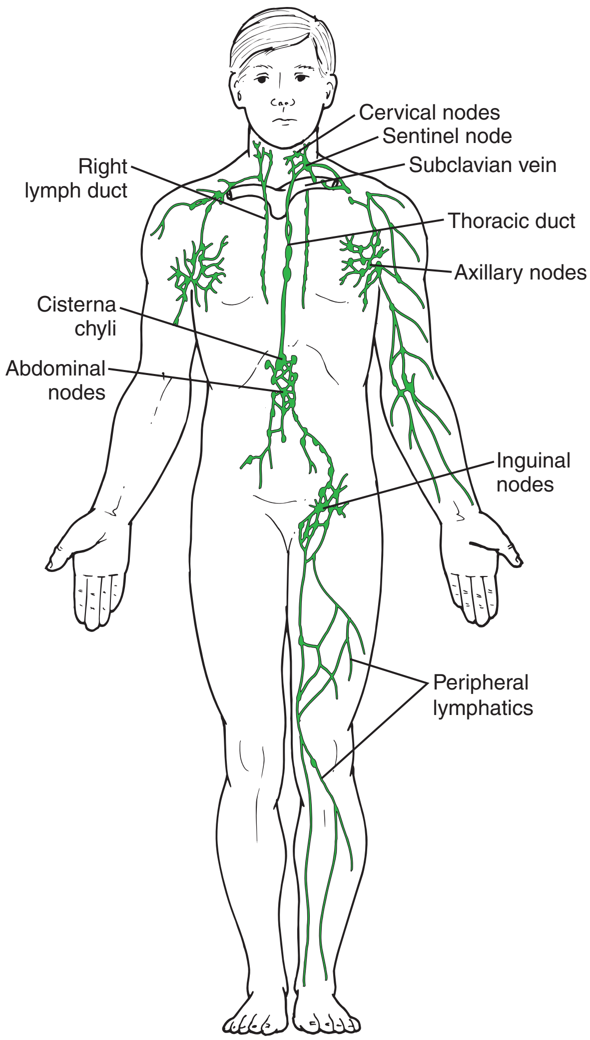

FIGURE 25.1 Major vessels of the lymphatic system.

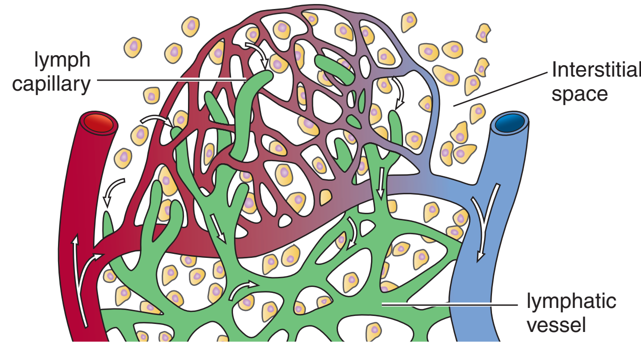

FIGURE 25.2 Lymph capillary and larger lymph vessel.

Lymphedema is an excessive and persistent accumulation of extravascular and extracellular fluid and proteins in tissue spaces.[11,18,26,47,61,107] It occurs when lymph volume exceeds the capacity of the lymph transport system, and it is associated with a disturbance of the water and protein balance across the capillary membrane. An increased concentration of proteins draws larger amounts of water into interstitial spaces, leading to lymphedema.[26,41,107] Furthermore, many disorders of the cardiopulmonary system can cause the load on lymphatic vessels to exceed their transport capacity and subsequently cause lymphedema.[41,61]

Anatomy of the Lymphatic System

The lymphatic system is an open system.[30,57,107] The lymphatic capillaries are situated close to the blood capillaries and are responsible for pulling the fluid into the lymphatic circulation (Fig. 25.2).[30,47,57,105,107] Once inside the lymphatic vessels, the fluid is transported from lymph nodes to lymphatic trunks.[30,57,105,107] The end result is the collection of the lymphatic fluid at the venous angles. In total, the body has 600 to 700 lymph nodes with the largest grouping found in the head and neck, around the intestines, and in the axilla and groin.[30,107]

Physiology of the Lymphatic System

The main components of lymphatic fluid are water and protein found in the extracellular spaces.[26,30,41,57] In a normal state, the lymphatic system transports this fluid back to the venous circulation. The amount of fluid transported is the lymphatic load, and the amount of fluid the lymphatic system can transport is the transport capacity.[30,107] When the balance in the interstitium is disrupted, whether by an increased lymphatic load or a decreased transport capacity, lymphedema can develop.[26,30,41,107] Lymphatic load is increased when the venous system is unable to transport the required amount of fluid, which can occur in a patient with a venous insufficiency. Transport capacity is affected when the structures of the lymphatic system are impaired, for example, following surgery to remove lymph nodes in a patient with cancer.

Types of Lymphedema

Lymphedema can be classified as primary, meaning there is an inherent problem with the structures of the lymphatic system, or secondary, meaning there is an injury to lymphatic structures.[30,41,107] This injury may be in the form of surgery, radiation, trauma, or infection. Lymphedema can also be caused by a combination of lymphatic-venous dysfunction commonly seen in patients with chronic venous insufficiency. Remember, lymphedema is not a disease but rather a symptom of a malfunctioning lymphatic system.

Primary Lymphedema

Primary lymphedema, although uncommon, is the result of insufficient development (dysplasia) and congenital malformation of the lymphatic system.[35,40]

Primary lymphedema can be divided into the age of presentation.[30,41]

- *Congenital*: presents at birth and is sometimes known as Milroy's disease
- *Praecox (early)*: develops prior to 35 years of age
- *Tarda*: develops after 35 years of age

Primary lymphedema typically affects more females than males and presents more often in the extremities, more so in the lower than upper extremities. However, it can be seen in other areas of the body as well.[30,41,57,107] If not managed

properly, this type of lymphedema can progress over time and present with skin changes (hyperkeratosis) and increased skin folds and skin creases.[30,41,52,98,102]

Secondary Lymphedema

Most of the patients seen by healthcare practitioners for management of lymphedema have secondary lymphedema.[83] By far, the most common causes of secondary lymphedema are related to the comprehensive management of cancers of the breast, pelvis, and abdomen.[3,10,11,35,40,41,83,84] Secondary lymphedema is classified by the cause of the injury to the lymphatic structures including:

- Surgery
- Inflammation and infection
- Obstruction or fibrosis
- Combined venous-lymphatic dysfunction (chronic venous insufficiency)

Surgical Dissection of Lymph Nodes

Lymph nodes and vessels often are surgically removed (lymphadenectomy) as an aspect of treatment of a primary malignancy or metastatic disease. For example, axillary lymph node dissection is performed in most types of breast cancer surgeries to determine the extent and progression of breast cancer.[12,15,35,49] Likewise, pelvic or inguinal lymph node excision often is necessary for the treatment of pelvic or abdominal cancers.[3,83,84]

Infection and Inflammation

Inflammation of the lymph vessels (*lymphangitis*) or lymph nodes (*lymphadenitis*) and enlargement of lymph nodes (*lymphadenopathy*) can occur as the result of a systemic infection or local trauma. Any of these conditions can cause disruption of lymph circulation.[35,40,41,107]

Obstruction or Fibrosis

Trauma, surgery, and neoplasms can block or impair the lymphatic circulation.[35,41,97] Radiation therapy associated with treatment of malignant tumors also can cause fibrosis of vessels.[3,12]

Combined Venous-Lymphatic Dysfunction

Although not a primary disorder of the lymphatic system, chronic venous insufficiency and varicose veins are associated with venous stasis and accumulation of edema in the extremities.[35,40,55,107] Dependent, peripheral edema occurring with long periods of standing or sitting is a common manifestation of chronic venous dysfunction. Edema decreases if the limb is elevated. Patients often report dull aching or tiredness in the affected extremity.[27,35,40,55,79,107] If the insufficiency is associated with varicose veins, venous distention (bulging) also is notable. When edema persists, the skin becomes less supple over time and takes on a brownish pigmentation.

With time, a continued increase in the lymphatic work load imposed by the venous system causes a combined venous-lymphatic dysfunction. The lymphatic system begins to lose efficiency with the increased workload imposed over time, and a mixed edema results.[107] A venous-lymphatic dysfunction has a mixture of low protein edema from the venous system and a high protein edema from the lymphatic system.

Clinical Manifestations of Lymphatic Disorders

Lymphedema

Location. When lymphedema develops, it is most often apparent in the distal extremities, particularly over the dorsum of the foot or hand.[26,41] The term dependent edema describes the accumulation of fluids in the peripheral aspects of the limbs, particularly when the distal segments are lower than the heart. In contrast, lymphedema can manifest more centrally, for example, in the axilla, groin, or even the trunk.[26,35,40,107] Thorough assessment of the entire limb and regional area is important to define the extent of swelling.

Severity. The severity of lymphedema may be described quantitatively or qualitatively. Lymphedema is described by the severity of changes that occur in skin and subcutaneous tissues. The three categories—pitting, brawny, and weeping edema—are described in Box 25.1. Although all three types reflect a significant degree of lymphedema, they are listed in order of severity, from least severe to most severe.[15,18,35,40,90]

CLINICAL TIP

When skin is interrupted in a patient with lymphedema, it is common to note a seeping of clear, yellow-tinged fluid that is slightly thicker than vascular fluid in consistency. This increased viscosity comes from the high level of protein contained in the fluid transported by the lymphatic system. If the fluid is leaking out of the pores without interruption of the skin, this signals a severe nature to the condition.

BOX 25.1 Severity of Lymphedema

- **Pitting edema.** Pressure on the edematous tissues with the fingertips causes an indentation of the skin that persists for several seconds after the pressure is removed. This reflects significant but short-duration edema with little or no fibrotic changes in skin or subcutaneous tissues.
- **Brawny edema.** Pressure on the edematous areas feels hard with palpation. This reflects a more severe form of interstitial swelling with progressive, fibrotic changes in subcutaneous tissues.
- **Weeping edema.** This represents the most severe and long-duration form of lymphedema. Fluids leak from cuts or sores; wound healing is significantly impaired. Lymphedema of this severity occurs almost exclusively in the lower extremities.

Another common way to define the severity of lymphedema is through staging. Staging refers to the physical condition of the limb only.[52] The stages are described in Box 25.2.[30,52,57,107] Stage 0 or the latency stage might present with the greatest possibility for reducing the onset of worsening lymphedema. This is especially true in the patient with secondary lymphedema from cancer surgery.

Increased Size of the Limb

As the volume of interstitial fluid in the limb increases, so does the size of the limb (weight and girth).[14,41,55,107] Increased volume, in turn, causes tautness of the skin and susceptibility to skin breakdown.[15,35]

Descriptors, such as mild, moderate, and severe, sometimes are based on how much larger the size of the edematous limb is compared to the noninvolved limb.[61] However, there are no standard definitions associated with size and severity.

Sensory Disturbances

Paresthesia (tingling, itching, or numbness) or occasionally a mild, aching pain may be felt, particularly in the fingers or toes. In many instances the condition is painless, and the patient perceives only a sense of heaviness of the limb. Fine finger coordination also may be impaired as the result of the sensory disturbances.[15,41,77,90]

Stiffness and Limited Range of Motion

Range of motion (ROM) decreases in the fingers and wrist or toes and ankle or even in the more proximal joints, leading to decreased functional mobility of the involved segments.[15,69]

BOX 25.2 Stages of Lymphedema

Stage 0—Latency Stage
- No outward swelling noted
- Essentially asymptomatic with occasional reports of heaviness in the extremity
- Despite reduced transport capacity, the body is still able to accommodate the lymphatic load

Stage I—Reversible Stage
- Elevation reduces swelling
- No tissue fibrosis
- Swelling is soft or pitting

Stage II—Spontaneously Irreversible
- Fibrosis of tissue; brawny, hard swelling
- Swelling is no longer pitting
- Positive Stemmer sign
- Frequent infections may occur

Stage III—Lymphostatic Elephantiasis
- Positive Stemmer sign
- Significant increase in limb volume
- Typical skin changes noted (hyperkeratosis, papillomas, deep skin folds)
- Bacterial and fungal infections of the skin and nails more common

Decreased Resistance to Infection

Wound healing is delayed; and frequent infections (e.g., cellulitis) may occur.[41,53,55,107] Early recognition and treatment of cellulitis has shown to be important in reducing further tissue damage.[24,103]

Examination and Evaluation of Lymphatic Function

A patient's history, a systems review, and specific tests and measures provide information to determine impairments and functional limitations that can arise from lymphatic disorders and the presence of lymphedema. Key components in the examination process that are particularly relevant when lymphatic dysfunction is suspected or lymphedema is present are summarized in this section.[16,27,55,69,93,107] Other tests and measurements, such as vital signs, ROM, strength, posture, and sensory, functional, and cardiopulmonary testing, are also appropriate.

History and Systems Review

Note any history of infection, trauma, surgery, or radiation therapy. If a patient has a history of cancer and received chemotherapy, a review of the treatment and duration of the chemotherapy treatment is also important. The onset and duration of lymphedema, delayed wound healing, or previous treatment of lymphedema are pertinent pieces of information. Identify the occupation or daily activities of the patient, and determine if long periods of standing or sitting are required. Specific questioning to determine a pattern to the swelling can also aid in treatment planning.

Examination of Skin Integrity

Visual inspection and palpation of the skin provide information about the integrity of the skin. The location of the edema should be noted. When the limb is in a dependent position, palpate the skin to determine the type and severity of lymphedema and changes in skin and subcutaneous tissues. Describe the thickness and density of the tissue in each area of the limb. Areas of pitting, brawny, or weeping edema should be noted.

CLINICAL TIP

When palpating the skin over lymph nodes, note any tenderness of the nodes (cervical, supraclavicular, inguinal). Tenderness may or may not indicate ongoing infection or serious disease.[36] Evidence of warm, enlarged, tender, painless, or adherent nodes should be reported to the physician.

The presence of wounds or scars and the color and appearance of the skin, which is often shiny and red in the edematous limb, should be noted. Document any papillomas, hyperkeratosis, or darkening of the skin, especially in the

lower extremities. Photographic documentation is convenient in the clinical or home setting and provides visual evidence of changes in skin integrity. If a wound or scar is identified, its size should be noted, as should scar mobility or the presence of inflammation or infection in a wound.

A positive Stemmer sign, an indication of Stage II or III lymphedema, may be identified during palpation (Fig. 25.3). It is considered positive if the skin on the dorsal surface of the fingers or toes cannot be pinched or is difficult to pinch compared with the uninvolved limb.[30,57,82,99,107] A positive Stemmer sign can be indicative of a worsening condition.

FIGURE 25.3 Stemmer sign: Objective test for lymphedema in the extremities. *(From Hetrick[47] p. 283 with permission.)*

Girth Measurements

Circumferential measurements of the involved limb should be taken and compared with the noninvolved limb if the problem is unilateral.[14,77] Identify specific intervals or landmarks at which measurements are taken so measurements during subsequent examinations are reliable. Use of circumferential measurements at anatomical landmarks has been shown to be a valid and reliable method of calculating limb volume.[2,93]

Volumetric Measurements

An alternative method of measuring limb size is to immerse the limb in a tank of water to a predetermined anatomical landmark and measure the volume of water displaced.[14,93] Although this method also has been shown to be valid and reliable, for routine clinical use, it is more cumbersome and less practical than girth measurements.[2,93]

Bioimpedance Measurements

Bioimpedance measurements involve the use of a low-level, alternating electrical current to measure the resistance to the flow through the extracellular fluid in the upper extremities.[25,81,96] The higher the resistance to flow, the more extracellular fluid present. Testing is fairly easy to perform, requiring only placement of skin electrodes.

For any bioimpedance value to be meaningful, initial testing must take place prior to surgery.[65] Testing can then be performed at set intervals throughout the treatment continuum. This affords the opportunity for intervention at an earlier stage in the development of lymphedema. Other factors that affect volume in the body can theoretically affect the bioimpedance reading; therefore, this must be considered.[25,65,81,82,96] There is still much to be learned about bioimpedance testing and how this correlates to lymphedema.

Lymphedema Risk Reduction

If a patient is at risk of developing lymphedema secondary to infection, inflammation, obstruction, surgical removal of lymphatic structures, or chronic venous insufficiency, reducing the risk of lymphedema should be the priority of patient management. In some situations, such as after removal of lymph nodes or vessels, risk-reducing measures may be needed for a lifetime. Even when a patient takes every measure to reduce the risk of edema, it still may develop at some time, particularly after trauma to or surgical removal of lymph vessels. Box 25.3 summarizes precautions and measures to reduce the risk of lymphedema.* The education of patients in the importance of risk eduction has been shown to be effective in lowering lymphedema symptoms.[32,39,65] The effect of an increased body mass index (BMI) has shown mixed effect on the risk of developing lymphedema.[43,45,65,68]

Management of Lymphedema

Background and Rationale

Comprehensive management of lymphedema involves a combination of appropriate medical management and direct therapeutic intervention by a therapist combined with self-management by the patient. Treatment also includes appropriate pharmacological management for infection control and prevention or removal of excessive fluid and proteins.[11,35,40]

Because there is no cure for lymphedema, the main goal of treatment is to minimize the lymphedema as much as possible or return the lymphedema to a latency stage. In addition, the health of the tissue is important. Other goals include reducing risk of infection and softening of fibrotic tissue.[30,107]

The overall objective of management when lymphedema has developed is to improve drainage of obstructed areas and, theoretically, to channel fluids into more centrally located lymph structures that carry the fluid to the venous system. In order to affect the reduction of lymphatic and/or venous edema, the following should be considered.

- Interstitial pressure is increased by external forces. These external forces can be from manual lymphatic drainage or compression therapy. An increased interstitial pressure causes an increased uptake of fluid. There is an increase of lymph production as more fluid enters the lymphatic system as well as an increase resorption of fluid by the venous system.[30,65,107]

*11,15,42,48,57,69,76,80,90,97

BOX 25.3 Precautions, Risk Reduction, and Self-Management of Lymphedema

Reducing the Risk of Lymphedema

- Keep moving. Standing or sitting for long periods of time can cause pooling of fluid in the legs. Sit with both feet on the floor instead of legs crossed.
- When traveling long distances by car, stop periodically, and walk around or support an involved upper extremity on the car's window ledge or seat back.
- Elevate involved limb(s), and perform repetitive pumping exercises frequently during the day.
- Be cautious about performing vigorous, repetitive activities with the involved limb.
- Monitor the weight used with exercise. Increase weight slowly, and assess for feelings of heaviness, throbbing or aching in the limb.
- Carry heavy loads, such as a heavy backpack or shoulder bag, over your uninvolved shoulder.
- If you have lymphedema, wear compressive garments while exercising.
- Wear clothing and jewelry that does not leave a mark or imprint on your skin when removed.
- Monitor diet to maintain an ideal weight, and minimize sodium intake.
- If possible, have blood pressures, needle sticks and blood draws performed in the uninvolved upper extremity or lower extremity.

Skin Care

- Keep the skin clean and supple; use moisturizers, but avoid perfumed lotions.
- Immediately attend to a skin abrasion or cut, an insect bite, a blister, or a burn.
- Protect hands and feet; wear socks or hose, properly fitting shoes, rubber gloves, oven mitts, etc.
- Use protective gloves when in contact with harsh detergents and chemicals.
- Use caution when cutting nails. Push back cuticles instead of trimming.
- Use an electric razor when shaving legs or underarms. If the underarm area is numb, use your eyes to ensure that good skin integrity was maintained.
- Avoid hot baths, whirlpools, and saunas that elevate the body's core temperature.
- Seek immediate medical care if infection is suspected. An infection may present with warmth, redness, tenderness, or rash on the skin. A fever may or may not be present.
- Consult your physician immediately if a new onset of swelling is noted that does not resolve in 1–2 days.

- Elevation can assist fluid return in stage I lymphedema or in venous edema. If elevation produces reduction, then a mild compression therapy (i.e., compression garment) may be indicated.[26,35,52,57,97]
- Dynamic pressure changes within the body can assist lymphatic flow. Pressure changes can be in the form of diaphragmatic breathing or with muscle contractions. Breathing changes intrathoracic pressure and causes an increased uptake of lymph fluid in lymphatic trunks and ducts. Active muscle contractions change pressure in a localized area, enhancing the movement of lymph within lymph vessels. A muscle contraction combined with external forces from a bandage or compression garment can be even more effective in the movement of fluid.[30,57,86,107]

Comprehensive Regimens and Components

A comprehensive approach to the management of lymphedema is referred to in the literature by a variety of terms, including complex lymphedema therapy, complete or complex decongestive therapy (CDT), or decongestive lymphatic therapy.* Treatment typically is divided into two phases. Phase I is the intensive treatment phase; Phase II is the maintenance phase. The goal of Phase I treatment is reduction, whereas the goal of Phase II treatment is long-term management.[15,52,57,107] Therapist-directed care is replaced by patient-directed care as treatment moves from Phase I to Phase II. Box 25.4 summarizes the components of these programs.

Manual lymphatic drainage. Manual lymphatic drainage (MLD) involves slow, very light repetitive stroking and circular massage movements done in a specific sequence with the involved extremity elevated whenever possible.[7,8,19,20,23,56,92,106,107] Proximal congestion in the trunk, groin, buttock, or axilla is cleared first to make room for fluid from the more distal areas. The direction of the massage is toward specific lymph nodes and usually involves distal-to-proximal stroking. Fluid in the involved extremity is then cleared, first in the proximal portion and then in the distal portion of the limb. Because manual lymphatic drainage is extremely labor- and time-intensive,

*7,8,19,20,23,50,62,63,85,91,106,107

BOX 25.4 Components of a Decongestive Lymphatic Therapy Program

Phase I

- Manual lymphatic drainage (MLD)
- Multiple layer compression bandaging
- Skin and nail care
- Exercise

Phase II

- Self-MLD by the patient
- Compression therapy
  - Compression garment during the day
  - Multiple layer bandaging in the evening/night
- Skin and nail care
- Exercise

methods of self-massage are taught to the patient as soon as possible in a treatment program.

Exercise. Active ROM, stretching, and low-intensity resistance exercises are integrated with manual drainage techniques.[5,11,15,19,21,22,67,70,71,107] Exercises are performed while wearing a compressive garment or bandages and in a specific sequence. A low-intensity cardiovascular/pulmonary endurance activity, such as bicycling, often follows ROM and strengthening exercises. Specific exercises and a suggested sequence for the upper and lower extremities, compiled from several sources, are described and illustrated in the last section of this chapter.

Compression therapy. The type of compression used depends on the phase of treatment. During Phase I of treatment, only low-stretch bandages are used, which provide a low resting pressure on a limb but a high working pressure.[30,107] High-stretch sports bandages, such as Ace™ wraps, are not recommended for treating lymphedema.[8,11,15,97] Given that a low-stretch bandage has a low resting pressure, the bandage can be worn during the day and at night. During the active reduction phase of treatment, it is recommended that compression be applied in the form of low-stretch bandaging at all times except for bathing.[30,87,107] Under the low-stretch bandage, nonwoven padding is used and can be combined with foam pads to aid in the softening and reduction of fibrotic tissue (Fig. 25.4).

FIGURE 25.4 Upper extremity multilayer bandaging with padding from the upper arm to the hand.

As a patient moves from Phase I to a maintenance phase of treatment, compression is transitioned from low-stretch bandaging at all times to a compression garment during the day. A compression garment has a high resting pressure and low working pressure.[30,107] Therefore, the use of a garment is not recommended during long periods of inactivity (night rest). The garment should be viewed as a method to maintain limb size during the day, giving a patient a more cosmetic appearance and ease of wearing clothing. During Phase II, it is still recommended that a patient wear the low-stretch bandages at night.[15,87] In summary, the bandages are used for continued limb reduction, and a garment keeps the size of the extremity stable.

Compression garments are made in specific compression categories or classes (Table 25.1).[15,87,107] Patients can most often be fit with a premade garment, but custom garments are available. For patients with lymphedema of the trunk, genital area, or face, custom garments can be fabricated.

FOCUS ON EVIDENCE

Forner-Cordero and co-investigators[31] conducted a study to identify the factors that best predicted response to CDT. A prospective multicenter, controlled cohort study was undertaken with 171 patients with breast cancer-related lymphedema. Following statistical analysis, compliance

TABLE 25.1 Garment Compression Classification

Class of Compression	mm Hg	Indications
Class 1		
	20–30 mm Hg	■ Mild lymphedema ■ Typically used for UE, not LE ■ Patient with fragile skin or the elderly
Class 2		
	30–40 mm Hg	■ Most commonly used for stage II UE lymphedema ■ Minimum compression for LE lymphedema
Class 3		
	40–50 mm Hg	■ Rarely used for UE lymphedema ■ Typically for stage II LE lymphedema ■ For patients with LE lymphedema involved in high-intensity, repetitive activities
Class 4		
	50–60 mm Hg	■ Rarely used ■ Only for LE lymphedema ■ Only available as custom-made garments

LE, Lower extremity; *UE,* upper extremity

with bandaging was one of the most predictive indicators of response to CDT. The length of time from the development of the lymphedema to treatment did not predict response to treatment in this study. However, there was an inverse correlation between severity of lymphedema and response to CDT.

Another form of compression therapy is a pneumatic compression pump.[66] The use of compression pumps, however, has been controversial over the years. Studies have shown that a compression pump can be a positive adjuvant therapy to CDT but should not be the sole therapeutic modality in the treatment of lymphedema.[64,69,91] The main criticism of pump compression is the pumping of fluid in a distal to proximal sequence, which is opposite of the principles of MLD. There is also the potential to cause swelling in adjoining areas of the body, mainly the genital area, for a patient with lower extremity edema.[9] When used correctly, a pneumatic compression pump can be a positive therapeutic intervention, especially in severe or refractory cases. More advanced pumps are now available that follow the sequence of MLD more closely, treating the trunk first and then the extremity in a proximal-to-distal sequence.

Skin care and hygiene. Lymphedema predisposes the patient to skin breakdown, infection, and delayed wound healing. Meticulous attention to skin care and protection of the edematous limb are essential elements of self-management of lymphedema.[11,20,69,97]

Use of Community Resources

A valuable resource for patients and healthcare professionals is the National Lymphedema Network (www.lymphnet.org). This nonprofit organization provides education and guidance about lymphedema. Other resources include the Peninsula Medical, Inc. website (www.lymphedema.org) and Lymph Notes (www.lymphnotes.com).

Breast Cancer-Related Lymphatic Dysfunction

Background

Breast cancer-related dysfunction of the lymphatic system and subsequent lymphedema of the upper extremity is a somewhat common and potentially serious complication of the treatment for breast cancer. The incidence of lymphedema following surgical intervention for breast cancer varies widely in the literature.[*] Much of the variation is related to how lymphedema is diagnosed and defined. Some studies quantify lymphedema in the upper extremity only, whereas other studies define breast cancer-related lymphedema as including the remaining breast or chest wall and trunk. Other factors contributing to the variation in incidence of lymphedema reported are the use of sentinel lymph node biopsy versus axillary dissection.

Current treatment for breast cancer involves a multimodality approach. Surgery, chemotherapy or hormonal therapy, and radiation may be employed. The type of surgery performed, the extent of axillary nodes removed, and the use of radiation all affect the incidence of lymphedema in a patient with breast cancer.

Axillary dissection and removal of lymph nodes interrupt and slow the circulation of lymph, which in turn can lead to lymphedema.[5,12,15,29] Radiation therapy can cause fibrosis of tissues in the area of the axilla, which obstructs the lymphatic vessels and contributes to pooling of lymph in the arm and hand.[5,12,15,29] The extent of the axillary dissection and exposure to radiation is associated with the degree of risk for lymphedema to develop. In addition, shoulder motion can become impaired as the result of incisional pain, delayed wound healing, and skin ulcerations (associated with radiation therapy), and postoperative weakness of the muscles of the shoulder girdle.[15,69]

A comprehensive approach to postoperative management that emphasizes patient education and includes therapeutic exercise and other direct interventions to reduce the risk of or to treat lymphedema and other impairments or functional limitations are key to successful outcomes.[3,6,11,15,69,80]

As with most cancers, the diagnosis of breast cancer and the ensuing treatments have an enormous emotional impact on patients and their families.[15,90] The advent of breast cancer-related lymphedema not only has an impact on a breast cancer survivor's physical function but is known to have a significantly adverse effect on health-related quality of life, making prevention—and if it develops, aggressive treatment—of lymphedema high priorities for management.[59,78,84]

Surgical Procedures

Surgical treatment of breast cancer falls into two broad categories—mastectomy and breast-conserving surgery, both of which are coupled with either sentinel lymph node biopsy and/or axillary lymph node dissection. Differences in surgical procedures are related to the extent of removal of breast tissue and surrounding or underlying soft tissues.[1,7,46] A course of radiation therapy routinely follows surgery to decrease the risk of regional recurrence of the disease in patients who undergo breast-conserving surgeries. Chemotherapy also may be initiated preoperatively or postoperatively to reduce the risk of systemic spread of the disease.

Mastectomy

Mastectomy involves removing the entire breast. In addition, a mastectomy may involve removing the fascia over the chest muscle. With late-stage, invasive disease, a radical mastectomy in which the pectoralis muscles also are excised may be required, leading to significant muscle weakness and impaired shoulder function.

[*] 2,34,44,58,68,78,88,94

Breast-Conserving Surgery

Options for resecting the tumor and preserving a portion of the breast include lumpectomy, which involves excision of the mass and a margin of healthy surrounding breast tissue, or segmental mastectomy (also known as quadrectomy), which is excision of the affected quadrant of the breast. Rather than mastectomy, these procedures are being used increasingly in combination with adjuvant therapy for patients with stage I or II tumors.[1,46]

There are now multiple randomized clinical trials that show that the 10- to 20-year survival rate for patients with stage I or II disease who underwent breast-conserving surgery combined with radiation therapy is equivalent to that achieved by patients who underwent mastectomy alone or mastectomy with adjuvant therapy.[1]

Patients who undergo breast-conserving procedures without removal of lymph nodes are still at risk for developing postoperative lymphedema and impaired shoulder mobility because of potential complications from radiation therapy and biopsy of at least one lymph node.[15,69]

Evaluation of Lymph Node Involvement

In the past, axillary lymph node dissection was a standard part of mastectomy and breast-conserving surgery.[1,46] A minimum of a level I and, most often, a level II axillary dissection was performed. Currently, the sentinel lymph node biopsy is used to determine disease presence in the axilla, therefore sparing removal of uninvolved lymph nodes when possible.

Sentinel lymph node biopsy is used with patients who present with no clinically evident disease in the axilla. With a radiosensitive substance, the specific lymph nodes that a tumor first drains into are identified and removed.[107] If clear, research has shown that an axillary dissection is not required and risk of disease in further lymph node is low.[13] If the sentinel lymph nodes show signs of disease, then axillary lymph nodes are removed. More extensive dissection for metastatic or regional bulky disease removes the nodes under the pectoralis minor muscle or around the clavicle.

Radiation Therapy

Radiation therapy is rarely used as the sole treatment intervention for breast cancer. Most often radiation is employed following breast-conserving surgery as an adjuvant treatment modality.[58] Radiation delivered to the whole breast is standard following breast-conserving therapy. The parameters of the radiation field include the tissue from the clavicle to 2 cm below the inframammary line and from the mid-sternum to the mid-axillary line laterally.[75] Radiation typically is delivered over a course of 5 to 6 weeks with effects not felt until 2 to 3 weeks into treatment. In patients who undergo mastectomy, depending on the disease presentation, radiation may be offered. The radiation field usually includes the surgical scar, chest wall, and sometimes the regional lymphatics.

Radiation causes changes in most types of soft tissue and can be categorized as having acute or chronic effects.[58] Acute effects of radiation include acute dermatitis or skin burn. Chronic or late effects of radiation involve tissue fibrosis and changes to the lymphatic vessel function. It is important to note that the chronic effects of radiation can extend for many years following the end of the radiation therapy.[95]

Impairments and Complications Related to Breast Cancer Treatment

The following impairments and complications may occur in association with treatment of breast cancer. Many of these problems are interrelated and must be considered jointly when a comprehensive postoperative rehabilitation program is developed for the patient.*

Postoperative Pain

Incisional pain. A transverse incision across the chest wall is made to remove the breast tissue and underlying fascia on the chest musculature. The incision extends into the axilla for lymph node dissection. Postoperatively, the sutured skin over the breast area may feel tight along the incision. Movement of the arm pulls on the incision and is uncomfortable for the patient. Healing of the incision may be delayed as the result of radiation therapy. Delayed wound healing, in turn, prolongs pain in the area of the incision.

Posterior cervical and shoulder girdle pain. Pain and muscle spasm may occur in the neck and shoulder region as a result of muscle guarding. The levator scapulae, teres major and minor, and infraspinatus often are tender to palpation and can restrict active shoulder motion. Decreased use of the involved upper extremity after surgery due to pain sets the stage for the patient to develop a chronic frozen shoulder and increases the likelihood of lymphedema in the hand and arm.

Postoperative Vascular and Pulmonary Complications

Decreased activity and extended time in bed increase venous stasis and the risk of DVT. Risk of pulmonary complications, such as pneumonia, also is higher because of the patient's reduced activity level. Incisional pain may make the patient reluctant to cough or breathe deeply, both of which are necessary postoperatively to keep the airways clear of fluid accumulation.

Lymphedema

As noted previously, patients who undergo any level of lymph node dissection or whose treatment regimen includes radiation therapy remain at risk throughout life for developing ipsilateral upper extremity lymphedema.[5,15,69,107] Lymphedema can occur almost immediately after lymph node dissection, during the course of radiation therapy, or many months or even years after treatment has been completed. It is typically evident in the hand and arm but occasionally develops in the

*4,6,10,12,15,33,37,38,49,69,77,101,104,107

anterior chest wall, remaining breast, or back area.[5,12,15,69,77,107] In turn, lymphedema leads to impaired upper extremity function, poor cosmesis, and emotional distress.[15,33,77,90]

Chest Wall Adhesions

Restrictive scarring of underlying tissues on the chest wall can develop as the result of surgery, radiation fibrosis, or wound infection. Chest wall adhesions can lead to increased risk of postoperative pulmonary complications, restricted mobility of the shoulder, postural asymmetry and dysfunction, and discomfort in the neck, shoulder girdle, and upper back.

Decreased Shoulder Mobility

It is well documented that patients may experience temporary and sometimes long-term loss of shoulder mobility after surgery or radiation therapy for treatment of breast cancer.[5,38,49,59,69,80,89,100,101,104] Factors contributing to impaired shoulder mobility after surgery are listed in Box 25.5.

One of these factors, lymphatic cording, or axillary web syndrome (AWS), is a fairly new term for a condition that is quite common in patients treated for breast cancer. The incidence varies in the literature, and onset can be as soon as one week following surgery to years later.[15,72] AWS is thought to be caused by the interruption of the lymphatics in the axilla following a sentinel lymph node biopsy or axillary dissection, with resulting thrombosis of lymphatic channels.[54,72] Visually, AWS can be described as a web of skin covering "cords" that are more visible with shoulder abduction (Fig. 25.5).[54,72] These cords can extend from the axilla distally to the antecubital space and into the forearm. Lymphatic cording can be painful and limit movement of the entire upper extremity.[15,54] Treatment for AWS typically includes gentle stretching and soft tissue release of the lymphatic cord.[54]

BOX 25.5 Factors Contributing to Impaired Shoulder Mobility After Breast Cancer Surgery

- Incisional pain immediately after surgery or associated with delayed wound healing
- Muscle guarding and tenderness of the shoulder and posterior cervical musculature
- Need for protected shoulder ROM until the surgical drain is removed
- Fibrosis of soft tissues in the axillary region due to adjuvant radiation therapy
- Adherence of scar tissue to the chest wall, causing adhesions
- Temporary or permanent weakness of the muscles of the shoulder girdle
- Rounded shoulders and kyphotic or scoliotic trunk posture associated with age or incisional pain
- A feeling of heaviness of the upper extremity due to lymphedema
- Decreased use of the hand and arm for functional activities
- Axillary Web Syndrome

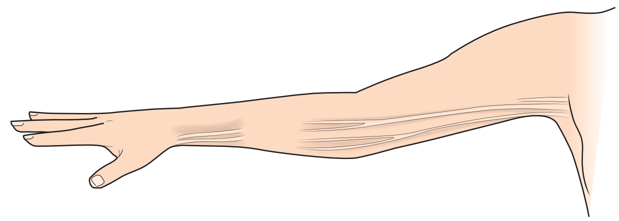

FIGURE 25.5 Axillary Web Syndrome.

Weakness of the Involved Upper Extremity

Shoulder weakness. If the long thoracic nerve is traumatized during axillary dissection and removal of lymph nodes, this results in weakness of the serratus anterior and compromised stability of the scapula, limiting active flexion and abduction of the arm. Faulty shoulder mechanics and use of substitute motions with the upper trapezius and levator scapulae during overhead reaching can cause subacromial impingement and shoulder pain. Shoulder impingement, in turn, can be a precursor to a frozen shoulder. If the pectoralis muscles were disturbed, which occurs with a radical mastectomy for advanced disease, weakness is evident in horizontal adduction.

Decreased grip strength. Grip strength is often diminished as the result of lymphedema and secondary stiffness of the fingers.

Postural Malalignment

The patient may sit or stand with rounded shoulders and kyphosis because of pain, skin tightness, or psychological reasons. An increase in thoracic kyphosis associated with aging is commonly seen in the older patient.[37] This contributes to faulty shoulder mechanics and eventually restricts active use of the involved upper extremity. Asymmetry of the trunk and abnormal scapular alignment may occur as the result of a subtle lateral weight shift, particularly in a large-breasted woman.

Fatigue and Decreased Endurance

Patients undergoing radiation therapy or chemotherapy often experience debilitating fatigue.[1,35,59] Fatigue has been reported by more than 60% of patients undergoing cancer treatment.[17,73] Anemia may develop as a result of chemotherapy. Nutritional intake and subsequent energy stores may be diminished, particularly if a patient is experiencing nausea for several days after a cycle of chemotherapy.

Fatigue also is associated with depression. As a result, exercise tolerance and endurance during functional activities are markedly reduced. Multiple studies support the initiation of an exercise program as one of the most effective methods to combat fatigue related to cancer treatment.[17,73,74]

Psychological Considerations

A patient undergoing treatment for breast cancer experiences a wide range of emotional and social issues.[90] The needs

and concerns of both the patient and the family must be considered. The patient and family members must cope with the potentially life-threatening nature of the disease and a difficult treatment regimen. It is common for a patient to feel anxiety, agitation, anger, depression, a sense of loss, and significant mood swings during treatment of and recovery from breast cancer.

In addition to the obvious physical disfigurement and altered body image associated with mastectomy, medications such as immunosuppressants and corticosteroids can affect the emotional state of a patient. Psychological manifestations affect physical well-being and can contribute to general fatigue, the patient's perception of functional disability, and motivation during treatment.

Guidelines for Management Following Breast Cancer Surgery

Guidelines for postoperative management for the patient who has undergone a mastectomy or breast-conserving surgery and who may currently be receiving adjuvant therapy are outlined in Box 25.6. The guidelines identify therapeutic interventions for common impairments during the early postoperative period and those that could develop at a later time.

BOX 25.6 MANAGEMENT GUIDELINES—
After Surgery for Breast Cancer

Potential Postoperative Structural and Functional Impairments

- Pulmonary and circulatory complications
- Lymphedema
- Restricted mobility of the upper extremity
- Postural malalignment
- Weakness and decreased functional use of the upper extremity
- Fatigue and decreased endurance for functional activities
- Emotional and social adjustments

Plan of Care	Interventions
1. Prepare the patient for postoperative self-management.	1. Interdisciplinary patient education involving all aspects of potential impairments and functional limitations Self-management activities and preparation for participation in a home program as indicated per surgical protocol
2. Prevent postoperative pulmonary complications and thromboemboli.	2. Pre- or postoperative instruction in deep breathing, emphasizing maximal inspirations and effective coughing Active ankle exercises (calf-pumping exercises)
3. Minimize postoperative swelling.	3. Elevation of the involved upper extremity on pillows (about 30°) while the patient is in bed or sitting in a chair Squeeze a ball on the operative side to produce a pumping action in the muscles Early ROM exercises **PRECAUTION:** Avoid static, dependent positioning of the arm.
4. Identify and treat early signs of lymphedema should it develop.	4. Manual lymphatic drainage massage Daily regimen of exercises to include flexibility and strengthening exercises Compression therapy (low-stretch compression bandaging and/or compression garments) Adherence to lymphedema risk reducing behaviors (see Box 25.3)

Continued

BOX 25.6 MANAGEMENT GUIDELINES—
After Surgery for Breast Cancer—cont'd

Plan of Care	Interventions
5. Prevent postural deformities.	5. Posture-awareness training; encourage the patient to assume an erect posture when sitting or standing to minimize a rounded shoulder posture Posture exercises with an emphasis on scapular retraction exercises
6. Prevent muscle tension and guarding in cervical musculature.	6. Active ROM of the cervical spine to promote relaxation Shoulder shrugging and shoulder circle exercises Gentle massage to cervical musculature
7. Prevent restricted mobility of the upper extremity.	7. Shoulder motion performed within protected ROM, usually no more than 90° of elevation of the arm until after removal of drains No repetitive motion until drains removed
8. Regain strength and functional use of the involved extremity.	8. Initiate resistance exercise following full postoperative healing. Consider exercise parameters if patient is at risk for lymphedema or has lingering weakness in the involved extremity
9. Improve exercise tolerance and sense of well-being; reduce fatigue.	9. Graded, low-intensity aerobic exercise such as walking or cycling
10. Provide information about resources for patient and family support and ongoing patient education.	10. Resources: American Cancer Society for family support and ongoing patient education (www.cancer.org); National Breast Cancer Coalition (www.nobreastcancer.org); National Lymphedema Network (www.lymphnet.org)

PRECAUTIONS: Observe the incision and sutures carefully during exercises. Avoid any undue tension on the incision or blanching of the scar during shoulder ROM. Avoid exercises with the involved arm in a dependent position. Progress graded exercise program slowly, particularly if the patient is receiving adjuvant therapy. Consider other adjuvant therapies when designing an exercise program.

NOTE: The guidelines outlined in Box 25.6 also can be modified to prevent or manage problems that can develop in the trunk and lower extremities after surgery for abdominal or pelvic cancers and accompanying inguinal lymph node dissection.

Special Considerations

Patient education. The length of an in-hospital stay following surgery for breast cancer is short. Ideally, intervention by the therapist is initiated preoperatively with an emphasis on patient education for reducing the risk of postoperative complications and impairments, including pulmonary complications, thromboemboli, lymphedema, and loss of shoulder mobility. Recommendations for reducing the risk of lymphedema or for self-management if it develops is reviewed with the patient (see Box 25.3). Following surgery, once the drains are removed, an exercise program can then be individualized based on a patient's surgical procedure and anticipated adjuvant treatments.

Exercise. The postoperative exercise program focuses on three main areas: improving shoulder function, regaining an overall level of fitness, and reducing the risk of or managing lymphedema. Early, but protected, assisted or active ROM of the shoulder is the key to restoring shoulder mobility. Postoperative risks that contribute to restricted shoulder mobility were summarized previously (see Box 25.5).[1,15,46,69,71] These risks are highest during the early postoperative period until drains have been removed and the incision has healed.

CLINICAL TIP

Radiation therapy to the axillary and breast areas can delay wound healing beyond the typical 3- to 4-week period.[1,46] Even after initial healing of the incision, the scar has a tendency to contract and can become adherent to underlying tissues,

which, in turn, can restrict shoulder motion. Because radiation changes can occur months following treatment, educating the patient to continue with ROM and flexibility exercises should be encouraged. Deep-breathing exercises should also be performed regularly if the chest wall was included in the radiation field.[95]

Although strengthening exercises and aerobic conditioning are important for upper extremity function and total body fitness, considerations should be taken in an exercise program. Programming considerations may include the type of chemotherapy given and the specific side effects of the drugs. For example, some chemotherapy can cause peripheral neuropathy, proximal muscle weakness, and differing fatigue patterns.[51,73] Exercises must be progressed gradually, excessive fatigue must be avoided, and energy conservation must be emphasized. Exercise precautions for a patient undergoing treatment are noted in Box 25.7.[5,15,59,71,73,80]

Early intervention for reducing the risk of lymphedema and upper extremity mobility impairments is often advocated by therapists and suggested in descriptive articles in the literature. However, patients often are not referred for postoperative rehabilitation until after impairments and functional limitations have developed. This may be due to concerns raised in the literature[29] that early postoperative ROM could delay wound healing or that exercises, if performed too vigorously, could initiate or exacerbate lymphedema. In addition, few studies have rigorously investigated the efficacy of specific interventions or rehabilitation protocols.[69,100] A recent review of the literature on exercise and cancer-related lymphedema revealed, however, that exercise neither worsened preexisting lymphedema nor was associated with a significant increase in the occurrence of lymphedema.[5]

BOX 25.7 Exercise Precautions During Treatment of Breast Cancer

- Exercise only at a moderate level and never to the point that the affected arm aches, throbs, or feels heavy during or after exercise, even if there is no evidence of lymphedema.
- Adjust the timing of exercise during cycles of radiation therapy or chemotherapy. With some chemotherapy medications, a patient can develop cardiac arrhythmia or cardiomyopathy.[51]
- Avoid exercising 1 to 2 hr before blood is drawn.
- Gradually return to a regular pattern of exercise and recreational activities based on the fitness level prior to diagnosis and specific side effects of treatment.
- Be aware of blood counts, including white blood cell count and hemoglobin and platelet counts when designing exercise programs.

From the information available in the literature, the following recommendations for exercise are made.*

- Integrate ROM, flexibility, and strengthening exercises into a patient's comprehensive plan of care.
- Implement posture-awareness training and exercise early in a postoperative program to prevent postural malalignment and muscle imbalance, especially following mastectomy.
- Include moderate-intensity aerobic conditioning exercises to improve fitness and quality of life and to reduce chemotherapy-related fatigue.
- Progress all forms of exercise gradually, and teach the patients individualized exercise parameters based on specific surgical interventions and adjuvant therapies.

Community resources. Reach to Recovery is a one-to-one patient education program sponsored by the American Cancer Society (www.cancer.org). Representatives of this program, most of whom are breast cancer survivors, provide emotional support to the patient and family, as well as current information on breast prostheses and reconstructive surgery. The National Lymphedema Network (www.lymphnet.org) is another valuable source of information for patients at risk for or who have developed lymphedema.

Exercises for the Management of Lymphedema

Background and Rationale

As noted previously in this chapter, exercise is just one aspect of a decongestive lymphatic therapy program. The rationale for including exercise in the comprehensive treatment of patients with upper or lower extremity lymphedema is to move and drain lymph fluid to reduce the edema and to improve the functional use of the involved limb or limbs. Principles on which exercises for lymphatic drainage are based are summarized in Box 25.8.[5,70,107]

The exercises employed in lymph drainage regimens cover a wide spectrum of therapeutic exercise interventions, specifically deep breathing, relaxation, flexibility, strengthening, cardiovascular conditioning exercises, and a sequence of lymphatic drainage exercises as well. Exercise regimens have been described in an extensive number of publications.†

No particular combination or sequence of exercises has been shown to be superior to another. Although a critical review of the literature a decade ago[62] indicated that the effectiveness of exercise regimens for lymph drainage was based primarily on clinical observations and opinions of experienced practitioners or case reports, there is now an emerging body of evidence documenting the efficacy of specific components of these programs.[5,50,67,69,91]

BOX 25.8 Exercises for Lymphatic Drainage: Principles and Rationale

- Contraction of muscles pumps fluids by direct compression of the collecting lymphatic vessels.
- Exercise reduces soft tissue and joint hypomobility that can contribute to static positioning and lead to lymphostasis.
- Exercise strengthens and prevents atrophy of muscles of the limbs, which improves the efficiency of the lymphatic pump.
- Exercise increases heart rate and arterial pulsations, which in turn contribute to lymph flow.
- Exercise should be sequenced to clear the central lymphatic reservoirs before the peripheral areas.
- Wearing a compression sleeve or compression bandaging during exercises enhances lymph flow and protein resorption more efficiently than exercising without bandages.

Components of Exercise Regimens for Management of Lymphedema

Deep Breathing and Relaxation Exercises

- Deep breathing is interwoven throughout exercise regimens for the management of lymphedema. It has been suggested that the use of abdominal-diaphragmatic breathing assists in the movement of lymphatic fluid as the diaphragm descends during a deep inspiration and the abdominals contract during a controlled, maximum expiration.[15] Changes in intra-abdominal and intrathoracic pressures create a gentle, continual pumping action that moves fluids in the central lymphatic vessels, which run superiorly in the chest cavity and drain into the venous system in the neck (see Fig. 25.1).
- Progressive, total body relaxation exercises[28] (described in Chapter 4) are performed at the beginning of each exercise session to decrease muscle tension, which may contribute to restricted mobility and lymph congestion.[15,19,22,107] Deep breathing is an integral component of the sequence of relaxation exercises.

Flexibility Exercises

Gentle, self-stretching exercises are used to minimize soft tissue and joint hypomobility, particularly in proximal areas of the body that may contribute to static postures and lymph congestion.

Strengthening and Muscular Endurance Exercises

Both isometric and dynamic exercises using self-resistance, elastic resistance, and weights or weight machines are appropriate if done against light resistance (initially, 1 to 2 lb) and by progressing resistance and repetitions gradually. Regardless of whether lymphedema has developed, it is important to monitor the circumferential size and the skin texture of the involved limb closely to determine whether an appropriate intensity of exercise has been established. Emphasis is placed on improving endurance and strength of central and peripheral muscle groups that enhance an erect posture and minimize fatigue in muscles that contribute to the efficiency of the lymphatic pump mechanism.

Cardiovascular Conditioning Exercises

Activities such as upper extremity ergometry, swimming, cycling, and walking increase circulation and stimulate lymphatic flow.[15] Thirty minutes of aerobic endurance exercises complement lymph drainage exercises. Conditioning exercises are done at low-intensity (at 40% to 50% of the target heart rate) when lymphedema is present and at higher intensities (as high as an 80% level) when the lymphedema has been reduced and exercise is otherwise safe.[15,70]

FOCUS ON EVIDENCE

In a randomized, controlled study by Schmitz and associates,[86] weight lifting was studied in a group of 141 breast cancer survivors with stable upper extremity lymphedema over a 1-year period. The exercise intervention consisted of progressive weight lifting twice a week and the use of compression sleeve during exercise. The authors of the investigation hypothesized that controlled resistance training could improve the functional ability of the affected arm to withstand the insults of daily living. Women in the study ranged from 1 to 15 years following diagnosis.

The intervention program included cardiovascular as well as resistance exercise in a controlled and supervised setting. Exercises were advanced gradually. Results of the study demonstrated that a program of weight lifting did not adversely affect lymphedema in the study participants. Additionally, the results showed that when compared with the control group, women in the intervention (weight-lifting) group reported fewer complaints about their affected arm and hand and had increased overall muscle strength and fewer lymphedema exacerbations following completion of the study.

Lymphatic Drainage Exercises

Lymphatic drainage exercises, often referred to as pumping exercises, move fluids through lymphatic channels. Active, repetitive ROM exercises are performed throughout each session. The exercises follow a specific sequence to move lymph away from congested areas.[15,19,21,22,107] It is similar to the sequence of massage applied during manual lymph drainage.[56,92] In general, the exercises first focus on proximal areas of the body to clear central collecting vessels and then involve distal muscle groups to begin to move peripheral edema in a centripetal direction to the central lymph vessels. The affected upper or lower extremity or extremities are held in an elevated position during many of the exercises. Static, dependent postures are avoided. Self-massage also is interspersed throughout the exercise sequence to further enhance drainage. These exercises also maintain mobility of the involved limbs.

Guidelines for Lymphatic Drainage Exercises

The patient should follow these guidelines when performing a sequence of lymphatic drainage exercises. These guidelines apply to management of upper or lower extremity lymphedema and reflect the combined opinions of several authors and experts in the field.[15,19–21,70,107]

Preparation for Lymphatic Drainage Exercises

- Set aside approximately 20 to 30 minutes for each exercise session.
- Perform exercises twice daily every day.
- Have needed equipment at hand, such as a foam roll, wedge, or exercise wand.

During Lymphatic Drainage Exercises

- Wear compression bandages or a customized compression garment if the patient has lymphedema.
- Precede lymphatic drainage exercises with total body relaxation activities.
- Follow a specified order of exercises.
- Perform active, repetitive movements slowly, about 1 to 2 seconds per repetition.
- Elevate the involved limb above the heart during distal pumping exercises.
- Combine deep-breathing exercises with active movements of the head, neck, trunk, and limbs.
- Initially, perform a low number of repetitions. Increase repetitions gradually to avoid excessive fatigue.
- Do not exercise to the point at which the edematous limb aches.
- Incorporate self-massage into the exercise sequence to further enhance lymph drainage.
- Maintain good posture during exercises.
- When strengthening exercises are added to the lymph drainage sequence, use light resistance and avoid excessive muscle fatigue.

After Lymphatic Drainage Exercises

- If possible, rest with the involved extremity elevated for 30 minutes.
- Set aside time several times per week for low-intensity aerobic exercise activities, such as walking or bicycling for 30 minutes.
- Carefully check for signs of redness or increased swelling or reports of aching or throbbing in the edematous limb, any of which could indicate that the level of exercise was excessive.

Selected Exercises for Lymphatic Drainage: Upper and Lower Extremity Sequences

The selection and sequences of exercises described in this section and summarized in Box 25.9 are designed to assist in the drainage of upper or lower extremity lymphedema. Many of the individual exercises suggested in lymphedema protocols, such as ROM of the cervical spine and some of the shoulder girdle or upper extremity exercises, are not exclusively used for lymph drainage. They also are used to improve mobility and strength. Several of the exercises highlighted in this section already have been described in previous chapters in this

BOX 25.9 Sequence of Selected Exercises for Management of Upper or Lower Extremity Lymphedema

Exercises Common to Upper and Lower Extremity Regimens

NOTE: Start an upper or lower extremity regimen with these exercises.

- Deep breathing and total body relaxation exercises
- Posterior pelvic tilts and partial curl-ups
- Cervical ROM
- Bilateral scapular movements

Upper Extremity Exercises

- Active circumduction with the involved arm elevated while lying supine
- Bilateral active movements of the arms while lying supine or on a foam roll
- Bilateral hand press while lying supine or sitting
- Shoulder stretches (with wand, doorway, or towel) while standing
- Active elbow, forearm, wrist, and finger exercises of the involved arm
- Bilateral horizontal abduction and adduction of the shoulders

Lower Extremity Exercises

- Alternate knee to chest exercises
- Bilateral knees to chest
- Gluteal setting and posterior pelvic tilts
- Single knee to chest with the involved lower extremity
- External rotation of the hips while lying supine with both legs elevated and resting on a wedge or wall
- Active knee flexion of the involved lower extremity while lying supine
- Active plantarflexion and dorsiflexion and circumduction of the ankles while lying supine with lower extremities elevated

Continued

BOX 25.9 Sequence of Selected Exercises for Management of Upper or Lower Extremity Lymphedema—cont'd

- Overhead wall press while standing
- Finger exercises
- Partial curl-ups
- Rest with involved upper extremity elevated
- Active hip and knee flexion with legs externally rotated and elevated against a wall
- Active cycling and scissoring movements with legs elevated
- Bilateral knee to chest exercises, followed by partial curl-ups
- Rest with lower extremities elevated

text. Only those exercises or variations of exercises that are somewhat unique or not previously addressed are described or illustrated in this section.

Sequence of Exercises

- Total body relaxation exercises are implemented prior to lymphatic drainage exercises.
- Exercises for lymphatic drainage should follow a particular sequence to assist lymph flow. The central and proximal lymphatic vessels, such as the abdominal, inguinal, and cervical nodes (see Fig. 25.1), are cleared first with trunk, pelvic, hip, and cervical exercises. Then, for the most part, exercises proceed distally from shoulders to fingers or from hips to toes. If lymph nodes have been surgically removed (e.g., with a unilateral axillary node dissection for breast cancer or a bilateral inguinal node dissection for cancers of the abdominal or pelvic organs), lymph must be channeled to the remaining nodes in the body.

NOTE: Because no single sequence of exercises has been shown to be more effective than another, the upper and lower extremity sequences of exercises outlined in this section do not reflect the exercises included in any one specific protocol. Rather, the exercise sequences are based on the recommendations of several authors.[15,19–21,50,67,69,70,91,107] Sequences of exercises for upper or lower extremity lymphedema are summarized in the remaining portion of this chapter. Therapists are encouraged to modify or add other exercises to the sequences in this chapter as they see fit to meet the individual needs of their patients.

Exercises Common to Upper and Lower Extremity Sequences

These initial exercises should be included in programs for unilateral or bilateral upper or lower extremity lymphedema. They are designed to help the patient relax and then to clear the central channels and nodes.

- ***Total body relaxation***
  - Have the patient assume a comfortable supine position and begin deep breathing. Then isometrically contract and relax the muscles of the lower trunk (abdominals and erector spinae), followed by the hips, lower legs, feet, and toes.
  - Then contract and relax the muscles of the upper back, shoulders, upper arms, forearms, wrist, and fingers.
  - Finally, contract and relax the muscles of the neck and face.
  - Relax the whole body for at least 1 minute.
  - Perform diaphragmatic breathing throughout the entire sequence. Avoid breath-holding and Valsalva's maneuver.
- ***Posterior pelvic tilts and partial curl-ups***
  - Perform these exercises with hips and knees flexed, in the supine position.
- ***Unilateral knee-to-chest movements.*** These exercises are designed to target the inguinal nodes. This is important even for upper extremity lymphedema
  - In the supine position, flex one hip and knee and grasp the lower leg. Pull the knee to the chest. Gently press or bounce the thigh against the abdomen and chest about 15 times.
  - Repeat the procedure with the opposite lower extremity.
  - If lymphedema is present in only one lower extremity, initiate the knee-to-chest exercises with the uninvolved lower extremity.
- ***Cervical ROM.*** Perform each motion for a count of five for five repetitions.
  - Rotation
  - Lateral flexion
- ***Scapular exercises.*** Perform exercise for a count of five for five repetitions.
  - Active elevation and depression (shoulder shrugs)
  - Active shoulder rolls
  - Active scapular retraction and protraction. With arms at sides and elbows flexed, bilaterally retract the scapulae, pointing elbows posteriorly and medially. Then protract the scapulae.

CLINICAL TIP

Be sure to shrug the shoulders as high as possible and then actively pull down the shoulders (depress the scapulae) as far as possible.

Exercises Specifically for Upper Extremity Lymphedema Clearance

The following sequence of exercises is performed after the general, total body exercises just described. The exercises, which are performed in a proximal-to-distal sequence, are done specifically for upper extremity lymph clearance.

CLINICAL TIP

Periodically during the exercise sequence, have the patient perform self-massage to the axillary node area of the uninvolved side proceeding from the axilla to the chest.

- ***Active circumduction of the arm (Fig. 25.6).*** While lying supine, flex the involved arm to 90° (reach toward the ceiling) and perform active circular movements of the arm about 6 to 12 in. in diameter. Do this clockwise and counterclockwise, five repetitions in each direction.

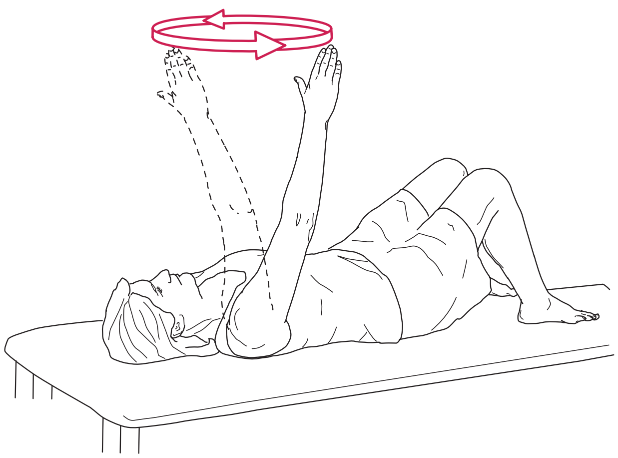

FIGURE 25.6 Active circumduction of the edematous extremity.

PRECAUTION: Avoid pendular motions or circumduction of the edematous upper extremity with the arm in a dependent position.

- ***Exercises on a foam roll (Fig. 25.7).*** While lying supine on a firm foam roll (approximately 6 in. in diameter), perform horizontal abduction and adduction, as well as flexion and extension of the shoulder. These movements target congested axillary nodes and are done unilaterally. For home exercises, if special equipment such as an Ethyfoam® roller is not available, have the patient perform these exercises on a foam pool "noodle." Although the diameter is smaller, a towel or folded sheet can be wrapped around the foam "noodle" to increase the diameter of the roll.

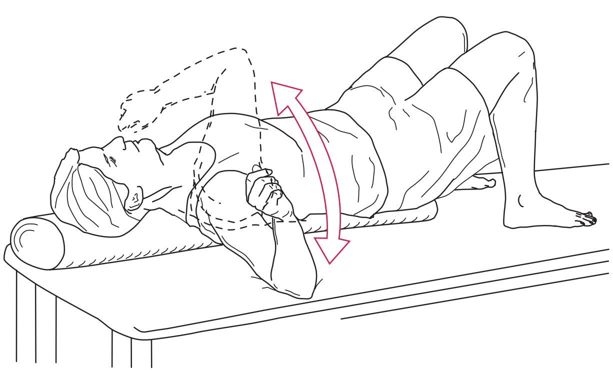

FIGURE 25.7 Active shoulder exercises while lying on a firm, foam roll.

- ***Bilateral hand press.*** With arms elevated to shoulder level or higher and with the elbows flexed, place the palms of the hands together in front of the chest or head. Press the palms together (for an isometric contraction of the pectoralis major muscles) while breathing in for a count of five. Relax, and then repeat as many as five times.
- ***Wand exercise, doorway or corner stretch, and towel stretch.*** Incorporate several exercises to increase shoulder mobility and to decrease congestion and assist lymph flow in the upper extremity. Hold the position of stretch for several seconds with each repetition. These exercises have been described and are illustrated in Chapter 17.
- ***Unilateral arm exercises with the arm elevated.*** The following exercises are done with the patient seated and the arm supported at shoulder level on a tabletop or countertop or with the patient supine and the arm supported on a wedge or elevated overhead.
  - Shoulder rotation with the elbow extended. Turn the palm up, then down, by rotating the shoulder, not simply pronating and supinating the forearm.
  - Elbow flexion and extension
  - Circumduction of the wrist
  - Hand opening and closing
- ***Bilateral horizontal abduction and horizontal adduction.*** While standing or sitting, place both hands behind the head. Horizontally adduct and abduct the shoulders by bringing the elbows together and then pointing them laterally.
- ***Overhead wall press.*** Face a wall; place one or both palms on the wall with the hands above shoulder level. Gently press the palms into the wall for several seconds without moving the body. Relax, and repeat approximately five times.
- ***Wrist and finger exercises.*** If swelling is present in the wrist and hand, repetitive active finger movements are indicated with the arm elevated.
  - After performing the overhead wall press as just described, keep the heel of the hand on the wall and alternatively move all of the fingers away from and back to the wall (Fig. 25.8).
  - In the same position as just described, alternately press individual fingers into the wall, as if playing a piano, while keeping the heel of the hand in contact with the wall.
  - Place the palms of both hands together with the hands overhead or at least above shoulder level. One finger at a time, press matching fingers together and then pull them away from each other.
- ***Partial curl-ups.*** To complete the exercise sequence, perform additional curl-ups (about five repetitions) with hands sliding on the thighs.

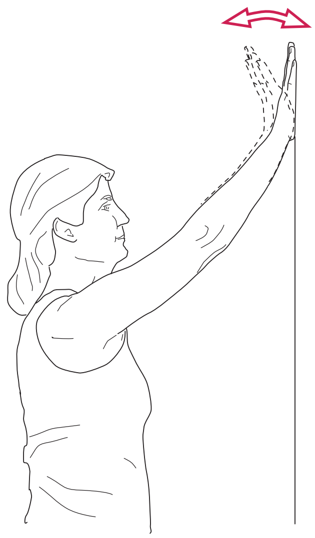

FIGURE 25.8 Overhead wall press.

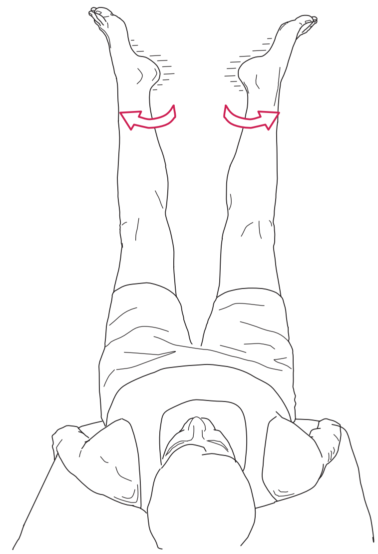

FIGURE 25.9 Repeated outward rotation of the hips with legs elevated and resting on a wall.

- ***Rest.*** Rest in a supine position with the involved arm elevated on pillows for about 30 minutes after completing the exercise sequence.

Exercises Specifically for Lower Extremity Lymphedema Clearance

NOTE: After completing the general lower body, neck, and shoulder exercises previously described, have the patient perform self-massage first to the axillary lymph nodes on the involved side of the body. Then massage the lower abdominal area superiorly to the waist and then laterally and superiorly to the axillary area of the involved side. This sequence is repeated periodically throughout the lower extremity exercise sequence.

- ***Unilateral knee-to-chest movements.*** In the supine position, repeat this exercise for another 15 repetitions. If lymphedema is present in only one lower extremity, perform repeated knee-to-chest movements with the uninvolved leg first and then the involved leg.
- ***Bilateral knees to chest.*** In the supine position, flex both hips and knees, grasp both thighs, and gently pull them to the abdomen and chest. Repeat 10 to 15 times.
- ***Gluteal setting and posterior pelvic tilts.*** Repeat five times, holding each contraction for several seconds and then slowly releasing.
- ***External rotation of the hips (Fig. 25.9).*** Lie in the supine position with the legs elevated and resting against a wall or on a wedge. Externally rotate the hips, pressing the buttocks together and holding the outwardly rotated position. Repeat several times.
- ***Knee flexion to clear the popliteal area.*** While lying in the supine position and keeping the uninvolved lower extremity extended, flex the involved hip and knee enough to clear the foot from the mat table. Actively flex the knee as far as possible by quickly moving the heel to the buttocks. Repeat approximately 15 times.
- ***Active ankle movements.*** With both legs elevated and propped against a wall, or with just the involved leg propped against a door frame and the uninvolved leg resting on the floor, actively plantarflex the ankle and curl the toes; then dorsiflex the ankle and extend the toes as far as possible for multiple repetitions. Lastly, actively circumduct the foot clockwise and counterclockwise for several repetitions.
- ***Wall slides in external rotation (Fig. 25.10).*** With the feet propped up against the wall, legs externally rotated, and heels touching, slide both feet down the wall as far as possible and then back up the wall for several repetitions.

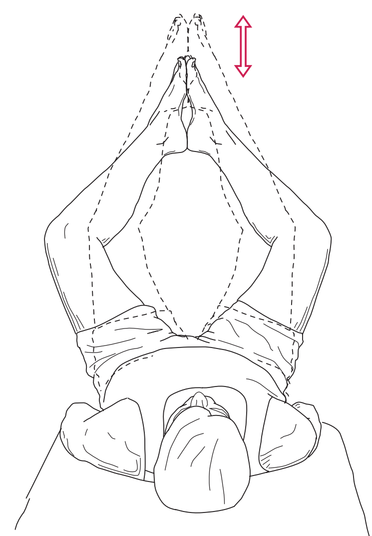

FIGURE 25.10 Sliding feet up and down a wall with hips externally rotated.

- ***Leg movements in the air (Fig. 25.11).*** With both hips flexed and the back flat on the floor and both feet pointed to the ceiling, alternately move the legs, simulating cycling, walking, and scissoring motions.

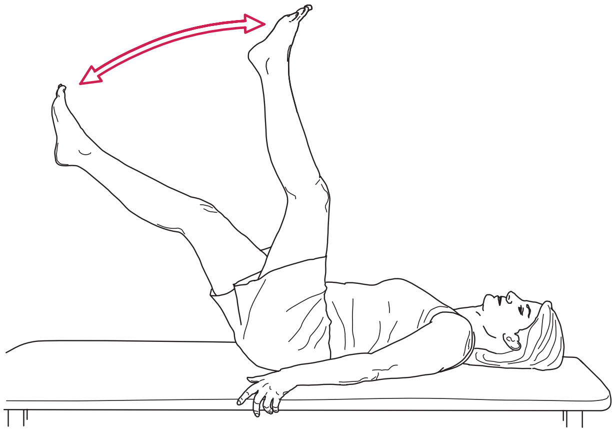

FIGURE 25.11 Repetitive walking movements.

- ***Hip adduction across the midline (Fig. 25.12).*** Lie in the supine position with the uninvolved leg extended. Flex the hip and knee of the involved leg. Grasp the lateral aspect of the knee with the contralateral hand; pull the involved knee repeatedly across the midline in a rocking motion.

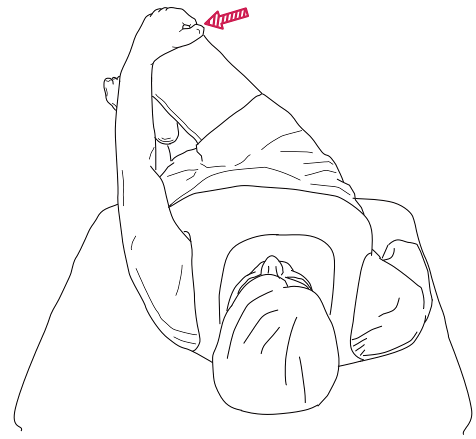

FIGURE 25.12 Hip adduction across the midline to clear inguinal nodes.

NOTE: If lymphedema is bilateral, repeat this exercise with the other lower extremity.

- ***Bilateral knee to chest.*** Repeat bilateral gentle, bouncing movements of the legs previously described.
- ***Partial curl-ups.*** To complete the exercise sequence, perform additional partial curl-ups, about five repetitions.
- ***Rest.*** With feet elevated and legs propped up against the wall, rest in this position for several minutes after completing exercises. Then rest the legs partially elevated on a wedge, and remain in this position for another 30 minutes.

Independent Learning Activities

Critical Thinking and Discussion

1. You have been asked to participate in a patient education program at your community's cancer society for patients who have undergone treatment for breast cancer. Your responsibility in this program is to help these breast cancer survivors reduce the risk of physical impairments and functional limitations associated with their surgery and any related adjuvant therapies. Outline the components of such a program, and explain the rationale for the activities you have chosen to include.
2. A patient has developed lymphedema as a result of a modified radical mastectomy 5 years ago. She presents to physical therapy with finger and hand swelling extending proximally to the upper arm. Elevation is not effective. The tissue is pitting in the hand but hard to palpation in the forearm. Stage this lymphedema, and outline a proposed treatment plan, including the elements of a home management program.
3. Describe the anatomy of the lymphatic system. Explain the terms transport capacity and lymphatic load.
4. Outline the components comprehensive decongestive therapy (CDT) and the relationship between each component.

Laboratory Practice

Perform the sequence of exercises and suggested repetitions for the exercise plan you have designed for Case 1 and Case 2.

Case Studies

Case 1

Ms. L underwent surgery for metastatic pelvic cancer and lymphadenectomy (lymph node dissection) 3 months ago. She also received a series of radiation therapy treatments as part of her comprehensive oncological management. About 2 weeks ago, she began to notice bilateral swelling in her legs, most notably in her feet and ankles.

She has been referred by her oncologist to the outpatient facility where you work to "evaluate and treat" her for her lymphedema. Describe the examination procedures you

would use in your evaluation, and then develop a plan of care, including a program of exercise, to help her manage and reduce her lymphedema and prevent potential complications related to the lymphedema.

Case 2

Mrs. B is a 50-year-old female who recently underwent a lumpectomy and axillary lymph node dissection. She is referred to physical therapy following the removal of her surgical drain. She will be starting chemotherapy shortly, followed by a course of radiation therapy. She reports that prior to her diagnosis and surgery, she was an active individual who enjoyed a variety of recreational activities, including swimming, doubles tennis, and camping, and would like to return to those activities as soon as possible. Design a postoperative exercise program taking into consideration the upcoming chemotherapy and radiation therapy.

Glossary

A

abruptio placentae Premature detachment of the placenta from the uterus

accessory movement Movement within a joint and surrounding soft tissues that is necessary for normal range of motion but cannot be voluntarily performed

accommodating resistance exercise A term used synonymously with **isokinetic exercise**

active inhibition A type of stretching exercise in which there is reflex inhibition and subsequent elongation of the contractile elements of muscles

activity limitation Difficulty executing or inability to perform tasks or actions of daily life. Synonymous with **functional limitation**.

adaptation The ability of an organism to change over time in response to a stimulus

adenosine triphosphate (ATP) A high-energy compound from which the body derives energy

adhesions Abnormal adherence of collagen fibers to surrounding structures during immobilization, following trauma, or as a complication of surgery, which restricts normal elasticity of the structures involved

aerobic exercise Submaximal, rhythmic, repetitive exercise of large muscle groups, during which the needed energy is supplied by inspired oxygen

aerobic system An aerobic energy system in which ATP is manufactured when food is broken down

amniotic fluid Liquid contained in the amniotic sac. The fetus floats in the fluid, which serves as a cushion against injury and helps maintain a constant fetal body temperature

anaerobic exercise Exercise that occurs without the presence of inspired oxygen

anaerobic glycolytic system (lactic acid system) Anaerobic energy system in which ATP is manufactured when glucose is broken down to lactic acid

arteriovenous oxygen difference (a-vO_2 difference) The difference between the oxygen content of arterial and venous blood

arthritis Inflammation of the structures of a joint

arthrodesis Surgical fusion of boney surfaces of a joint with internal fixation such as pins, nails, plates, and bone grafts; usually done in cases of severe joint pain and instability in which mobility of the joint is a lesser concern

arthroplasty Any reconstructive joint procedure, with or without a joint implant, designed to relieve pain and/or restore joint motion

arthroscopy Examination of the internal structures of a joint by means of an endoscopic viewing apparatus inserted into the joint

arthrotomy Surgical incision into a joint

ATP-PC system Anaerobic energy system in which adenosine triphosphate (ATP) is manufactured when phosphocreatine (PC) is broken down

atrophy Wasting or reduction of the size of cells, tissues, organs, or body parts

B

balance Ability to maintain the body's center of gravity over the base of support

bursitis Inflammation of a bursa

C

capsular pattern Pattern of limitation, characteristic for a given joint, that indicates a problem exists with that joint

cardiac output Volume of blood pumped from a ventricle of the heart per unit of time; the product of heart rate and stroke volume

cardiopulmonary endurance Ability of the lungs and heart to take in and transport adequate amounts of oxygen to the working muscle, allowing activities that involve large muscle masses to be performed over long periods of time

chondromalacia patellae Deterioration of the articular cartilage at the posterior aspect of the patella

chondroplasty Débridement procedure to repair joint cartilage, usually at the patellofemoral joint; also called *abrasion arthroplasty*

chronic pain syndrome Used to describe patients with long-standing low back pain who have developed illness behavior and hopelessness. There is no longer a direct relationship between the pain and the apparent disability, and treatment of the painful symptoms usually does not change the condition. The patient may require psychological and sociological intervention and behavior modification techniques

circuit training Training program that uses selective exercises or activities performed in sequence

closed-chain exercise Exercise in which the distal end of the segment is fixed to a supporting surface as the trunk and proximal segments move over the fixed part. This includes functional exercises, especially for the lower extremities, in which the foot is stabilized on the ground and the muscles control the hips, knees, and ankles in activities such as squatting, climbing steps, and getting in and out of a chair

co-contraction Simultaneous contraction of muscles on opposite sides of a joint; source of dynamic stability of a joint

comparable sign Test procedure that can be repeated following a therapeutic maneuver to determine the effectiveness of the maneuver

complex regional pain syndrome A grouping of complex painful disorders that develops as a consequence of trauma affecting the extremities with or without an obvious nerve lesion; formerly called reflex sympathetic dystrophy and causalgia

compression dressing Sterile bandage applied around or over a new surgical incision to compress the wound site and control swelling

concentric exercise Overall shortening of the muscle occurs as it generates tension and contracts against resistance

conditioning Augmentation of the energy capacity of the muscle through an exercise program

continuous training Training program that uses exercise over a given duration without rest periods

contracture Shortening or hypomobility of the skin, fascia, muscle, or joint capsule that prevents normal mobility or flexibility of that structure

contusion Bruising from a direct blow, resulting in capillary rupture

coordination Using the right muscles at the right time with correct intensity. Coordination is the basis of smooth and efficient movement, which often occurs automatically

cross-training See **transfer** or **training**.

cumulative trauma disorder Musculoskeletal symptoms from excessive or repetitive motion causing connective tissue or boney breakdown. Initially, the inflammatory response from the microtrauma is subthreshold but eventually builds to the point of perceived pain and resulting dysfunction. Syndromes include shin splints, carpal tunnel, bursitis, tendonitis, cervical tension, thoracic outlet, tennis elbow, and marching fracture. Also known as cumulative trauma syndrome, repetitive strain injury, and **overuse syndrome**

cyanosis Bluish appearance of skin and mucous membranes due to insufficient oxygenation of the blood

D

deconditioning Change that takes place in cardiovascular, neuromuscular, and metabolic functions as a result of prolonged bed rest or inactivity

decongestive lymphatic therapy Comprehensive approach to management of lymphedema that combines elevation, compression, exercise, massage, and skin care

degenerative joint disease (DJD) See **osteoarthritis**

delayed-onset muscle soreness (DOMS) Exercise-induced muscle tenderness or stiffness that occurs 24 to 48 hours after vigorous exercise

derangement (disk protrusion) Any change in the shape of the nucleus pulposus of the intervertebral disk that causes it to protrude beyond its normal limits

diagnosis Recognition or determination of the cause and nature of a pathological condition

diastasis recti Separation of the rectus abdominis muscle in the midline at the linea alba; continuity of the abdominal wall is disrupted

disability Inability to undertake normal activities of daily living (ADL) as a result of physical, mental, social, or emotional impairments

dislocation Displacement of a part, usually the boney partners within a joint

distensibility Ability of an organ or tissue to be stretched out or enlarged

distraction Pulling apart or separation of joint surfaces

dorsal clearance Surgical removal of diseased synovium from the extensor tendons of the fingers and wrist

dynamic stabilization Isometric or stabilizing contraction of trunk or proximal girdle muscles to maintain control of the functional position in response to imposed fluctuating forces through the moving extremities

dynamometer Device that quantitatively measures muscle strength

dysfunction Loss of function as a result of adaptive shortening of soft tissues and loss of mobility

dyspnea Shortness of breath; labored, distressed breathing

E

eccentric exercise Overall lengthening of the muscle occurs as it develops tension and contracts to control motion against the resistance of an outside force; negative work is done

efficiency Ratio of work output to work input

elasticity Ability of soft tissue to return to its original length after a stretch force has been released

embolus Thrombus or clot of material that has been dislodged and transported in the bloodstream from a larger to a smaller vessel, resulting in occlusion of the vessel

end-feel Quality of feel the evaluator experiences when passively applying pressure at the end of the available range of motion

endurance Ability to resist fatigue

endurance, general (total body) Ability of an individual to sustain low-intensity exercises, such as walking, jogging, or climbing, over an extended period

endurance, muscular Ability of a muscle to perform repeated contractions over a prolonged period

energy systems Metabolic systems involving a series of chemical reactions resulting in the formation of waste products and the manufacture of adenosine triphosphate (ATP). The systems include the ATP-PC (adenosine triphosphate-phosphocreatine) system, the anaerobic glycolytic system, and the aerobic system

epicondylalgia Pain in the region of the medial or lateral epicondyle at the elbow

epicondylitis Common term referring to overuse of the medial or lateral musculotendinous structures at the elbow that occurs as a result of microscopic tears and inflammation

ergometer Apparatus, such as a stationary bicycle or treadmill, used to quantitatively measure the physiological effects of exercise

exercise bouts Number of sets of a repetition maximum performed during each exercise session

exercise duration Total number of days, weeks, or months during which an exercise program is performed

exercise frequency Number of times exercise is performed within a day or within a week

exercise load Amount of weight used as resistance during an exercise

exercise prescription Individualized exercise program involving the duration, frequency, intensity, and mode of exercise

extension bias Describes the preferred position of spinal extension (lordosis) in which the patient's symptoms are decreased. Usually the symptoms increase in spinal flexion

extensor lag The range of active extension is less than the range of passive extension of a joint; in the knee, usually the result of inhibition or dysfunction of the quadriceps mechanism; (synonymous with **quadriceps lag**); in the fingers, usually the result of adhesions restricting mobility of the extensor tendons

extrapment Tissue trapped on the outside of a structure unable to assume its normal relationship. When a meniscoid tissue becomes trapped outside a zygapophyseal joint as the surfaces slide together, the motion is blocked and tension is placed on the capsular tissue

extrusion Protrusion of the nucleus pulposus of the intervertebral disk in which the nuclear material ruptures through the outer annulus and lies under the posterior longitudinal ligament

F

fast-twitch (FT) fiber Skeletal muscle fiber with a fast reaction time that has a high anaerobic capacity and is suited for phasic muscle activity

fatigue, general (total body) Diminished response of a person during prolonged physical activity, such as walking or jogging, that may be due to a decrease in blood sugar (glucose) levels, decrease in glycogen stores in the muscle and liver, or depletion of potassium, especially in the elderly

fatigue, local (muscle) Diminished response of the muscle due to a decrease in energy stores, insufficient oxygen, and buildup of lactic acid; protective influences from the central nervous system; or a decrease in the conduction of impulses at the myoneural junction

fetus Developing embryo in the uterus from 7 to 8 weeks after fertilization until birth

fitness General term indicating a level of cardiovascular functioning that results in heightened energy reserves for optimum performance and well-being

flat low-back posture Posture characterized by decreased lumbosacral angle, decreased lumbar lordosis, and posterior tilting of the pelvis

flexibility Ability of muscle and other soft tissue to yield to a stretch force

flexibility, dynamic The degree to which an active muscle contraction moves a body segment through the available ROM

flexibility, passive The degree to which a body segment can be moved passively through the available ROM

flexibility exercise General term used to describe exercises performed by a person to passively or actively elongate soft tissues without the assistance of a therapist

flexion bias Position of spinal flexion in which the patient's symptoms are lessened. Usually the symptoms are provoked in spinal extension

forward head posture Posture characterized by increased flexion of the lower cervical and upper thoracic regions, increased extension of the occiput on the first cervical vertebra, and increased extension of the upper cervical vertebrae

functional excursion Distance a muscle can shorten after it has been stretched to its maximum length

functional exercise Exercise that mimics functional activities but is performed in a controlled manner or environment

functional limitation Limitation due to an impairment that is not disabling yet interferes with normal function

functional position Position or ROM in which the patient experiences the greatest comfort or least amount of stress on the tissues in the region. It may also be referred to as the **resting position** or neutral position. The position is not static and may change as the patient's condition changes

functional skills Motor skills that are necessary to perform activities or tasks of daily living independently: refined movements requiring coordination, agility, balance, and timing

G

ganglion (pl., **ganglia**) Ballooning of the wall of a joint capsule or tendon sheath

gestation Period of development from the time of fertilization to birth (pregnancy)

glycogen Storage form of carbohydrates in the body, found predominantly in the muscles and the liver

H

handicap Social disadvantage resulting from an impairment or disability that prevents or limits persons in their occupation, environment, or social setting

hemarthrosis Bleeding into a joint, usually from severe trauma

herniation Abnormal protrusion of an organ or other body structure through a defect or natural opening in a covering membrane, muscle, or bone

hyperplasia Increase in the number of fibers or cells

hypertrophy Increase in the cross-sectional size of a fiber or cell

I

impairment Any loss or abnormality of psychological, physiological, or anatomical structure or function that limits or changes an individual's ability to perform a task or activity

incontinence, urinary or fecal Involuntary loss of bladder or bowel contents; often a result of both neuromuscular and musculoskeletal impairments; may occur in combination with prolapse of the uterus

intermittent traction Traction force that is alternately applied and released at frequent intervals, usually in a rhythmic pattern

interval training Training program that alternates bouts of heavy work with periods of rest or light work

intrinsic muscle spasm Prolonged contraction of a muscle in response to the local circulatory and metabolic changes that occur when a muscle is in a continued state of contraction

involution Progressive contraction of the uterus following childbirth, returning the organ to near its prepregnant size

isokinetic exercise Form of active-resistive exercise in which the speed of movement of the limb is controlled by a preset rate-limiting device

isometric (static) exercise Form of exercise in which tension develops in the muscle but no mechanical work is performed. There is no appreciable joint movement, and the overall length of the muscle remains the same

J

joint mobilization/manipulation Passive traction and/or gliding movements applied to joint surfaces that maintain or restore the joint play normally allowed by the capsule, so the normal roll-slide joint mechanics can occur as a person moves

joint play Capsular laxity or elasticity that allows movement of the joint surfaces. The movements include distraction, sliding, compression, rolling, and spinning

K

kypholordotic posture Posture characterized by an exaggerated thoracic kyphosis and lumbar lordosis and usually forward head

kyphosis Posterior convexity in the spinal column. A posterior curve is primary because it is present at birth and remains in the thoracic and sacral regions of the spine

kyphotic posture Posture characterized by an exaggerated posterior curvature of the thoracic spine; syn: humpback, **round back**

L

labor Physiological process by which the uterus contracts and expels the products of conception after 20 or more weeks of gestation

load-resisting exercise Any exercise in which a load or a weight-producing external force resists the internal force generated by a muscle as it contracts

lordosis Anterior convexity in the spinal column. An anterior curve is secondary or compensatory and occurs in the cervical and lumbar spinal regions as the spine of a young child adapts to the upright position

lordotic posture Posture characterized by an increase in the lumbosacral angle, causing increased lumbar lordosis, anterior pelvic tilt, and hip flexion

lymphadenitis Inflammation of lymph nodes

lymphangitis Inflammation of lymph vessels

lymphatic load The amount of lymph fluid transported back to venous circulation

lymphatic transport capacity The amount of fluid the lymphatic system can transport

lymphedema Excessive accumulation of extravascular and extracellular fluid in tissue spaces

M

manipulation See **mobilization**

mastectomy Removal of a breast

maximal aerobic power (max VO_2) Maximum volume of oxygen consumed per unit of time

maximal heart rate reserve (HRR) Difference between the resting heart rate and the maximum heart rate

meniscectomy Intra-articular procedure at the knee by which the meniscus (fibrocartilage) is removed surgically

metabolic equivalent (MET) Amount of oxygen required per minute under quiet resting conditions; equal to 3.5 mL of oxygen consumed per kilogram of body weight per minute

mobilization/manipulation Passive, skilled manual therapy techniques applied to joints and related soft tissues at varying speeds and amplitudes using physiological or accessory motions, for therapeutic purposes

motor learning A complex set of internal processes that involves the acquisition and relatively permanent retention of a skilled movement or task through practice

multiple-angle isometrics Application of resistance at multiple points in the ROM to isometric muscle contractions

muscle-setting exercise Form of isometric exercise but one not performed against any appreciable resistance; gentle static muscle contractions used to maintain mobility between muscle fibers and to decrease muscle spasm and pain

muscle soreness, acute Pain or tenderness in muscle that occurs during strenuous exercise as the muscle fatigues

muscle soreness, delayed-onset See **delayed-onset muscle soreness**

muscle spasm See **intrinsic muscle spasm**

N

nonweight-bearing bias Preferred position in which the patient's symptoms are lessened when in nonweight-bearing positions, such as lying down or in traction or when reducing spinal pressure by leaning on the upper extremities (using arm rests to unweight the trunk), by leaning the trunk against a support, or while in a pool. The condition is considered gravity sensitive because the symptoms are worsened during standing, walking, running, coughing, or similar activities that increase spinal pressure

O

open-chain exercise Exercise in which a distal segment of the body moves freely in space

osteoarthritis (degenerative joint disease) Chronic degenerative disorder primarily affecting the articular cartilage with eventual boney over-growth at the margins of the joints

osteoporosis (bone atrophy) Condition of bone that leads to loss of bone mass, narrowing of the bone shaft, and widening of the medullary canal

osteotomy Surgical cutting and realignment of bone to correct deformity and reduce pain

outcome measure Activity that is objectively documented and is part of the goal for therapeutic intervention

overload Stressing the body or parts of the body to levels beyond those normally experienced

overpressure Stretch force applied to soft tissues at the end of the ROM

overstretch Stretch beyond the normal ROM of a joint and the surrounding soft tissues

overtraining A temporary decline in physical performance associated with cumulative fatigue in healthy individuals participating in high-intensity, high-volume exercise programs with inadequate rest intervals. Synonymous with **overwork** and **overuse syndromes**. See **cumulative trauma disorders.**

overuse syndrome See **cumulative trauma disorders**

overwork Phenomenon that causes temporary or permanent deterioration of strength as a result of exercise, most often observed clinically in patients with nonprogressive lower motor neuron diseases who participate in excessively vigorous resistance exercise programs. Also known as overwork weakness or **overtraining**

oxygen deficit Time period during exercise in which the level of oxygen consumption is below that necessary to supply all the ATP required for the exercise

oxygen transport system Composed of stroke volume, heart rate, and arterial-mixed venous oxygen difference

P

pacing Performance of functional activities within the available cardiopulmonary capacity

pallor Chalky white appearance or blanching of the skin

paresthesia Abnormal sensation perceived as burning, tingling, or prickling

participation restriction Limited ability or inability to fulfill personal or social roles, responsibilities, or societal expectations in the context of attitudes and the environment

pathological fracture Fracture resulting from minor stresses to bone already weakened by disease (osteoporosis)

pendulum (Codman's) exercises Self-mobilization techniques that use the effects of gravity to distract the humerus from the glenoid fossa and gentle pendulum motions to move the joint surfaces

perturbation Displacement or disturbance of the body. Anterior/posterior and medial/lateral movement of a person, or the supporting surface under the person, is used to test and develop balance and postural reactions

phosphocreatine (PC) Creatine phosphate; an energy-rich compound that plays a critical role in providing energy for muscular contraction

physiological movement Movement a person normally can carry out, such as flexion, extension, rotation, abduction, and adduction

plasticity The quality of soft tissue that allows it to maintain a lengthened state after a stretch force has been removed

plyometric training High-intensity, high-velocity resistance exercise characterized by a resisted eccentric muscle contraction followed by a rapid concentric contraction and designed to increase muscular power and coordination; also known as **stretch-shortening drills**

postural dysfunction Faulty posture in which adaptive shortening of soft tissues and muscle weakness has occurred

postural fault (postural pain syndrome) Posture that deviates from normal alignment but has no structural limitations

posture Position or attitude of the body, the relative arrangement of body parts for a specific activity, or a characteristic manner of bearing one's body

power Work per unit of time (force × distance/time) or force × velocity

progressive resistance exercise (PRE) Approach to exercise whereby the load or resistance to the muscle is applied by some mechanical means and is quantitatively and progressively increased over time

pumping exercises Active repetitive exercises, usually of the ankles or wrists, performed to maintain or improve circulation in the extremities

Q

Q angle Angle formed by intersecting lines drawn from the anterior-superior iliac spine through the midportion of the patella and from the anterior tibial tuberosity through the mid-patella. The norm is 15°.

quadriceps lag Synonymous with **extensor lag** of the knee

R

range of motion (ROM) Amount of angular motion allowed at the joint between any two boney levers

range of motion, active (AROM) Movement within the unrestricted ROM for a segment that is produced by active contraction of the muscles crossing that joint

range of motion, active-assistive (A-AROM) Type of active ROM in which assistance is provided by an outside force, either manually or mechanically, because the prime-mover muscles need assistance to complete the motion

range of motion, passive (PROM) Movement within the unrestricted ROM for a segment produced entirely by an external force. There is no voluntary muscle contraction

reflex muscle guarding Prolonged contraction of a muscle in response to a painful stimulus. Guarding ceases when the pain is relieved but may progress to muscle spasm

reflux Backward or return flow of urine toward the kidneys from the bladder

relaxation Conscious effort to relieve tension in muscles

relaxed (slouched) posture Also called **sway back posture**. A posture characterized by shifting of the pelvic segment anteriorly, resulting in hip extension, and shifting of the thoracic segment posteriorly, resulting in flexion of the thorax on the upper lumbar spine. Increased lordosis in the lower lumbar region, increased kyphosis in the thoracic region, and a forward head are usually observed with relaxed posture

repetition maximum (RM) Greatest amount of weight a muscle can move through the range of motion a specific number of times in a load-resisting exercise routine

resistance exercise Any form of active exercise in which a dynamic or static muscular contraction is resisted by an outside force

resistance exercise, manual Type of active exercise in which resistance is provided by a therapist or other health professional to a dynamic or a static muscular contraction

resistance exercise, mechanical Type of active exercise in which resistance is applied through the use of equipment or mechanical apparatus

resistance exercise, variable Form of dynamic exercise carried out using equipment that varies the resistance to the contracting muscle throughout the ROM

resting position Position of the joint in which there is maximum laxity in the capsule and surrounding structures

rheumatoid arthritis A chronic connective tissue disease that is often systemic; characterized by inflammation of synovial joints with periods of exacerbation and remission

rhythmic stabilization Form of isometric exercise in which manual resistance is applied to one side of a proximal joint, then to the other; no movement occurs as the individual stabilizes against the antagonistic forces

round-back posture Posture characterized by an increased thoracic curve, protracted scapulae, and a forward head

rubor Redness of the skin associated with inflammation

S

scaption Elevation of the humerus in the plane of the scapula that is 30° to 45° anterior to the frontal plane; also called scapular plane abduction

scoliosis Abnormal lateral curvature of the vertebral column

scoliosis, functional Nonstructural reversible lateral curvature of the spine; also called **nonstructural or postural scoliosis**

scoliosis, structural Irreversible lateral curvature of the spine with fixed rotation of the vertebrae

selective tension Administration of specific tests in a systematic manner to determine whether the site of a lesion is in an inert structure (joint capsule, ligament, bursa, fascia, dura mater, or dural sheath around nerve roots) or in a contractile unit (muscle with its tendons and attachments)

self-mobilizing Techniques whereby the patient is taught to apply joint mobilization techniques to restricted joints using proper gliding techniques

self-stretching Techniques whereby the patient is taught to stretch a joint or soft tissue passively by using another part of the body for applying the stretch force

setting exercise See *muscle-setting exercise*

short-arc extension (terminal extension) exercise Active or active-resisted extension of a joint through the final degrees of its ROM; most often applied to the knee from 35° flexion to full extension

slow-twitch (ST) fiber Skeletal muscle fiber with a slow reaction time and high aerobic capacity, suitable for tonic muscle activity

specificity of training Principle underlying the development of a training program for a specific activity or skill and the primary energy systems involved during performance

sprain Severe stress, stretch, or tear of soft tissues such as the joint capsule, ligament, tendon, or muscle

stability Synergistic coordination of muscle contractions around a joint that provides a stable base for movement

stability, dynamic joint The ability of a joint to remain stable when subjected to rapidly shifting loads during motion

stabilization exercise Form of exercise designed to develop control of proximal areas of the body in a stable, symptom-free position in response to fluctuating resistance loads. Exercises begin with easy activity so control is maintained; then they progress in duration, intensity, speed, and variety. Often called **dynamic stabilization** exercise

static traction Steady traction force applied and maintained for an extended time interval. It may be continuous (prolonged) or sustained

steady state Pertaining to the time period during which a physiological function remains at a constant value

strain Overstretching, overexertion, overuse of soft tissue; tends to be less severe than a sprain; results from slight trauma or unaccustomed repeated trauma of a minor degree. It also refers to the amount of deformation that occurs in tissues when a stress is applied

strength Force output of a contracting muscle. It is directly related to the amount of tension a contracting muscle can produce

stress Load or force applied to tissues per unit area

stress testing Multistage test that determines the cardiovascular functional capacity of the individual

stretch-shortening drills Synonymous with **plyometric training**

stretch weakness Weakening of muscles that are habitually kept in a stretched position beyond their physiological resting length

stretching Any therapeutic maneuver designed to lengthen (elongate) pathologically shortened soft tissue structures, thereby increasing the ROM

stretching, acute Stretching exercises performed as part of a warm-up routine just prior to a strenuous physical activity

stretching, chronic A program of stretching exercises carried out on a regular basis over a period of time to improve or maintain flexibility

stretching, cyclic Repeated passive stretch usually applied by a mechanical device

stretching, passive Type of mobility exercise in which manual, mechanical, or positional stretch is applied to soft tissues and in which the force is applied opposite to the direction of shortening

stretching, selective Process of stretching some muscle groups while selectively allowing others to adaptively shorten to improve function in a patient with paralysis

stretching, self See **self-stretching**

stroke volume Amount of blood pumped out of the ventricles with each contraction (systole)

subluxation An incomplete or partial dislocation that often involves secondary trauma to surrounding soft tissue

sway-back posture See **relaxed (slouched) posture synovectomy**. Surgical removal of the synovium (lining of the joint) in patients with chronic joint swelling

synovectomy Surgical removal of synovial tissue within a joint

synovitis Inflammation of a synovial membrane; an excess of normal synovial tissue and fluid within a joint or tendon sheath

T

target heart rate Predetermined heart rate to be obtained during exercise

tendinopathy General term that refers to chronic tendon pathology

tendinosis Degeneration of a tendon from repetitive microtrauma; collagen degeneration without inflammation

tendon-gliding exercises Exercises designed to maintain or develop mobility between the multijoint-musculotendinous units and other connective tissue structures in the wrist and hand; also used to develop neuromuscular control and coordinated movement

tendonitis Scarring or calcium deposits in a tendon

tenosynovectomy Surgical removal of proliferated synovium from tendon sheaths

tenosynovitis Inflammation of the synovial sheath covering a tendon

tenovaginitis Thickening of a tendon sheath

terminal extension See **short-arc extension**

thrombophlebitis Inflammatory occlusion of a deep or superficial vein with a thrombus

thrombosis Formation of a clot in a blood vessel

thrombus Blood clot

traction Process of drawing or pulling

transfer of training Carryover of the effects of an exercise program from one mode of exercise or performance to another. Also known as **cross-training**

transitional stabilization Stabilization technique whereby the functional position of the spine is stabilized by the trunk muscles while the body moves from one position to another. It requires graded contractions and adjustments between the trunk flexor and extensor muscles

V

Valsalva maneuver Expiratory effort against a closed glottis, also known as Valsalva's maneuver

vasoconstriction Narrowing of a blood vessel because of contraction of smooth muscle in the walls of the vessels, resulting in decreased blood flow

velocity spectrum rehabilitation Isokinetic exercises performed over a wide range of exercise speeds
